Introduction to ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

By Daniel Roth, Rick Anderson, and Shaun Luttin

ASP.NET Core is a cross-platform, high-performance, open-source framework for building modern, cloud-enabled, Internet-connected apps. With ASP.NET Core, you can:

- Build web apps and services, Internet of Things (IoT) apps, and mobile backends.
- Use your favorite development tools on Windows, macOS, and Linux.
- Deploy to the cloud or on-premises.
- Run on .NET Core.

Why choose ASP.NET Core?

Millions of developers use or have used ASP.NET 4.x to create web apps. ASP.NET Core is a redesign of ASP.NET 4.x, including architectural changes that result in a leaner, more modular framework.

ASP.NET Core provides the following benefits:

- A unified story for building web UI and web APIs.
- Architected for testability.
- Razor Pages makes coding page-focused scenarios easier and more productive.
- Blazor lets you use C# in the browser alongside JavaScript. Share server-side and client-side app logic all written with .NET.
- Ability to develop and run on Windows, macOS, and Linux.
- Open-source and community-focused.
- Integration of modern, client-side frameworks and development workflows.
- Support for hosting Remote Procedure Call (RPC) services using gRPC.
- A cloud-ready, environment-based configuration system.
- Built-in dependency injection.
- A lightweight, high-performance, and modular HTTP request pipeline.
- Ability to host on the following:
  - Kestrel
  - IIS
  - HTTP.sys
  - Nginx
  - Apache
  - Docker
- Side-by-side versioning.
- Tooling that simplifies modern web development.

Build web APIs and web UI using ASP.NET Core MVC

ASP.NET Core MVC provides features to build web APIs and web apps:

- The Model-View-Controller (MVC) pattern helps make your web APIs and web apps testable.
- Razor Pages is a page-based programming model that makes building web UI easier and more productive.

- Razor markup provides a productive syntax for Razor Pages and MVC views.
- Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files.
- Built-in support for multiple data formats and content negotiation lets your web APIs reach a broad range of clients, including browsers and mobile devices.
- Model binding automatically maps data from HTTP requests to action method parameters.
- Model validation automatically performs client-side and server-side validation.

Client-side development

ASP.NET Core integrates seamlessly with popular client-side frameworks and libraries, including Blazor, Angular, React, and Bootstrap. For more information, see Introduction to ASP.NET Core Blazor and related topics under *Client-side development*.

ASP.NET Core target frameworks

ASP.NET Core 3.x and later can only target .NET Core. Generally, ASP.NET Core is composed of .NET Standard libraries. Libraries written with .NET Standard 2.0 run on any .NET platform that implements .NET Standard 2.0.

There are several advantages to targeting .NET Core, and these advantages increase with each release. Some advantages of .NET Core over .NET Framework include:

- Cross-platform. Runs on Windows, macOS, and Linux.
- Improved performance
- Side-by-side versioning
- New APIs
- Open source

Recommended learning path

We recommend the following sequence of tutorials for an introduction to developing ASP.NET Core apps:

1. Follow a tutorial for the app type you want to develop or maintain.

APP TYPE	SCENARIO	TUTORIAL
Web app	New server-side web UI development	Get started with Razor Pages
Web app	Maintaining an MVC app	Get started with MVC
Web app	Client-side web UI development	Get started with Blazor
Web API	RESTful HTTP services	Create a web API†
Remote Procedure Call app	Contract-first services using Protocol Buffers	Get started with a gRPC service
Real-time app	Bidirectional communication between servers and connected clients	Get started with SignalR

2. Follow a tutorial that shows how to do basic data access.

SCENARIO	TUTORIAL
New development	Razor Pages with Entity Framework Core
Maintaining an MVC app	MVC with Entity Framework Core

3. Read an overview of ASP.NET Core fundamentals that apply to all app types.

4. Browse the table of contents for other topics of interest.

†There's also an interactive web API tutorial. No local installation of development tools is required. The code runs in an Azure Cloud Shell in your browser, and curl is used for testing.

Migrate from .NET Framework

For a reference guide to migrating ASP.NET 4.x apps to ASP.NET Core, see Migrate from ASP.NET to ASP.NET Core.

ASP.NET Core is a cross-platform, high-performance, open-source framework for building modern, cloud-enabled, Internet-connected apps. With ASP.NET Core, you can:

- Build web apps and services, Internet of Things (IoT) apps, and mobile backends.
- Use your favorite development tools on Windows, macOS, and Linux.
- Deploy to the cloud or on-premises.
- Run on .NET Core or .NET Framework.

Why choose ASP.NET Core?

Millions of developers use or have used ASP.NET 4.x to create web apps. ASP.NET Core is a redesign of ASP.NET 4.x, with architectural changes that result in a leaner, more modular framework.

ASP.NET Core provides the following benefits:

- A unified story for building web UI and web APIs.
- Architected for testability.
- Razor Pages makes coding page-focused scenarios easier and more productive.
- Blazor lets you use C# in the browser alongside JavaScript. Share server-side and client-side app logic all written with .NET.
- Ability to develop and run on Windows, macOS, and Linux.
- Open-source and community-focused.
- Integration of modern, client-side frameworks and development workflows.
- Support for hosting Remote Procedure Call (RPC) services using gRPC.
- A cloud-ready, environment-based configuration system.
- Built-in dependency injection.
- A lightweight, high-performance, and modular HTTP request pipeline.
- Ability to host on the following:
  - Kestrel
  - IIS
  - HTTP.sys
  - Nginx
  - Apache
  - Docker
- Side-by-side versioning.

- Tooling that simplifies modern web development.

Build web APIs and web UI using ASP.NET Core MVC

ASP.NET Core MVC provides features to build web APIs and web apps:

- The Model-View-Controller (MVC) pattern helps make your web APIs and web apps testable.
- Razor Pages is a page-based programming model that makes building web UI easier and more productive.
- Razor markup provides a productive syntax for Razor Pages and MVC views.
- Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files.
- Built-in support for multiple data formats and content negotiation lets your web APIs reach a broad range of clients, including browsers and mobile devices.
- Model binding automatically maps data from HTTP requests to action method parameters.
- Model validation automatically performs client-side and server-side validation.

Client-side development

ASP.NET Core integrates seamlessly with popular client-side frameworks and libraries, including Blazor, Angular, React, and Bootstrap. For more information, see Introduction to ASP.NET Core Blazor and related topics under *Client-side development*.

ASP.NET Core targeting .NET Framework

ASP.NET Core 2.x can target .NET Core or .NET Framework. ASP.NET Core apps targeting .NET Framework aren't cross-platform—they run on Windows only. Generally, ASP.NET Core 2.x is made up of .NET Standard libraries. Libraries written with .NET Standard 2.0 run on any .NET platform that implements .NET Standard 2.0.

ASP.NET Core 2.x is supported on .NET Framework versions that implement .NET Standard 2.0:

- .NET Framework latest version is recommended.
- .NET Framework 4.6.1 and later.

ASP.NET Core 3.0 and later will only run on .NET Core. For more details regarding this change, see A first look at changes coming in ASP.NET Core 3.0.

There are several advantages to targeting .NET Core, and these advantages increase with each release. Some advantages of .NET Core over .NET Framework include:

- Cross-platform. Runs on macOS, Linux, and Windows.
- Improved performance
- Side-by-side versioning
- New APIs
- Open source

To help close the API gap from .NET Framework to .NET Core, the Windows Compatibility Pack made thousands of Windows-only APIs available in .NET Core. These APIs weren't available in .NET Core 1.x.

Recommended learning path

We recommend the following sequence of tutorials and articles for an introduction to developing ASP.NET Core apps:

1. Follow a tutorial for the type of app you want to develop or maintain.

APP TYPE	SCENARIO	TUTORIAL
Web app	For new development	Get started with Razor Pages
Web app	For maintaining an MVC app	Get started with MVC
Web API		Create a web API†
Real-time app		Get started with SignalR

2. Follow a tutorial that shows how to do basic data access.

SCENARIO	TUTORIAL
For new development	Razor Pages with Entity Framework Core
For maintaining an MVC app	MVC with Entity Framework Core

3. Read an overview of ASP.NET Core fundamentals that apply to all app types.

4. Browse the Table of Contents for other topics of interest.

†There's also a web API tutorial that you follow entirely in the browser, no local IDE installation required. The code runs in an Azure Cloud Shell, and curl is used for testing.

Migrate from .NET Framework

For a reference guide to migrating ASP.NET apps to ASP.NET Core, see Migrate from ASP.NET to ASP.NET Core.

How to download a sample

Many of the articles and tutorials include links to sample code.

1. Download the ASP.NET repository zip file.
2. Unzip the *Docs-master.zip* file.
3. Use the URL in the sample link to help you navigate to the sample directory.

Preprocessor directives in sample code

To demonstrate multiple scenarios, sample apps use the `#define` and `#if-#else/#elif-#endif` preprocessor directives to selectively compile and run different sections of sample code. For those samples that make use of this approach, set the `#define` directive at the top of the C# files to define the symbol associated with the scenario that you want to run. Some samples require defining the symbol at the top of multiple files in order to run a scenario.

For example, the following `#define` symbol list indicates that four scenarios are available (one scenario per symbol). The current sample configuration runs the `TemplateCode` scenario:

```
#define TemplateCode // or LogFromMain or ExpandDefault or FilterInCode
```

To change the sample to run the `ExpandDefault` scenario, define the `ExpandDefault` symbol and leave the remaining symbols commented-out:

```
#define ExpandDefault // TemplateCode or LogFromMain or FilterInCode
```

For more information on using C# preprocessor directives to selectively compile sections of code, see #define (C# Reference) and #if (C# Reference).

Regions in sample code

Some sample apps contain sections of code surrounded by #region and #endregion C# directives. The documentation build system injects these regions into the rendered documentation topics.

Region names usually contain the word "snippet." The following example shows a region named `snippet_WebHostDefaults`:

```
#region snippet_WebHostDefaults
Host.CreateDefaultBuilder(args)
    .ConfigureWebHostDefaults(webBuilder =>
    {
        webBuilder.UseStartup<Startup>();
    });
#endregion
```

The preceding C# code snippet is referenced in the topic's markdown file with the following line:

```
[!code-csharp[](sample/SampleApp/Program.cs?name=snippet_WebHostDefaults)]
```

You may safely ignore (or remove) the `#region` and `#endregion` directives that surround the code. Don't alter the code within these directives if you plan to run the sample scenarios described in the topic. Feel free to alter the code when experimenting with other scenarios.

For more information, see Contribute to the ASP.NET documentation: Code snippets.

Next steps

Choose between ASP.NET 4.x and ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

ASP.NET Core is a redesign of ASP.NET 4.x. This article lists the differences between them.

ASP.NET Core

ASP.NET Core is an open-source, cross-platform framework for building modern, cloud-based web apps on Windows, macOS, or Linux.

ASP.NET Core provides the following benefits:

- A unified story for building web UI and web APIs.
- Architected for testability.
- Razor Pages makes coding page-focused scenarios easier and more productive.
- Blazor lets you use C# in the browser alongside JavaScript. Share server-side and client-side app logic all written with .NET.
- Ability to develop and run on Windows, macOS, and Linux.
- Open-source and community-focused.
- Integration of modern, client-side frameworks and development workflows.
- Support for hosting Remote Procedure Call (RPC) services using gRPC.
- A cloud-ready, environment-based configuration system.
- Built-in dependency injection.
- A lightweight, high-performance, and modular HTTP request pipeline.
- Ability to host on the following:
  - Kestrel
  - IIS
  - HTTP.sys
  - Nginx
  - Apache
  - Docker
- Side-by-side versioning.
- Tooling that simplifies modern web development.

ASP.NET 4.x

ASP.NET 4.x is a mature framework that provides the services needed to build enterprise-grade, server-based web apps on Windows.

Framework selection

The following table compares ASP.NET Core to ASP.NET 4.x.

ASP.NET CORE	ASP.NET 4.X
Build for Windows, macOS, or Linux	Build for Windows

ASP.NET CORE	ASP.NET 4.X
Razor Pages is the recommended approach to create a Web UI as of ASP.NET Core 2.x. See also MVC, Web API, and SignalR.	Use Web Forms, SignalR, MVC, Web API, WebHooks, or Web Pages
Multiple versions per machine	One version per machine
Develop with Visual Studio, Visual Studio for Mac, or Visual Studio Code using C# or F#	Develop with Visual Studio using C#, VB, or F#
Higher performance than ASP.NET 4.x	Good performance
Use .NET Core runtime	Use .NET Framework runtime

See ASP.NET Core targeting .NET Framework for information on ASP.NET Core 2.x support on .NET Framework.

ASP.NET Core scenarios

- Websites
- APIs
- Real-time
- Deploy an ASP.NET Core app to Azure

ASP.NET 4.x scenarios

- Websites
- APIs
- Real-time
- Create an ASP.NET 4.x web app in Azure

Additional resources

- Introduction to ASP.NET
- Introduction to ASP.NET Core
- Deploy ASP.NET Core apps to Azure App Service

Tutorial: Get started with ASP.NET Core

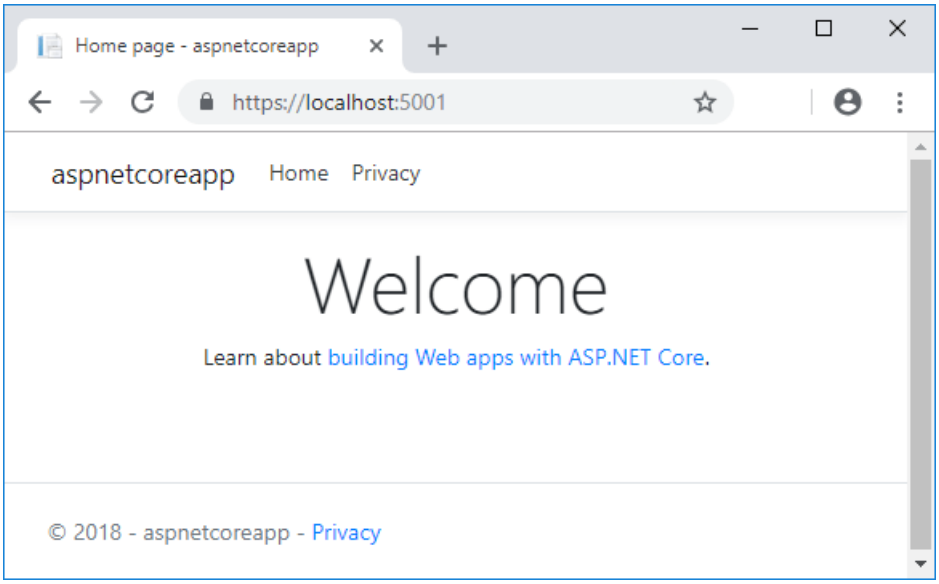
9/22/2020 • 2 minutes to read • Edit Online

This tutorial shows how to create and run an ASP.NET Core web app using the .NET Core CLI.

You'll learn how to:

- Create a web app project.
- Trust the development certificate.
- Run the app.
- Edit a Razor page.

At the end, you'll have a working web app running on your local machine.



Prerequisites

.NET Core 3.1 SDK or later

Create a web app project

Open a command shell, and enter the following command:

```
dotnet new webapp -o aspnetcoreapp
```

The preceding command:

- Creates a new web app.
- The `-o aspnetcoreapp` parameter creates a directory named *aspnetcoreapp* with the source files for the app.

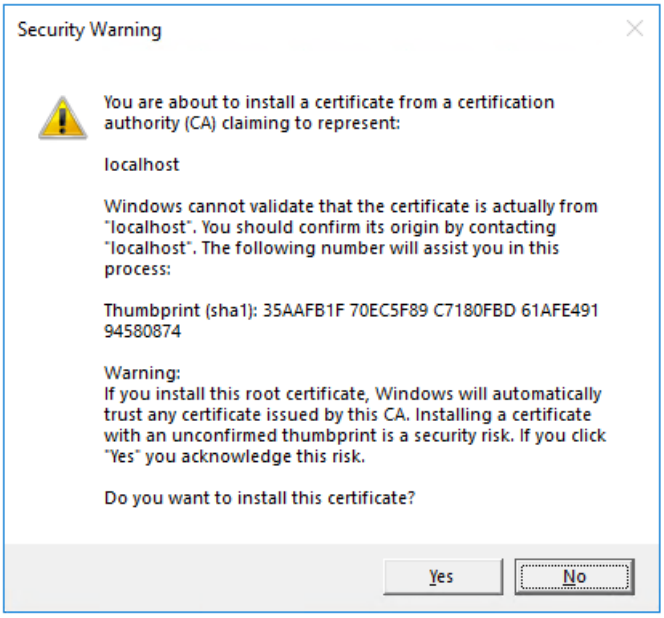
Trust the development certificate

Trust the HTTPS development certificate:

- Windows
- macOS
- Linux

```
dotnet dev-certs https --trust
```

The preceding command displays the following dialog:



Select **Yes** if you agree to trust the development certificate.

For more information, see Trust the ASP.NET Core HTTPS development certificate

Run the app

Run the following commands:

```
cd aspnetcoreapp
dotnet watch run
```

After the command shell indicates that the app has started, browse to `https://localhost:5001`.

Edit a Razor page

Open *Pages/Index.cshtml* and modify and save the page with the following highlighted markup:

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="text-center">
    <h1 class="display-4">Welcome</h1>
    <p>Hello, world! The time on the server is @DateTime.Now</p>
</div>
```

Browse to `https://localhost:5001`, refresh the page, and verify the changes are displayed.

Next steps

In this tutorial, you learned how to:

- Create a web app project.
- Trust the development certificate.
- Run the project.
- Make a change.

To learn more about ASP.NET Core, see the recommended learning path in the introduction:

Introduction to ASP.NET Core

What's new in ASP.NET Core 3.1

9/22/2020 • 2 minutes to read • Edit Online

This article highlights the most significant changes in ASP.NET Core 3.1 with links to relevant documentation.

Partial class support for Razor components

Razor components are now generated as partial classes. Code for a Razor component can be written using a code-behind file defined as a partial class rather than defining all the code for the component in a single file. For more information, see Partial class support.

Blazor Component Tag Helper and pass parameters to top-level components

In Blazor with ASP.NET Core 3.0, components were rendered into pages and views using an HTML Helper (`Html.RenderComponentAsync`). In ASP.NET Core 3.1, render a component from a page or view with the new Component Tag Helper:

```
<component type="typeof(Counter)" render-mode="ServerPrerendered" />
```

The HTML Helper remains supported in ASP.NET Core 3.1, but the Component Tag Helper is recommended.

Blazor Server apps can now pass parameters to top-level components during the initial render. Previously you could only pass parameters to a top-level component with RenderMode.Static. With this release, both RenderMode.Server and RenderMode.ServerPrerendered are supported. Any specified parameter values are serialized as JSON and included in the initial response.

For example, prerender a `Counter` component with an increment amount (`IncrementAmount`):

```
<component type="typeof(Counter)" render-mode="ServerPrerendered"
    param-IncrementAmount="10" />
```

For more information, see Integrate components into Razor Pages and MVC apps.

Support for shared queues in HTTP.sys

HTTP.sys supports creating anonymous request queues. In ASP.NET Core 3.1, we've added to ability to create or attach to an existing named HTTP.sys request queue. Creating or attaching to an existing named HTTP.sys request queue enables scenarios where the HTTP.sys controller process that owns the queue is independent of the listener process. This independence makes it possible to preserve existing connections and enqueued requests between listener process restarts:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
     Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            // ...
            webBuilder.UseHttpSys(options =>
            {
                options.RequestQueueName = "MyExistingQueue";
                options.RequestQueueMode = RequestQueueMode.CreateOrAttach;
            });
        });
```

Breaking changes for SameSite cookies

The behavior of SameSite cookies has changed to reflect upcoming browser changes. This may affect authentication scenarios like AzureAd, OpenIdConnect, or WsFederation. For more information, see Work with SameSite cookies in ASP.NET Core.

Prevent default actions for events in Blazor apps

Use the `@on{EVENT}:preventDefault` directive attribute to prevent the default action for an event. In the following example, the default action of displaying the key's character in the text box is prevented:

```
<input value="@_count" @onkeypress="KeyHandler" @onkeypress:preventDefault />
```

For more information, see Prevent default actions.

Stop event propagation in Blazor apps

Use the `@on{EVENT}:stopPropagation` directive attribute to stop event propagation. In the following example, selecting the check box prevents click events from the child `<div>` from propagating to the parent `<div>`:

```
<input @bind="_stopPropagation" type="checkbox" />

<div @onclick="OnSelectParentDiv">
    <div @onclick="OnSelectChildDiv" @onclick:stopPropagation="_stopPropagation">
        ...
    </div>
</div>

@code {
    private bool _stopPropagation = false;
}
```

For more information, see Stop event propagation.

Detailed errors during Blazor app development

When a Blazor app isn't functioning properly during development, receiving detailed error information from the app assists in troubleshooting and fixing the issue. When an error occurs, Blazor apps display a gold bar at the bottom of the screen:

- During development, the gold bar directs you to the browser console, where you can see the exception.
- In production, the gold bar notifies the user that an error has occurred and recommends refreshing the browser.

For more information, see Detailed errors during development.

What's new in ASP.NET Core 3.0

9/22/2020 • 14 minutes to read • Edit Online

This article highlights the most significant changes in ASP.NET Core 3.0 with links to relevant documentation.

Blazor

Blazor is a new framework in ASP.NET Core for building interactive client-side web UI with .NET:

- Create rich interactive UIs using C# instead of JavaScript.
- Share server-side and client-side app logic written in .NET.
- Render the UI as HTML and CSS for wide browser support, including mobile browsers.

Blazor framework supported scenarios:

- Reusable UI components (Razor components)
- Client-side routing
- Component layouts
- Support for dependency injection
- Forms and validation
- Build component libraries with Razor class libraries
- JavaScript interop

For more information, see Introduction to ASP.NET Core Blazor.

Blazor Server

Blazor decouples component rendering logic from how UI updates are applied. Blazor Server provides support for hosting Razor components on the server in an ASP.NET Core app. UI updates are handled over a SignalR connection. Blazor Server is supported in ASP.NET Core 3.0.

Blazor WebAssembly (Preview)

Blazor apps can also be run directly in the browser using a WebAssembly-based .NET runtime. Blazor WebAssembly is in preview and *not* supported in ASP.NET Core 3.0. Blazor WebAssembly will be supported in a future release of ASP.NET Core.

Razor components

Blazor apps are built from components. Components are self-contained chunks of user interface (UI), such as a page, dialog, or form. Components are normal .NET classes that define UI rendering logic and client-side event handlers. You can create rich interactive web apps without JavaScript.

Components in Blazor are typically authored using Razor syntax, a natural blend of HTML and C#. Razor components are similar to Razor Pages and MVC views in that they both use Razor. Unlike pages and views, which are based on a request-response model, components are used specifically for handling UI composition.

gRPC

gRPC:

- Is a popular, high-performance RPC (remote procedure call) framework.
- Offers an opinionated contract-first approach to API development.

- Uses modern technologies such as:
  - HTTP/2 for transport.
  - Protocol Buffers as the interface description language.
  - Binary serialization format.
- Provides features such as:
  - Authentication
  - Bidirectional streaming and flow control.
  - Cancellation and timeouts.

gRPC functionality in ASP.NET Core 3.0 includes:

- Grpc.AspNetCore: An ASP.NET Core framework for hosting gRPC services. gRPC on ASP.NET Core integrates with standard ASP.NET Core features like logging, dependency injection (DI), authentication, and authorization.
- Grpc.Net.Client: A gRPC client for .NET Core that builds upon the familiar `HttpClient`.
- Grpc.Net.ClientFactory: gRPC client integration with `HttpClientFactory`.

For more information, see Introduction to gRPC on .NET Core.

SignalR

See Update SignalR code for migration instructions. SignalR now uses `System.Text.Json` to serialize/deserialize JSON messages. See Switch to Newtonsoft.Json for instructions to restore the `Newtonsoft.Json`-based serializer.

In the JavaScript and .NET Clients for SignalR, support was added for automatic reconnection. By default, the client tries to reconnect immediately and retry after 2, 10, and 30 seconds if necessary. If the client successfully reconnects, it receives a new connection ID. Automatic reconnect is opt-in:

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withAutomaticReconnect()
    .build();
```

The reconnection intervals can be specified by passing an array of millisecond-based durations:

```
.withAutomaticReconnect([0, 3000, 5000, 10000, 15000, 30000])
//.withAutomaticReconnect([0, 2000, 10000, 30000]) The default intervals.
```

A custom implementation can be passed in for full control of the reconnection intervals.

If the reconnection fails after the last reconnect interval:

- The client considers the connection is offline.
- The client stops trying to reconnect.

During reconnection attempts, update the app UI to notify the user that the reconnection is being attempted.

To provide UI feedback when the connection is interrupted, the SignalR client API has been expanded to include the following event handlers:

- `onreconnecting`: Gives developers an opportunity to disable UI or to let users know the app is offline.
- `onreconnected`: Gives developers an opportunity to update the UI once the connection is reestablished.

The following code uses `onreconnecting` to update the UI while trying to connect:

```
connection.onreconnecting((error) => {
    const status = `Connection lost due to error "${error}". Reconnecting.`;
    document.getElementById("messageInput").disabled = true;
    document.getElementById("sendButton").disabled = true;
    document.getElementById("connectionStatus").innerText = status;
});
```

The following code uses `onreconnected` to update the UI on connection:

```
connection.onreconnected((connectionId) => {
    const status = `Connection reestablished. Connected.`;
    document.getElementById("messageInput").disabled = false;
    document.getElementById("sendButton").disabled = false;
    document.getElementById("connectionStatus").innerText = status;
});
```

SignalR 3.0 and later provides a custom resource to authorization handlers when a hub method requires authorization. The resource is an instance of `HubInvocationContext`. The `HubInvocationContext` includes the:

- `HubCallerContext`
- Name of the hub method being invoked.
- Arguments to the hub method.

Consider the following example of a chat room app allowing multiple organization sign-in via Azure Active Directory. Anyone with a Microsoft account can sign in to chat, but only members of the owning organization can ban users or view users' chat histories. The app could restrict certain functionality from specific users.

```
public class DomainRestrictedRequirement :
    AuthorizationHandler<DomainRestrictedRequirement, HubInvocationContext>,
    IAuthorizationRequirement
{
    protected override Task HandleRequirementAsync(AuthorizationHandlerContext context,
        DomainRestrictedRequirement requirement,
        HubInvocationContext resource)
    {
        if (context.User?.Identity?.Name == null)
        {
            return Task.CompletedTask;
        }

        if (IsUserAllowedToDoThis(resource.HubMethodName, context.User.Identity.Name))
        {
            context.Succeed(requirement);
        }

        return Task.CompletedTask;
    }

    private bool IsUserAllowedToDoThis(string hubMethodName, string currentUsername)
    {
        if (hubMethodName.Equals("banUser", StringComparison.OrdinalIgnoreCase))
        {
            return currentUsername.Equals("bob42@jabbr.net", StringComparison.OrdinalIgnoreCase);
        }

        return currentUsername.EndsWith("@jabbr.net", StringComparison.OrdinalIgnoreCase));
    }
}
```

In the preceding code, `DomainRestrictedRequirement` serves as a custom `IAuthorizationRequirement`. Because the

`HubInvocationContext` resource parameter is being passed in, the internal logic can:

- Inspect the context in which the Hub is being called.
- Make decisions on allowing the user to execute individual Hub methods.

Individual Hub methods can be marked with the name of the policy the code checks at run-time. As clients attempt to call individual Hub methods, the `DomainRestrictedRequirement` handler runs and controls access to the methods. Based on the way the `DomainRestrictedRequirement` controls access:

- All logged-in users can call the `SendMessage` method.
- Only users who have logged in with a `@jabbr.net` email address can view users' histories.
- Only `bob42@jabbr.net` can ban users from the chat room.

```
[Authorize]
public class ChatHub : Hub
{
    public void SendMessage(string message)
    {
    }

    [Authorize("DomainRestricted")]
    public void BanUser(string username)
    {
    }

    [Authorize("DomainRestricted")]
    public void ViewUserHistory(string username)
    {
    }
}
```

Creating the `DomainRestricted` policy might involve:

- In *Startup.cs*, adding the new policy.
- Provide the custom `DomainRestrictedRequirement` requirement as a parameter.
- Registering `DomainRestricted` with the authorization middleware.

```
services
    .AddAuthorization(options =>
    {
        options.AddPolicy("DomainRestricted", policy =>
        {
            policy.Requirements.Add(new DomainRestrictedRequirement());
        });
    });
```

SignalR hubs use Endpoint Routing. SignalR hub connection was previously done explicitly:

```
app.UseSignalR(routes =>
{
    routes.MapHub<ChatHub>("hubs/chat");
});
```

In the previous version, developers needed to wire up controllers, Razor pages, and hubs in a variety of places. Explicit connection results in a series of nearly-identical routing segments:

```
app.UseSignalR(routes =>
{
    routes.MapHub<ChatHub>("hubs/chat");
});

app.UseRouting(routes =>
{
    routes.MapRazorPages();
});
```

SignalR 3.0 hubs can be routed via endpoint routing. With endpoint routing, typically all routing can be configured in `UseRouting`:

```
app.UseRouting(routes =>
{
    routes.MapRazorPages();
    routes.MapHub<ChatHub>("hubs/chat");
});
```

ASP.NET Core 3.0 SignalR added:

Client-to-server streaming. With client-to-server streaming, server-side methods can take instances of either an `IAsyncEnumerable<T>` or `ChannelReader<T>`. In the following C# sample, the `UploadStream` method on the Hub will receive a stream of strings from the client:

```
public async Task UploadStream(IAsyncEnumerable<string> stream)
{
    await foreach (var item in stream)
    {
        // process content
    }
}
```

.NET client apps can pass either an `IAsyncEnumerable<T>` or `ChannelReader<T>` instance as the `stream` argument of the `UploadStream` Hub method above.

After the `for` loop has completed and the local function exits, the stream completion is sent:

```
async IAsyncEnumerable<string> clientStreamData()
{
    for (var i = 0; i < 5; i++)
    {
        var data = await FetchSomeData();
        yield return data;
    }
}

await connection.SendAsync("UploadStream", clientStreamData());
```

JavaScript client apps use the SignalR `Subject` (or an RxJS Subject) for the `stream` argument of the `UploadStream` Hub method above.

```
let subject = new signalR.Subject();
await connection.send("StartStream", "MyAsciiArtStream", subject);
```

The JavaScript code could use the `subject.next` method to handle strings as they are captured and ready to be sent to the server.

```
subject.next("example");
subject.complete();
```

Using code like the two preceding snippets, real-time streaming experiences can be created.

New JSON serialization

ASP.NET Core 3.0 now uses System.Text.Json by default for JSON serialization:

- Reads and writes JSON asynchronously.
- Is optimized for UTF-8 text.
- Typically higher performance than `Newtonsoft.Json`.

To add Json.NET to ASP.NET Core 3.0, see Add Newtonsoft.Json-based JSON format support.

New Razor directives

The following list contains new Razor directives:

- `@attribute`: The `@attribute` directive applies the given attribute to the class of the generated page or view. For example, `@attribute [Authorize]`.
- `@implements`: The `@implements` directive implements an interface for the generated class. For example, `@implements IDisposable`.

IdentityServer4 supports authentication and authorization for web APIs and SPAs

ASP.NET Core 3.0 offers authentication in Single Page Apps (SPAs) using the support for web API authorization. ASP.NET Core Identity for authenticating and storing users is combined with IdentityServer4 for implementing OpenID Connect.

IdentityServer4 is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core 3.0. It enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

For more information, see the IdentityServer4 documentation or Authentication and authorization for SPAs.

Certificate and Kerberos authentication

Certificate authentication requires:

- Configuring the server to accept certificates.
- Adding the authentication middleware in `Startup.Configure`.
- Adding the certificate authentication service in `Startup.ConfigureServices`.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(
        CertificateAuthenticationDefaults.AuthenticationScheme)
            .AddCertificate();
    // Other service configuration removed.
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseAuthentication();
    // Other app configuration removed.
}
```

Options for certificate authentication include the ability to:

- Accept self-signed certificates.
- Check for certificate revocation.
- Check that the proffered certificate has the right usage flags in it.

A default user principal is constructed from the certificate properties. The user principal contains an event that enables supplementing or replacing the principal. For more information, see Configure certificate authentication in ASP.NET Core.

Windows Authentication has been extended onto Linux and macOS. In previous versions, Windows Authentication was limited to IIS and HttpSys. In ASP.NET Core 3.0, Kestrel has the ability to use Negotiate, Kerberos, and NTLM on Windows, Linux, and macOS for Windows domain-joined hosts. Kestrel support of these authentication schemes is provided by the Microsoft.AspNetCore.Authentication.Negotiate NuGet package. As with the other authentication services, configure authentication app wide, then configure the service:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAuthentication(NegotiateDefaults.AuthenticationScheme)
        .AddNegotiate();
    // Other service configuration removed.
}

public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    app.UseAuthentication();
    // Other app configuration removed.
}
```

Host requirements:

- Windows hosts must have Service Principal Names (SPNs) added to the user account hosting the app.
- Linux and macOS machines must be joined to the domain.
  - SPNs must be created for the web process.
  - Keytab files must be generated and configured on the host machine.

For more information, see Configure Windows Authentication in ASP.NET Core.

Template changes

The web UI templates (Razor Pages, MVC with controller and views) have the following removed:

- The cookie consent UI is no longer included. To enable the cookie consent feature in an ASP.NET Core 3.0 template-generated app, see General Data Protection Regulation (GDPR) support in ASP.NET Core.

- Scripts and related static assets are now referenced as local files instead of using CDNs. For more information, see Scripts and related static assets are now referenced as local files instead of using CDNs based on the current environment (aspnet/AspNetCore.Docs #14350).

The Angular template updated to use Angular 8.

The Razor class library (RCL) template defaults to Razor component development by default. A new template option in Visual Studio provides template support for pages and views. When creating an RCL from the template in a command shell, pass the `--support-pages-and-views` option (`dotnet new razorclasslib --support-pages-and-views`).

Generic Host

The ASP.NET Core 3.0 templates use .NET Generic Host. Previous versions used WebHostBuilder. Using the .NET Core Generic Host (HostBuilder) provides better integration of ASP.NET Core apps with other server scenarios that aren't web-specific. For more information, see HostBuilder replaces WebHostBuilder.

Host configuration

Prior to the release of ASP.NET Core 3.0, environment variables prefixed with `ASPNETCORE_` were loaded for host configuration of the Web Host. In 3.0, `AddEnvironmentVariables` is used to load environment variables prefixed with `DOTNET_` for host configuration with `CreateDefaultBuilder` .

Changes to Startup constructor injection

The Generic Host only supports the following types for `Startup` constructor injection:

- IHostEnvironment
- `IWebHostEnvironment`
- IConfiguration

All services can still be injected directly as arguments to the `Startup.Configure` method. For more information, see Generic Host restricts Startup constructor injection (aspnet/Announcements #353).

Kestrel

- Kestrel configuration has been updated for the migration to the Generic Host. In 3.0, Kestrel is configured on the web host builder provided by `ConfigureWebHostDefaults` .
- Connection Adapters have been removed from Kestrel and replaced with Connection Middleware, which is similar to HTTP Middleware in the ASP.NET Core pipeline but for lower-level connections.
- The Kestrel transport layer has been exposed as a public interface in `Connections.Abstractions` .
- Ambiguity between headers and trailers has been resolved by moving trailing headers to a new collection.
- Synchronous I/O APIs, such as `HttpRequest.Body.Read` , are a common source of thread starvation leading to app crashes. In 3.0, `AllowSynchronousIO` is disabled by default.

For more information, see Migrate from ASP.NET Core 2.2 to 3.0.

HTTP/2 enabled by default

HTTP/2 is enabled by default in Kestrel for HTTPS endpoints. HTTP/2 support for IIS or HTTP.sys is enabled when supported by the operating system.

EventCounters on request

The Hosting EventSource, `Microsoft.AspNetCore.Hosting` , emits the following new EventCounter types related to incoming requests:

- `requests-per-second`
- `total-requests`
- `current-requests`
- `failed-requests`

Endpoint routing

Endpoint Routing, which allows frameworks (for example, MVC) to work well with middleware, is enhanced:

- The order of middleware and endpoints is configurable in the request processing pipeline of `Startup.Configure`.
- Endpoints and middleware compose well with other ASP.NET Core-based technologies, such as Health Checks.
- Endpoints can implement a policy, such as CORS or authorization, in both middleware and MVC.
- Filters and attributes can be placed on methods in controllers.

For more information, see Routing in ASP.NET Core.

Health Checks

Health Checks use endpoint routing with the Generic Host. In `Startup.Configure`, call `MapHealthChecks` on the endpoint builder with the endpoint URL or relative path:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHealthChecks("/health");
});
```

Health Checks endpoints can:

- Specify one or more permitted hosts/ports.
- Require authorization.
- Require CORS.

For more information, see the following articles:

- Migrate from ASP.NET Core 2.2 to 3.0
- Health checks in ASP.NET Core

Pipes on HttpContext

It's now possible to read the request body and write the response body using the System.IO.Pipelines API. The `HttpRequest.BodyReader` property provides a PipeReader that can be used to read the request body. The `HttpResponse.BodyWriter` property provides a PipeWriter that can be used to write the response body. `HttpRequest.BodyReader` is an analogue of the `HttpRequest.Body` stream. `HttpResponse.BodyWriter` is an analogue of the `HttpResponse.Body` stream.

Improved error reporting in IIS

Startup errors when hosting ASP.NET Core apps in IIS now produce richer diagnostic data. These errors are reported to the Windows Event Log with stack traces wherever applicable. In addition, all warnings, errors, and unhandled exceptions are logged to the Windows Event Log.

Worker Service and Worker SDK

.NET Core 3.0 introduces the new Worker Service app template. This template provides a starting point for writing

long running services in .NET Core.

For more information, see:

- .NET Core Workers as Windows Services
- Background tasks with hosted services in ASP.NET Core
- Host ASP.NET Core in a Windows Service

Forwarded Headers Middleware improvements

In previous versions of ASP.NET Core, calling UseHsts and UseHttpsRedirection were problematic when deployed to an Azure Linux or behind any reverse proxy other than IIS. The fix for previous versions is documented in Forward the scheme for Linux and non-IIS reverse proxies.

This scenario is fixed in ASP.NET Core 3.0. The host enables the Forwarded Headers Middleware when the `ASPNETCORE_FORWARDEDHEADERS_ENABLED` environment variable is set to `true`. `ASPNETCORE_FORWARDEDHEADERS_ENABLED` is set to `true` in our container images.

Performance improvements

ASP.NET Core 3.0 includes many improvements that reduce memory usage and improve throughput:

- Reduction in memory usage when using the built-in dependency injection container for scoped services.
- Reduction in allocations across the framework, including middleware scenarios and routing.
- Reduction in memory usage for WebSocket connections.
- Memory reduction and throughput improvements for HTTPS connections.
- New optimized and fully asynchronous JSON serializer.
- Reduction in memory usage and throughput improvements in form parsing.

ASP.NET Core 3.0 only runs on .NET Core 3.0

As of ASP.NET Core 3.0, .NET Framework is no longer a supported target framework. Projects targeting .NET Framework can continue in a fully supported fashion using the .NET Core 2.1 LTS release. Most ASP.NET Core 2.1.x related packages will be supported indefinitely, beyond the three-year LTS period for .NET Core 2.1.

For migration information, see Port your code from .NET Framework to .NET Core.

Use the ASP.NET Core shared framework

The ASP.NET Core 3.0 shared framework, contained in the Microsoft.AspNetCore.App metapackage, no longer requires an explicit `<PackageReference />` element in the project file. The shared framework is automatically referenced when using the `Microsoft.NET.Sdk.Web` SDK in the project file:

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

Assemblies removed from the ASP.NET Core shared framework

The most notable assemblies removed from the ASP.NET Core 3.0 shared framework are:

- Newtonsoft.Json (Json.NET). To add Json.NET to ASP.NET Core 3.0, see Add Newtonsoft.Json-based JSON format support. ASP.NET Core 3.0 introduces `System.Text.Json` for reading and writing JSON. For more information, see New JSON serialization in this document.
- Entity Framework Core

For a complete list of assemblies removed from the shared framework, see Assemblies being removed from Microsoft.AspNetCore.App 3.0. For more information on the motivation for this change, see Breaking changes to Microsoft.AspNetCore.App in 3.0 and A first look at changes coming in ASP.NET Core 3.0.

What's new in ASP.NET Core 2.2

9/22/2020 • 5 minutes to read • Edit Online

This article highlights the most significant changes in ASP.NET Core 2.2, with links to relevant documentation.

OpenAPI Analyzers & Conventions

OpenAPI (formerly known as Swagger) is a language-agnostic specification for describing REST APIs. The OpenAPI ecosystem has tools that allow for discovering, testing, and producing client code using the specification. Support for generating and visualizing OpenAPI documents in ASP.NET Core MVC is provided via community driven projects such as NSwag and Swashbuckle.AspNetCore. ASP.NET Core 2.2 provides improved tooling and runtime experiences for creating OpenAPI documents.

For more information, see the following resources:

- Use web API analyzers
- Use web API conventions
- ASP.NET Core 2.2.0-preview1: OpenAPI Analyzers & Conventions

Problem details support

ASP.NET Core 2.1 introduced `ProblemDetails`, based on the RFC 7807 specification for carrying details of an error with an HTTP Response. In 2.2, `ProblemDetails` is the standard response for client error codes in controllers attributed with `ApiControllerAttribute`. An `IActionResult` returning a client error status code (4xx) now returns a `ProblemDetails` body. The result also includes a correlation ID that can be used to correlate the error using request logs. For client errors, `ProducesResponseType` defaults to using `ProblemDetails` as the response type. This is documented in OpenAPI / Swagger output generated using NSwag or Swashbuckle.AspNetCore.

Endpoint Routing

ASP.NET Core 2.2 uses a new *endpoint routing* system for improved dispatching of requests. The changes include new link generation API members and route parameter transformers.

For more information, see the following resources:

- Endpoint routing in 2.2
- Route parameter transformers (see **Routing** section)
- Differences between IRouter- and endpoint-based routing

Health checks

A new health checks service makes it easier to use ASP.NET Core in environments that require health checks, such as Kubernetes. Health checks includes middleware and a set of libraries that define an `IHealthCheck` abstraction and service.

Health checks are used by a container orchestrator or load balancer to quickly determine if a system is responding to requests normally. A container orchestrator might respond to a failing health check by halting a rolling deployment or restarting a container. A load balancer might respond to a health check by routing traffic away from the failing instance of the service.

Health checks are exposed by an application as an HTTP endpoint used by monitoring systems. Health checks can

be configured for a variety of real-time monitoring scenarios and monitoring systems. The health checks service integrates with the BeatPulse project. which makes it easier to add checks for dozens of popular systems and dependencies.

For more information, see Health checks in ASP.NET Core.

HTTP/2 in Kestrel

ASP.NET Core 2.2 adds support for HTTP/2.

HTTP/2 is a major revision of the HTTP protocol. Notable features of HTTP/2 include:

- Support for header compression.
- Fully multiplexed streams over a single connection.

While HTTP/2 preserves HTTP's semantics (for example, HTTP headers and methods), it's a breaking change from HTTP/1.x on how data is framed and sent between the client and server.

As a consequence of this change in framing, servers and clients need to negotiate the protocol version used. Application-Layer Protocol Negotiation (ALPN) is a TLS extension that allows the server and client to negotiate the protocol version used as part of their TLS handshake. While it is possible to have prior knowledge between the server and the client on the protocol, all major browsers support ALPN as the only way to establish an HTTP/2 connection.

For more information, see HTTP/2 support.

Kestrel configuration

In earlier versions of ASP.NET Core, Kestrel options are configured by calling `UseKestrel`. In 2.2, Kestrel options are configured by calling `ConfigureKestrel` on the host builder. This change resolves an issue with the order of `IServer` registrations for in-process hosting. For more information, see the following resources:

- Mitigate UseIIS conflict
- Configure Kestrel server options with ConfigureKestrel

IIS in-process hosting

In earlier versions of ASP.NET Core, IIS serves as a reverse proxy. In 2.2, the ASP.NET Core Module can boot the CoreCLR and host an app inside the IIS worker process (*w3wp.exe*). In-process hosting provides performance and diagnostic gains when running with IIS.

For more information, see in-process hosting for IIS.

SignalR Java client

ASP.NET Core 2.2 introduces a Java Client for SignalR. This client supports connecting to an ASP.NET Core SignalR Server from Java code, including Android apps.

For more information, see ASP.NET Core SignalR Java client.

CORS improvements

In earlier versions of ASP.NET Core, CORS Middleware allows `Accept`, `Accept-Language`, `Content-Language`, and `Origin` headers to be sent regardless of the values configured in `CorsPolicy.Headers`. In 2.2, a CORS Middleware policy match is only possible when the headers sent in `Access-Control-Request-Headers` exactly match the headers stated in `WithHeaders`.

For more information, see CORS Middleware.

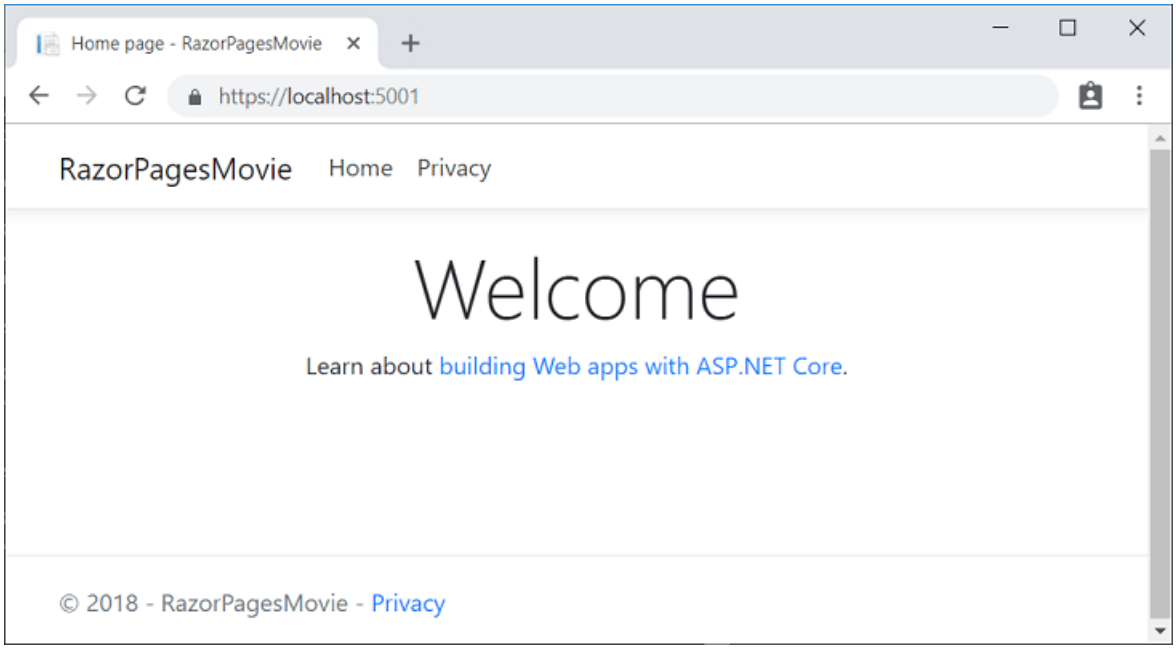
Response compression

ASP.NET Core 2.2 can compress responses with the Brotli compression format.

For more information, see Response Compression Middleware supports Brotli compression.

Project templates

ASP.NET Core web project templates were updated to Bootstrap 4 and Angular 6. The new look is visually simpler and makes it easier to see the important structures of the app.



Validation performance

MVC's validation system is designed to be extensible and flexible, allowing you to determine on a per request basis which validators apply to a given model. This is great for authoring complex validation providers. However, in the most common case an application only uses the built-in validators and don't require this extra flexibility. Built-in validators include DataAnnotations such as [Required] and [StringLength], and `IValidatableObject`.

In ASP.NET Core 2.2, MVC can short-circuit validation if it determines that a given model graph doesn't require validation. Skipping validation results in significant improvements when validating models that can't or don't have any validators. This includes objects such as collections of primitives (such as `byte[]`, `string[]`, `Dictionary<string, string>`), or complex object graphs without many validators.

HTTP Client performance

In ASP.NET Core 2.2, the performance of `SocketsHttpHandler` was improved by reducing connection pool locking contention. For apps that make many outgoing HTTP requests, such as some microservices architectures, throughput is improved. Under load, `HttpClient` throughput can be improved by up to 60% on Linux and 20% on Windows.

For more information, see the pull request that made this improvement.

Additional information

For the complete list of changes, see the ASP.NET Core 2.2 Release Notes.

What's new in ASP.NET Core 2.1

9/22/2020 • 6 minutes to read • Edit Online

This article highlights the most significant changes in ASP.NET Core 2.1, with links to relevant documentation.

SignalR

SignalR has been rewritten for ASP.NET Core 2.1. ASP.NET Core SignalR includes a number of improvements:

- A simplified scale-out model.
- A new JavaScript client with no jQuery dependency.
- A new compact binary protocol based on MessagePack.
- Support for custom protocols.
- A new streaming response model.
- Support for clients based on bare WebSockets.

For more information, see ASP.NET Core SignalR.

Razor class libraries

ASP.NET Core 2.1 makes it easier to build and include Razor-based UI in a library and share it across multiple projects. The new Razor SDK enables building Razor files into a class library project that can be packaged into a NuGet package. Views and pages in libraries are automatically discovered and can be overridden by the app. By integrating Razor compilation into the build:

- The app startup time is significantly faster.
- Fast updates to Razor views and pages at runtime are still available as part of an iterative development workflow.

For more information, see Create reusable UI using the Razor Class Library project.

Identity UI library & scaffolding

ASP.NET Core 2.1 provides ASP.NET Core Identity as a Razor Class Library. Apps that include Identity can apply the new Identity scaffolder to selectively add the source code contained in the Identity Razor Class Library (RCL). You might want to generate source code so you can modify the code and change the behavior. For example, you could instruct the scaffolder to generate the code used in registration. Generated code takes precedence over the same code in the Identity RCL.

Apps that do **not** include authentication can apply the Identity scaffolder to add the RCL Identity package. You have the option of selecting Identity code to be generated.

For more information, see Scaffold Identity in ASP.NET Core projects.

HTTPS

With the increased focus on security and privacy, enabling HTTPS for web apps is important. HTTPS enforcement is becoming increasingly strict on the web. Sites that don't use HTTPS are considered insecure. Browsers (Chromium, Mozilla) are starting to enforce that web features must be used from a secure context. GDPR requires the use of HTTPS to protect user privacy. While using HTTPS in production is critical, using HTTPS in development can help prevent issues in deployment (for example, insecure links). ASP.NET Core 2.1 includes a number of improvements

that make it easier to use HTTPS in development and to configure HTTPS in production. For more information, see Enforce HTTPS.

On by default

To facilitate secure website development, HTTPS is now enabled by default. Starting in 2.1, Kestrel listens on `https://localhost:5001` when a local development certificate is present. A development certificate is created:

- As part of the .NET Core SDK first-run experience, when you use the SDK for the first time.
- Manually using the new `dev-certs` tool.

Run `dotnet dev-certs https --trust` to trust the certificate.

HTTPS redirection and enforcement

Web apps typically need to listen on both HTTP and HTTPS, but then redirect all HTTP traffic to HTTPS. In 2.1, specialized HTTPS redirection middleware that intelligently redirects based on the presence of configuration or bound server ports has been introduced.

Use of HTTPS can be further enforced using HTTP Strict Transport Security Protocol (HSTS). HSTS instructs browsers to always access the site via HTTPS. ASP.NET Core 2.1 adds HSTS middleware that supports options for max age, subdomains, and the HSTS preload list.

Configuration for production

In production, HTTPS must be explicitly configured. In 2.1, default configuration schema for configuring HTTPS for Kestrel has been added. Apps can be configured to use:

- Multiple endpoints including the URLs. For more information, see Kestrel web server implementation: Endpoint configuration.
- The certificate to use for HTTPS either from a file on disk or from a certificate store.

GDPR

ASP.NET Core provides APIs and templates to help meet some of the EU General Data Protection Regulation (GDPR) requirements. For more information, see GDPR support in ASP.NET Core. A sample app shows how to use and lets you test most of the GDPR extension points and APIs added to the ASP.NET Core 2.1 templates.

Integration tests

A new package is introduced that streamlines test creation and execution. The Microsoft.AspNetCore.Mvc.Testing package handles the following tasks:

- Copies the dependency file (**.deps*) from the tested app into the test project's *bin* folder.
- Sets the content root to the tested app's project root so that static files and pages/views are found when the tests are executed.
- Provides the WebApplicationFactory class to streamline bootstrapping the tested app with TestServer.

The following test uses xUnit to check that the Index page loads with a success status code and with the correct Content-Type header:

```
public class BasicTests
    : IClassFixture<WebApplicationFactory<RazorPagesProject.Startup>>
{
    private readonly HttpClient _client;

    public BasicTests(WebApplicationFactory<RazorPagesProject.Startup> factory)
    {
        _client = factory.CreateClient();
    }

    [Fact]
    public async Task GetHomePage()
    {
        // Act
        var response = await _client.GetAsync("/");

        // Assert
        response.EnsureSuccessStatusCode(); // Status Code 200-299
        Assert.Equal("text/html; charset=utf-8",
            response.Content.Headers.ContentType.ToString());
    }
}
```

For more information, see the Integration tests topic.

[ApiController], ActionResult<T>

ASP.NET Core 2.1 adds new programming conventions that make it easier to build clean and descriptive web APIs. `ActionResult<T>` is a new type added to allow an app to return either a response type or any other action result (similar to IActionResult), while still indicating the response type. The `[ApiController]` attribute has also been added as the way to opt in to Web API-specific conventions and behaviors.

For more information, see Build Web APIs with ASP.NET Core.

IHttpClientFactory

ASP.NET Core 2.1 includes a new `IHttpClientFactory` service that makes it easier to configure and consume instances of `HttpClient` in apps. `HttpClient` already has the concept of delegating handlers that could be linked together for outgoing HTTP requests. The factory:

- Makes registering of instances of `HttpClient` per named client more intuitive.
- Implements a Polly handler that allows Polly policies to be used for Retry, CircuitBreakers, etc.

For more information, see Initiate HTTP Requests.

Kestrel transport configuration

With the release of ASP.NET Core 2.1, Kestrel's default transport is no longer based on Libuv but instead based on managed sockets. For more information, see Kestrel web server implementation: Transport configuration.

Generic host builder

The Generic Host Builder (`HostBuilder`) has been introduced. This builder can be used for apps that don't process HTTP requests (Messaging, background tasks, etc.).

For more information, see .NET Generic Host.

Updated SPA templates

The Single Page Application templates for Angular, React, and React with Redux are updated to use the standard project structures and build systems for each framework.

The Angular template is based on the Angular CLI, and the React templates are based on create-react-app.

For more information, see:

- Use the Angular project template with ASP.NET Core
- Use the React project template with ASP.NET Core
- Use the React-with-Redux project template with ASP.NET Core

Razor Pages search for Razor assets

In 2.1, Razor Pages search for Razor assets (such as layouts and partials) in the following directories in the listed order:

1. Current Pages folder.
2. */Pages/Shared/*
3. */Views/Shared/*

Razor Pages in an area

Razor Pages now support areas. To see an example of areas, create a new Razor Pages web app with individual user accounts. A Razor Pages web app with individual user accounts includes */Areas/Identity/Pages*.

MVC compatibility version

The SetCompatibilityVersion method allows an app to opt-in or opt-out of potentially breaking behavior changes introduced in ASP.NET Core MVC 2.1 or later.

For more information, see Compatibility version for ASP.NET Core MVC.

Migrate from 2.0 to 2.1

See Migrate from ASP.NET Core 2.0 to 2.1.

Additional information

For the complete list of changes, see the ASP.NET Core 2.1 Release Notes.

What's new in ASP.NET Core 2.0

9/22/2020 • 5 minutes to read • Edit Online

This article highlights the most significant changes in ASP.NET Core 2.0, with links to relevant documentation.

Razor Pages

Razor Pages is a new feature of ASP.NET Core MVC that makes coding page-focused scenarios easier and more productive.

For more information, see the introduction and tutorial:

- Introduction to Razor Pages
- Get started with Razor Pages

ASP.NET Core metapackage

A new ASP.NET Core metapackage includes all of the packages made and supported by the ASP.NET Core and Entity Framework Core teams, along with their internal and 3rd-party dependencies. You no longer need to choose individual ASP.NET Core features by package. All features are included in the Microsoft.AspNetCore.All package. The default templates use this package.

For more information, see Microsoft.AspNetCore.All metapackage for ASP.NET Core 2.0.

Runtime Store

Applications that use the `Microsoft.AspNetCore.All` metapackage automatically take advantage of the new .NET Core Runtime Store. The Store contains all the runtime assets needed to run ASP.NET Core 2.0 applications. When you use the `Microsoft.AspNetCore.All` metapackage, no assets from the referenced ASP.NET Core NuGet packages are deployed with the application because they already reside on the target system. The assets in the Runtime Store are also precompiled to improve application startup time.

For more information, see Runtime store

.NET Standard 2.0

The ASP.NET Core 2.0 packages target .NET Standard 2.0. The packages can be referenced by other .NET Standard 2.0 libraries, and they can run on .NET Standard 2.0-compliant implementations of .NET, including .NET Core 2.0 and .NET Framework 4.6.1.

The `Microsoft.AspNetCore.All` metapackage targets .NET Core 2.0 only, because it's intended to be used with the .NET Core 2.0 Runtime Store.

Configuration update

An `IConfiguration` instance is added to the services container by default in ASP.NET Core 2.0. `IConfiguration` in the services container makes it easier for applications to retrieve configuration values from the container.

For information about the status of planned documentation, see the GitHub issue.

Logging update

In ASP.NET Core 2.0, logging is incorporated into the dependency injection (DI) system by default. You add providers and configure filtering in the *Program.cs* file instead of in the *Startup.cs* file. And the default `ILoggerFactory` supports filtering in a way that lets you use one flexible approach for both cross-provider filtering and specific-provider filtering.

For more information, see Introduction to Logging.

Authentication update

A new authentication model makes it easier to configure authentication for an application using DI.

New templates are available for configuring authentication for web apps and web APIs using Azure AD B2C.

For information about the status of planned documentation, see the GitHub issue.

Identity update

We've made it easier to build secure web APIs using Identity in ASP.NET Core 2.0. You can acquire access tokens for accessing your web APIs using the Microsoft Authentication Library (MSAL).

For more information on authentication changes in 2.0, see the following resources:

- Account confirmation and password recovery in ASP.NET Core
- Enable QR Code generation for authenticator apps in ASP.NET Core
- Migrate Authentication and Identity to ASP.NET Core 2.0

SPA templates

Single Page Application (SPA) project templates for Angular, Aurelia, Knockout.js, React.js, and React.js with Redux are available. The Angular template has been updated to Angular 4. The Angular and React templates are available by default; for information about how to get the other templates, see Create a new SPA project. For information about how to build a SPA in ASP.NET Core, see Use JavaScript Services to Create Single Page Applications in ASP.NET Core.

Kestrel improvements

The Kestrel web server has new features that make it more suitable as an Internet-facing server. A number of server constraint configuration options are added in the `KestrelServerOptions` class's new `Limits` property. Add limits for the following:

- Maximum client connections
- Maximum request body size
- Minimum request body data rate

For more information, see Kestrel web server implementation in ASP.NET Core.

WebListener renamed to HTTP.sys

The packages `Microsoft.AspNetCore.Server.WebListener` and `Microsoft.Net.Http.Server` have been merged into a new package `Microsoft.AspNetCore.Server.HttpSys`. The namespaces have been updated to match.

For more information, see HTTP.sys web server implementation in ASP.NET Core.

Enhanced HTTP header support

When using MVC to transmit a `FileStreamResult` or a `FileContentResult`, you now have the option to set an `ETag`

or a `LastModified` date on the content you transmit. You can set these values on the returned content with code similar to the following:

```
var data = Encoding.UTF8.GetBytes("This is a sample text from a binary array");
var entityTag = new EntityTagHeaderValue("\"MyCalculatedEtagValue\"");
return File(data, "text/plain", "downloadName.txt", lastModified: DateTime.UtcNow.AddSeconds(-5), entityTag:
entityTag);
```

The file returned to your visitors has the appropriate HTTP headers for the `ETag` and `LastModified` values.

If an application visitor requests content with a Range Request header, ASP.NET Core recognizes the request and handles the header. If the requested content can be partially delivered, ASP.NET Core appropriately skips and returns just the requested set of bytes. You don't need to write any special handlers into your methods to adapt or handle this feature; it's automatically handled for you.

Hosting startup and Application Insights

Hosting environments can now inject extra package dependencies and execute code during application startup, without the application needing to explicitly take a dependency or call any methods. This feature can be used to enable certain environments to "light-up" features unique to that environment without the application needing to know ahead of time.

In ASP.NET Core 2.0, this feature is used to automatically enable Application Insights diagnostics when debugging in Visual Studio and (after opting in) when running in Azure App Services. As a result, the project templates no longer add Application Insights packages and code by default.

For information about the status of planned documentation, see the GitHub issue.

Automatic use of anti-forgery tokens

ASP.NET Core has always helped HTML-encode content by default, but with the new version an extra step is taken to help prevent cross-site request forgery (XSRF) attacks. ASP.NET Core will now emit anti-forgery tokens by default and validate them on form POST actions and pages without extra configuration.

For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Automatic precompilation

Razor view pre-compilation is enabled during publish by default, reducing the publish output size and application startup time.

For more information, see Razor view compilation and precompilation in ASP.NET Core.

Razor support for C# 7.1

The Razor view engine has been updated to work with the new Roslyn compiler. That includes support for C# 7.1 features like Default Expressions, Inferred Tuple Names, and Pattern-Matching with Generics. To use C# 7.1 in your project, add the following property in your project file and then reload the solution:

```
<LangVersion>latest</LangVersion>
```

For information about the status of C# 7.1 features, see the Roslyn GitHub repository.

Other documentation updates for 2.0

- Visual Studio publish profiles for ASP.NET Core app deployment
- Key Management
- Configure Facebook authentication
- Configure Twitter authentication
- Configure Google authentication
- Configure Microsoft Account authentication

Migration guidance

For guidance on how to migrate ASP.NET Core 1.x applications to ASP.NET Core 2.0, see the following resources:

- Migrate from ASP.NET Core 1.x to ASP.NET Core 2.0
- Migrate Authentication and Identity to ASP.NET Core 2.0

Additional Information

For the complete list of changes, see the ASP.NET Core 2.0 Release Notes.

To connect with the ASP.NET Core development team's progress and plans, tune in to the ASP.NET Community Standup.

What's new in ASP.NET Core 1.1

9/22/2020 • 2 minutes to read • Edit Online

ASP.NET Core 1.1 includes the following new features:

- URL Rewriting Middleware
- Response Caching Middleware
- View Components as Tag Helpers
- Middleware as MVC filters
- Cookie-based TempData provider
- Azure App Service logging provider
- Azure Key Vault configuration provider
- Azure and Redis Storage Data Protection Key Repositories
- WebListener Server for Windows
- WebSockets support

Choosing between versions 1.0 and 1.1 of ASP.NET Core

ASP.NET Core 1.1 has more features than ASP.NET Core 1.0. In general, we recommend you use the latest version.

Additional Information

- ASP.NET Core 1.1.0 Release Notes
- To connect with the ASP.NET Core development team's progress and plans, tune in to the ASP.NET Community Standup.

Tutorial: Create a Razor Pages web app with ASP.NET Core

9/22/2020 • 2 minutes to read • Edit Online

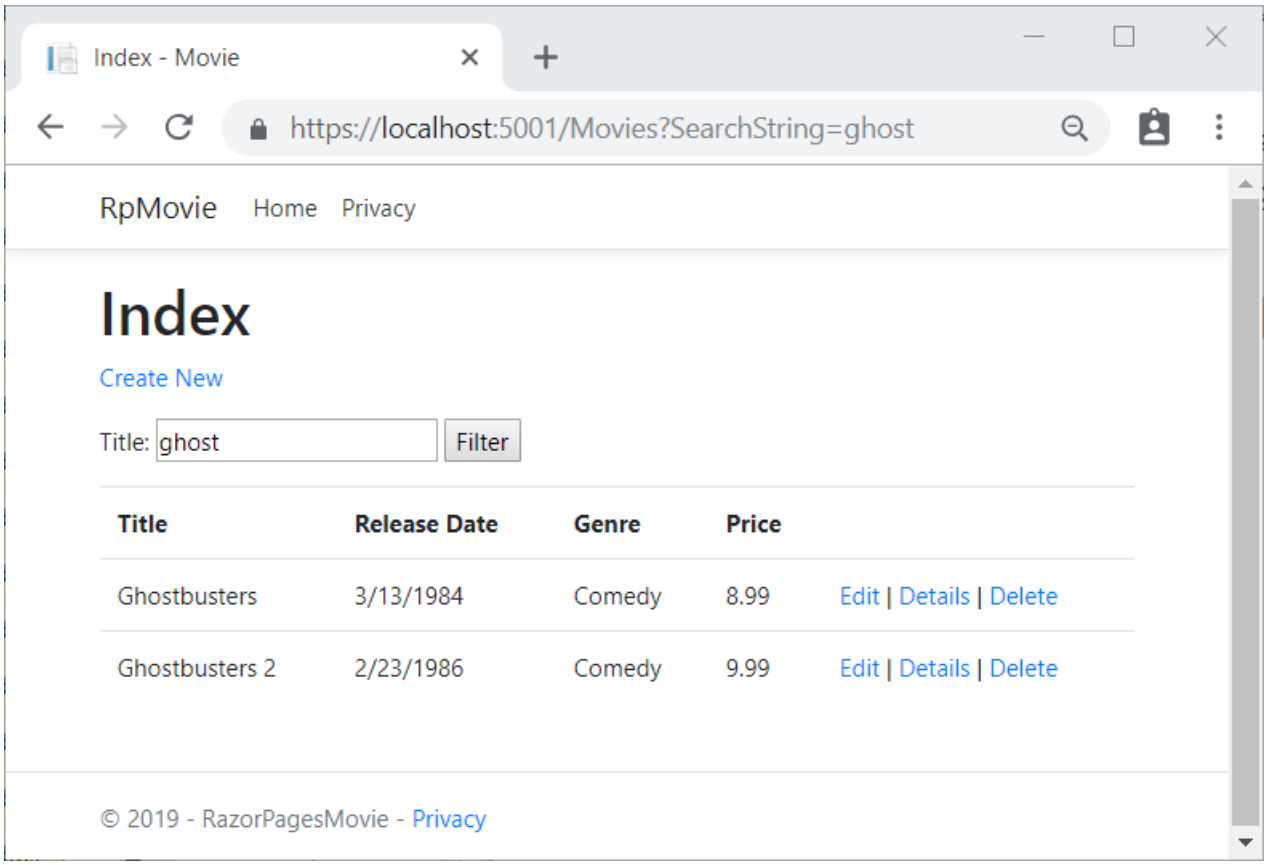
This series of tutorials explains the basics of building a Razor Pages web app.

For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages.

This series includes the following tutorials:

1. Create a Razor Pages web app
2. Add a model to a Razor Pages app
3. Scaffold (generate) Razor pages
4. Work with a database
5. Update Razor pages
6. Add search
7. Add a new field
8. Add validation

At the end, you'll have an app that can display and manage a database of movies.



Tutorial: Get started with Razor Pages in ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Rick Anderson

This is the first tutorial of a series that teaches the basics of building an ASP.NET Core Razor Pages web app.

For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages.

At the end of the series, you'll have an app that manages a database of movies.

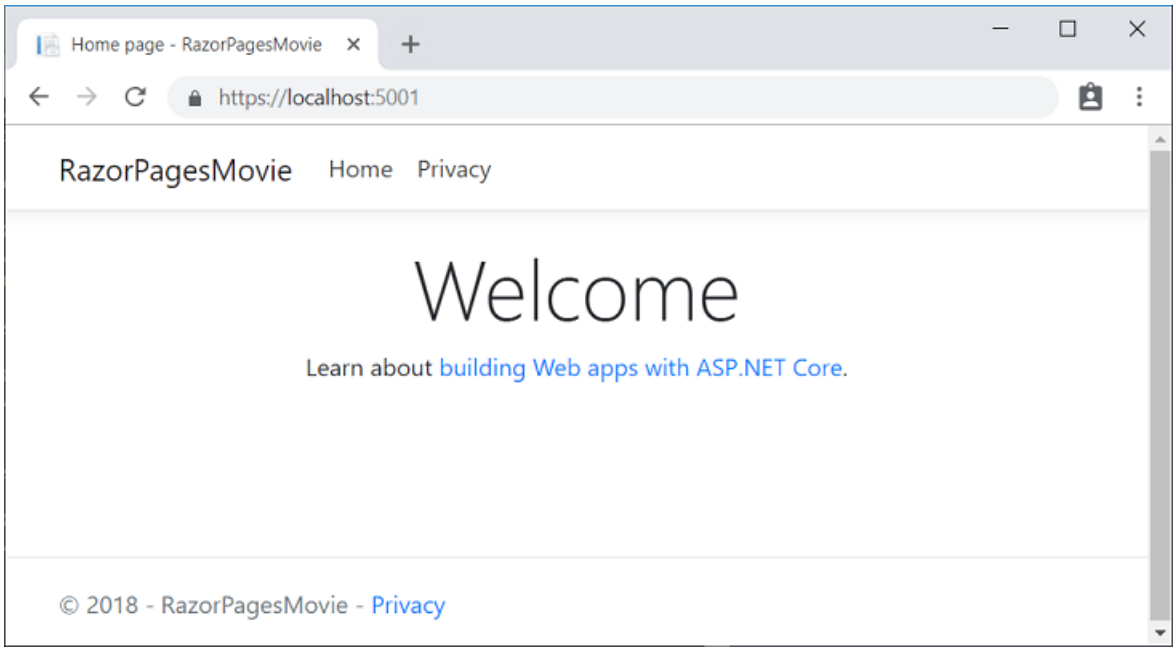
View or download sample code (how to download).

View or download sample code (how to download).

In this tutorial, you:

- Create a Razor Pages web app.
- Run the app.
- Examine the project files.

At the end of this tutorial, you'll have a working Razor Pages web app that you'll build on in later tutorials.



Prerequisites

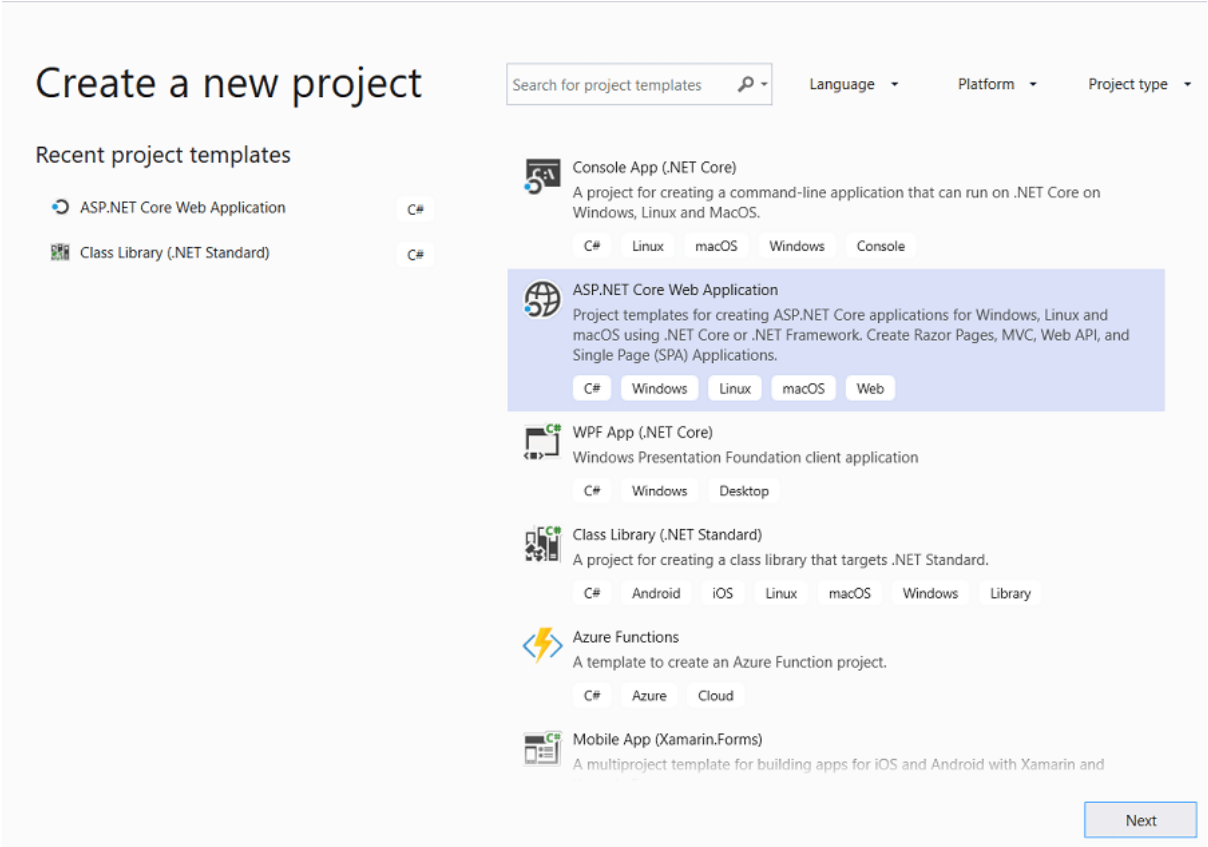
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

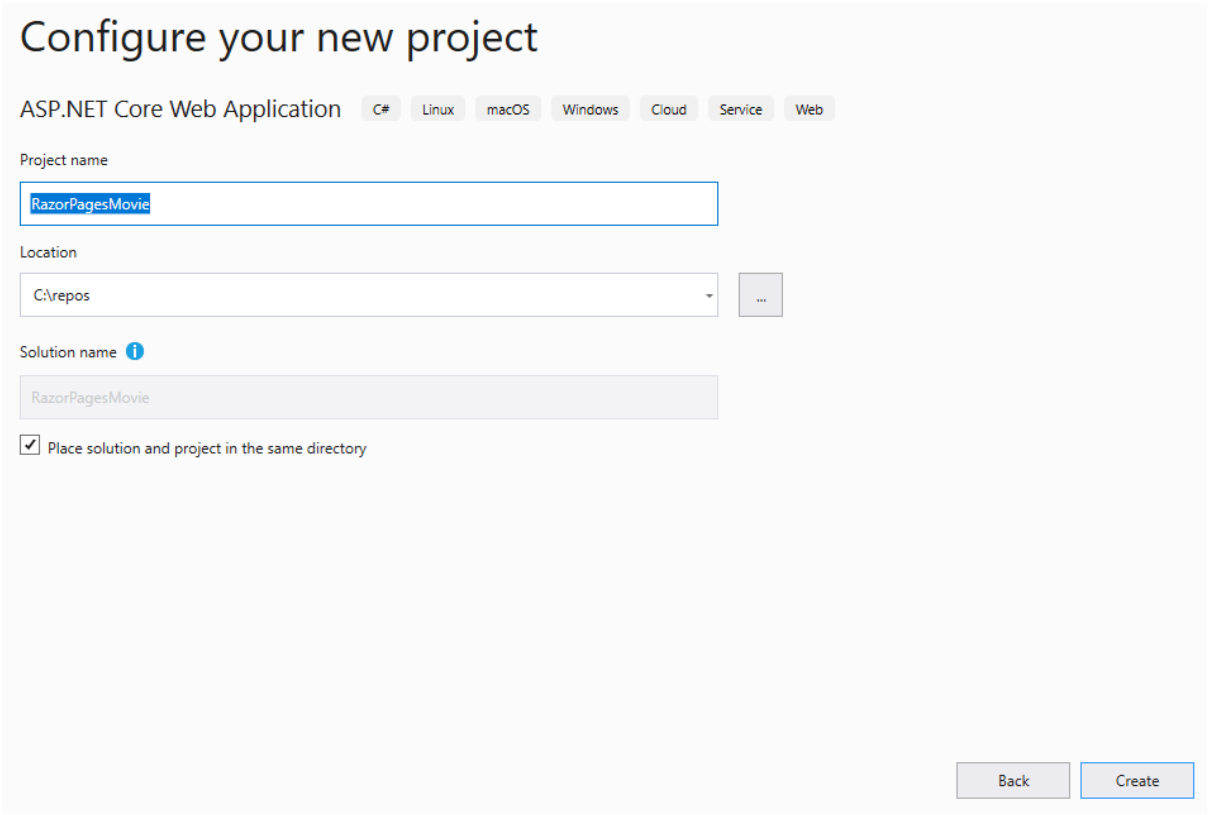
Create a Razor Pages web app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

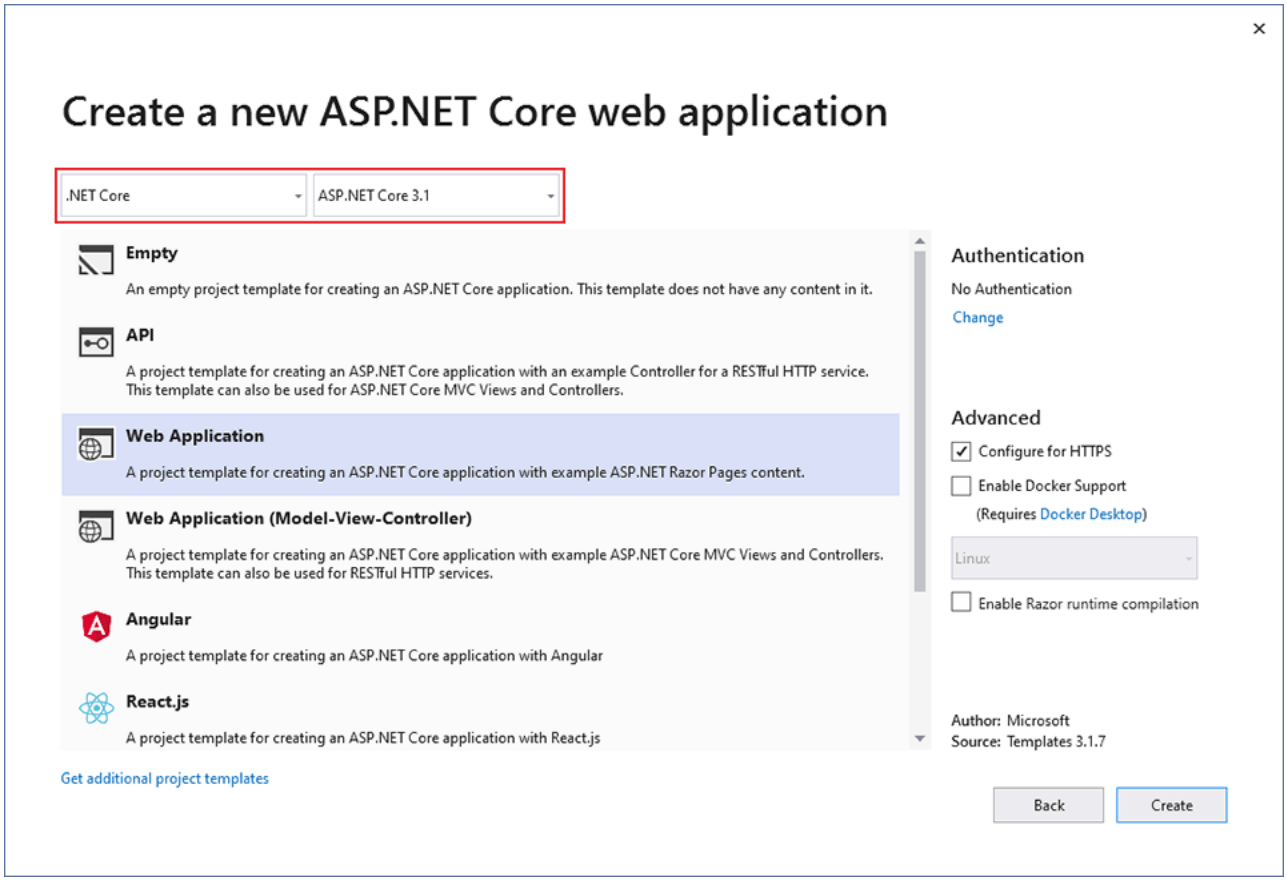
- From the Visual Studio **File** menu, select **New** > **Project**.
- Create a new ASP.NET Core Web Application and select **Next**.



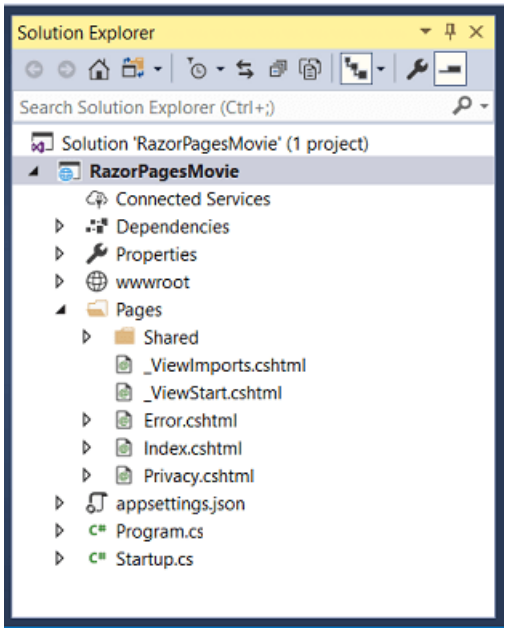
- Name the project **RazorPagesMovie**. It's important to name the project *RazorPagesMovie* so the namespaces will match when you copy and paste code.



- Select **ASP.NET Core 3.1** in the dropdown, **Web Application**, and then select **Create**.



The following starter project is created:



Run the app

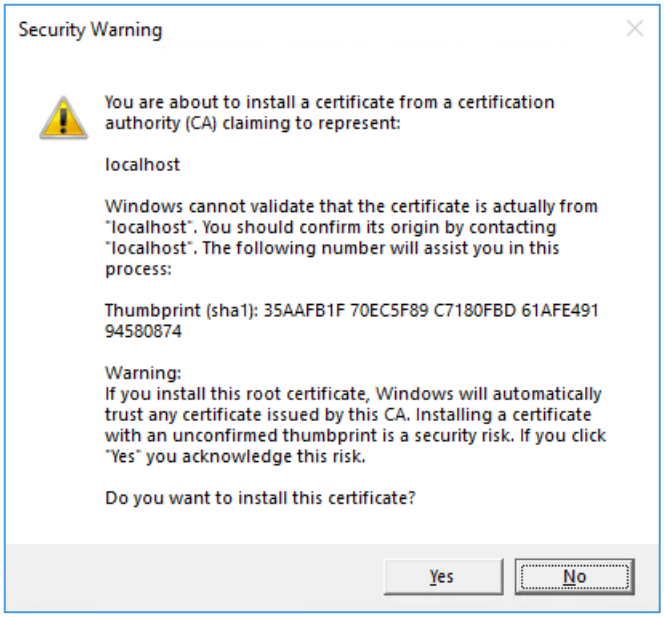
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Press Ctrl+F5 to run without the debugger.

  Visual Studio displays the following dialog:

  Select **Yes** if you trust the IIS Express SSL certificate.

  The following dialog is displayed:



Select **Yes** if you agree to trust the development certificate.

Visual Studio starts IIS Express and runs the app. The address bar shows `localhost:port#` and not something like `example.com`. That's because `localhost` is the standard hostname for the local computer. Localhost only serves web requests from the local computer. When Visual Studio creates a web project, a random port is used for the web server.

Examine the project files

Here's an overview of the main project folders and files that you'll work with in later tutorials.

Pages folder

Contains Razor pages and supporting files. Each Razor page is a pair of files:

- A *.cshtml* file that contains HTML markup with C# code using Razor syntax.
- A *.cshtml.cs* file that contains C# code that handles page events.

Supporting files have names that begin with an underscore. For example, the *_Layout.cshtml* file configures UI elements common to all pages. This file sets up the navigation menu at the top of the page and the copyright notice at the bottom of the page. For more information, see Layout in ASP.NET Core.

wwwroot folder

Contains static files, such as HTML files, JavaScript files, and CSS files. For more information, see Static files in ASP.NET Core.

appSettings.json

Contains configuration data, such as connection strings. For more information, see Configuration in ASP.NET Core.

Program.cs

Contains the entry point for the program. For more information, see .NET Generic Host.

Startup.cs

Contains code that configures app behavior. For more information, see App startup in ASP.NET Core.

Next steps

Advance to the next tutorial in the series:

This is the first tutorial of a series. The series teaches the basics of building an ASP.NET Core Razor Pages web app.

For a more advanced introduction aimed at developers who are familiar with controllers and views, see Introduction to Razor Pages.

At the end of the series, you'll have an app that manages a database of movies.

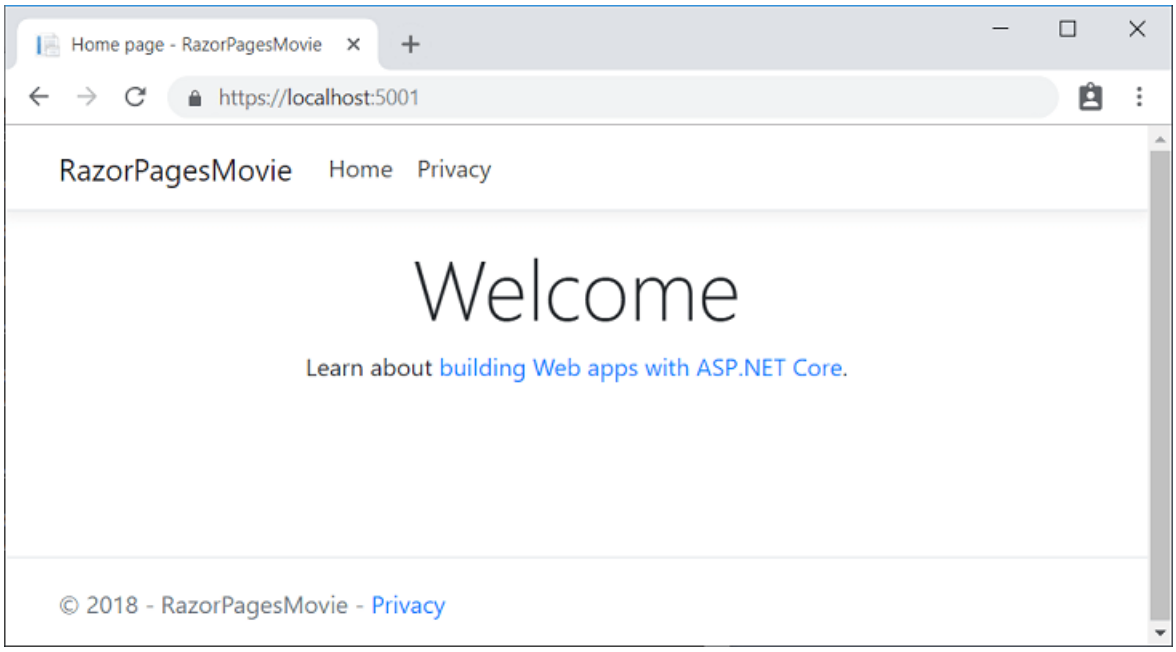
View or download sample code (how to download).

View or download sample code (how to download).

In this tutorial, you:

- Create a Razor Pages web app.
- Run the app.
- Examine the project files.

At the end of this tutorial, you'll have a working Razor Pages web app that you'll build on in later tutorials.



Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

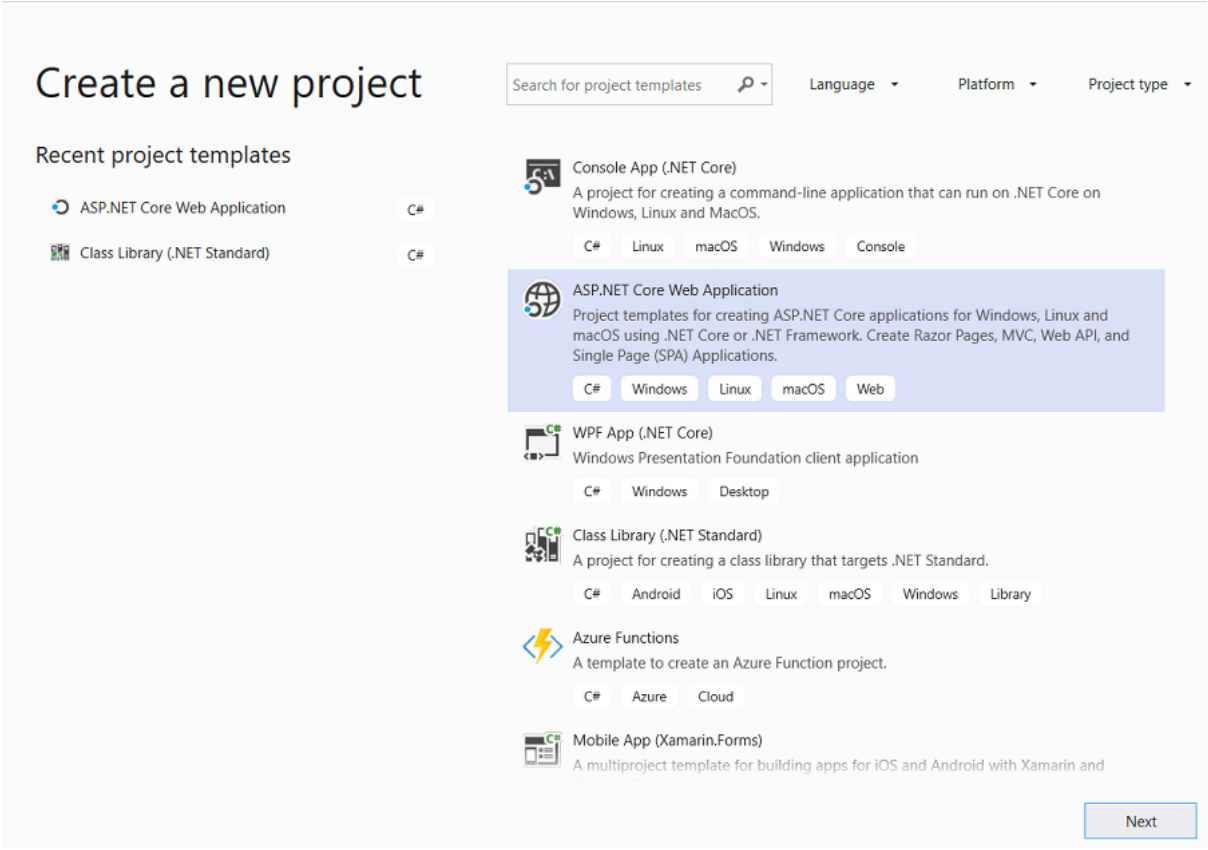
WARNING

If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

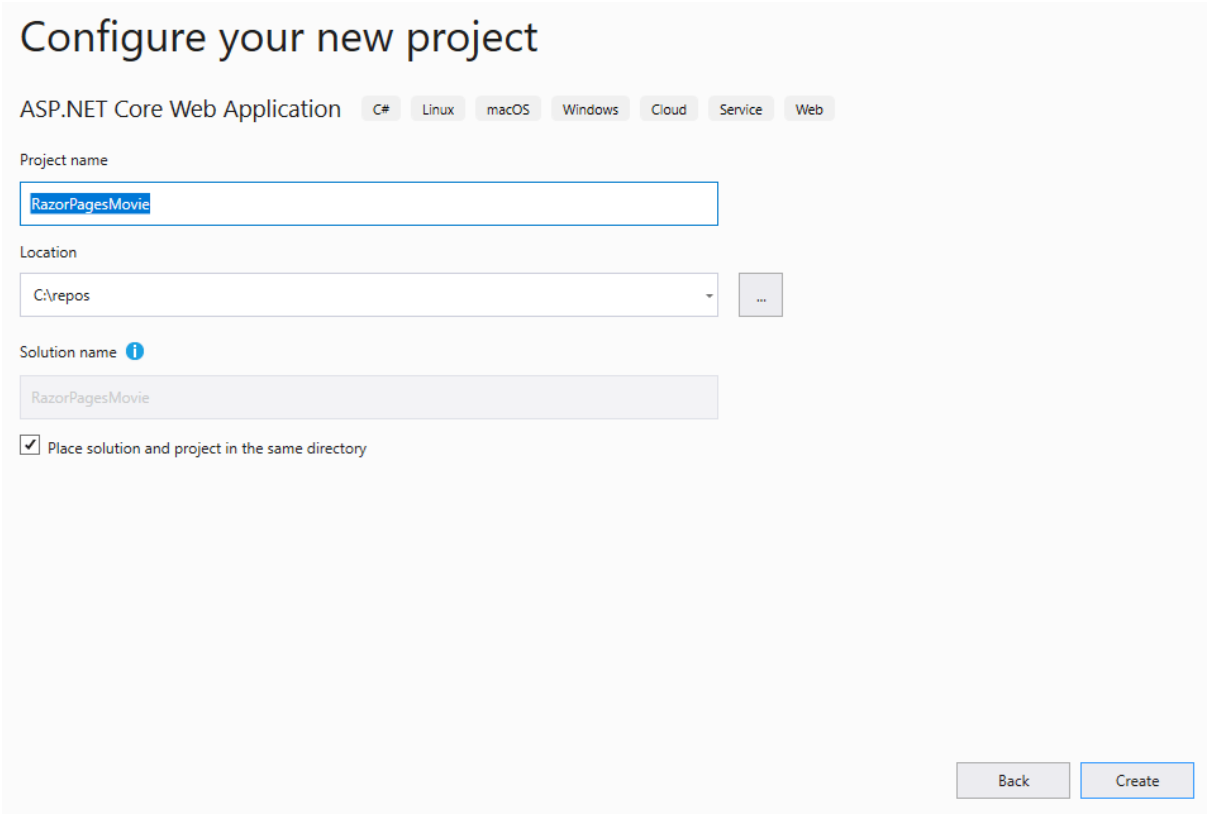
Create a Razor Pages web app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

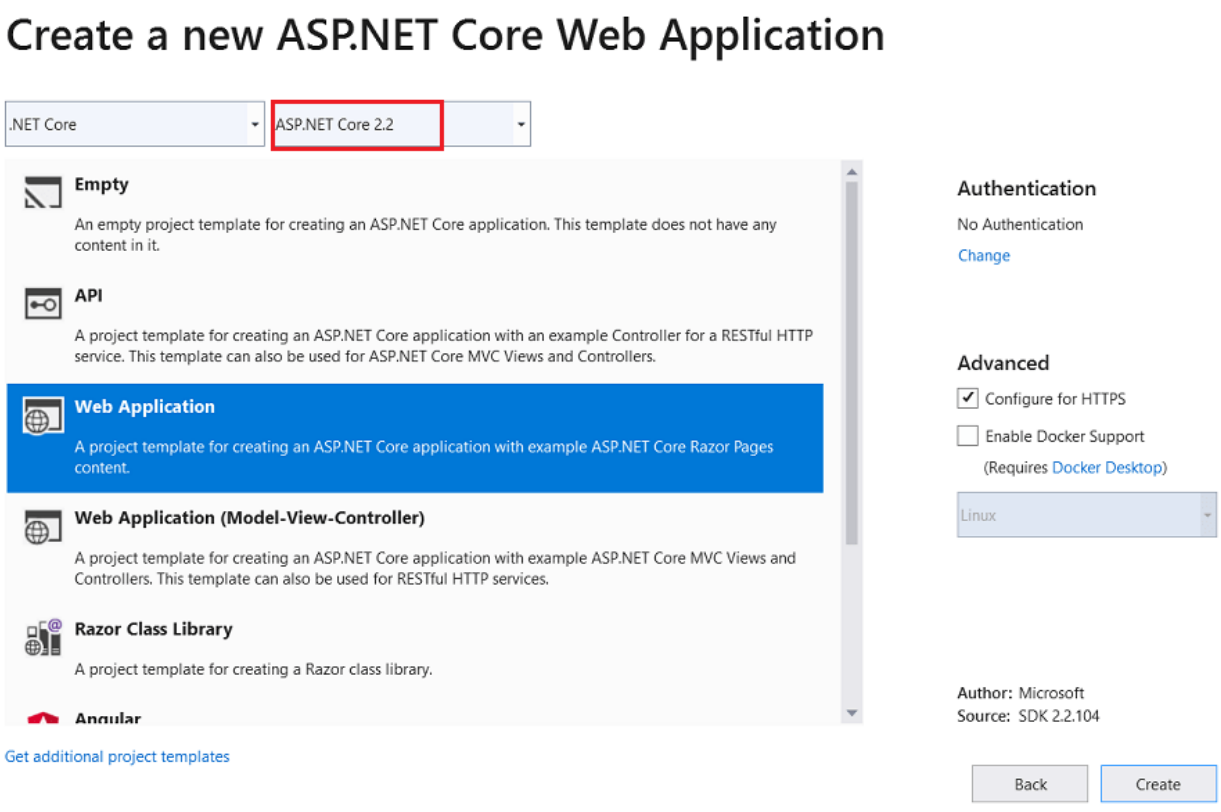
- From the Visual Studio **File** menu, select **New** > **Project**.
- Create a new ASP.NET Core Web Application and select **Next**.



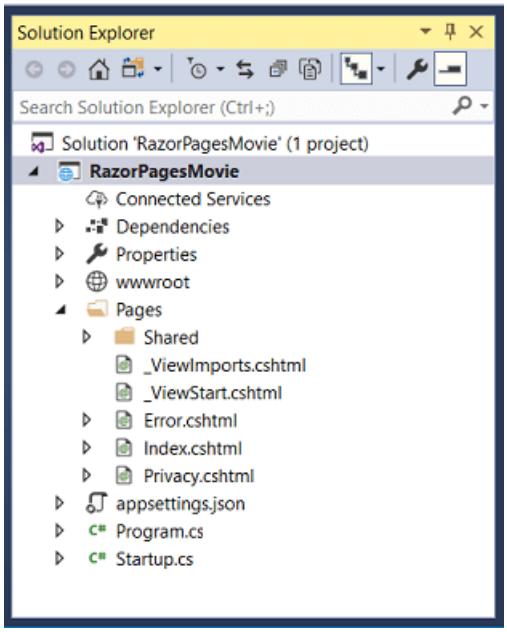
- Name the project **RazorPagesMovie**. It's important to name the project *RazorPagesMovie* so the namespaces will match when you copy and paste code.



- Select **ASP.NET Core 2.2** in the dropdown, **Web Application**, and then select **Create**.



The following starter project is created:



Run the app

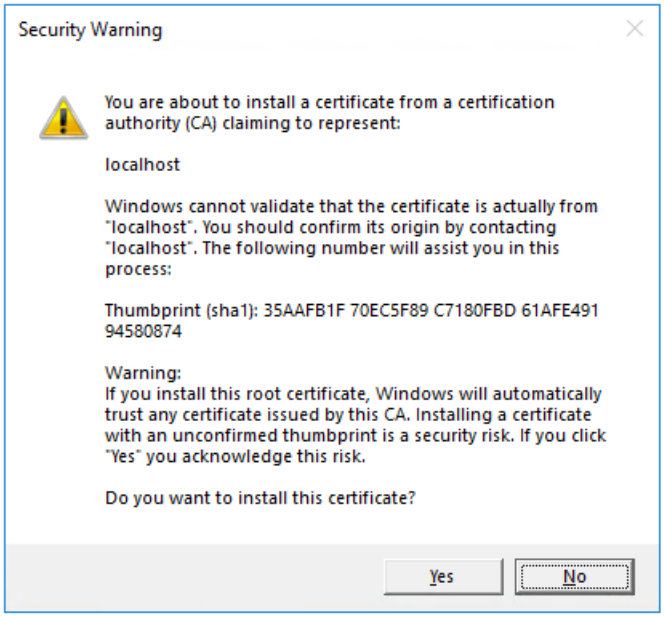
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Press Ctrl+F5 to run without the debugger.

  Visual Studio displays the following dialog:

  Select **Yes** if you trust the IIS Express SSL certificate.

  The following dialog is displayed:

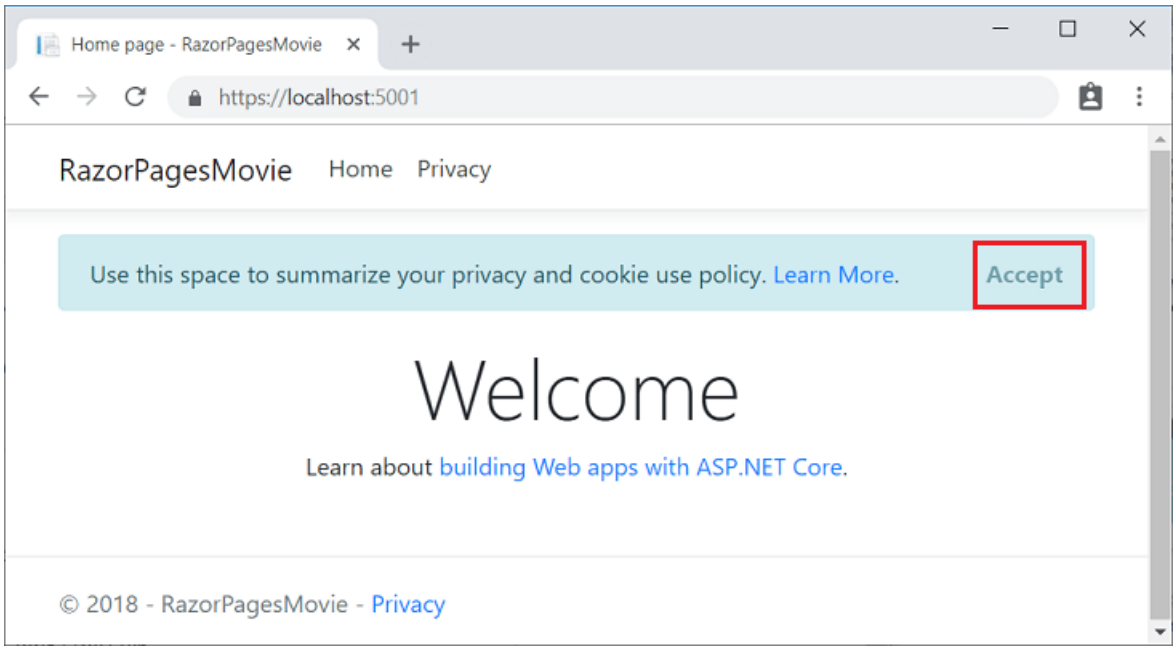


Select **Yes** if you agree to trust the development certificate.

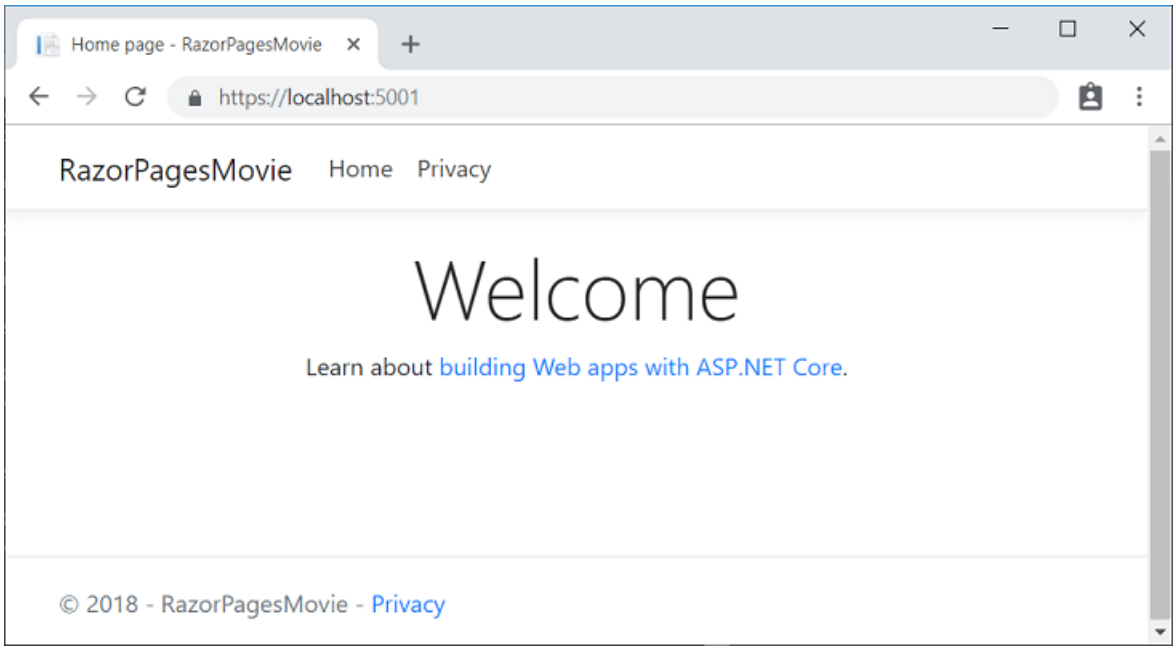
Visual Studio starts IIS Express and runs the app. The address bar shows `localhost:port#` and not something like `example.com`. That's because `localhost` is the standard hostname for the local computer. Localhost only serves web requests from the local computer. When Visual Studio creates a web project, a random port is used for the web server.

- On the app's home page, select **Accept** to consent to tracking.

  This app doesn't track personal information, but the project template includes the consent feature in case you need it to comply with the European Union's General Data Protection Regulation (GDPR).



The following image shows the app after you give consent to tracking:



Examine the project files

Here's an overview of the main project folders and files that you'll work with in later tutorials.

Pages folder

Contains Razor pages and supporting files. Each Razor page is a pair of files:

- A *.cshtml* file that contains HTML markup with C# code using Razor syntax.
- A *.cshtml.cs* file that contains C# code that handles page events.

Supporting files have names that begin with an underscore. For example, the *_Layout.cshtml* file configures UI elements common to all pages. This file sets up the navigation menu at the top of the page and the copyright notice at the bottom of the page. For more information, see Layout in ASP.NET Core.

wwwroot folder

Contains static files, such as HTML files, JavaScript files, and CSS files. For more information, see Static files in ASP.NET Core.

appSettings.json

Contains configuration data, such as connection strings. For more information, see Configuration in ASP.NET Core.

Program.cs

Contains the entry point for the program. For more information, see .NET Generic Host.

Startup.cs

Contains code that configures app behavior, such as whether it requires consent for cookies. For more information, see App startup in ASP.NET Core.

Next steps

Advance to the next tutorial in the series:

ADD A MODEL

Part 2, add a model to a Razor Pages app in ASP.NET Core

9/22/2020 • 22 minutes to read • Edit Online

By Rick Anderson

In this section, classes are added for managing movies. The app's model classes use Entity Framework Core (EF Core) to work with the database. EF Core is an object-relational mapper (O/RM) that simplifies data access.

The model classes are known as POCO classes (from "plain-old CLR objects") because they don't have any dependency on EF Core. They define the properties of the data that are stored in the database.

View or download sample code (how to download).

View or download sample code (how to download).

Add a data model

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Right-click the **RazorPagesMovie** project > **Add** > **New Folder**. Name the folder *Models*.

Right click the *Models* folder. Select **Add** > **Class**. Name the class **Movie**.

Add the following properties to the `Movie` class:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace RazorPagesMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }

        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }
}
```

The `Movie` class contains:

- The `ID` field is required by the database for the primary key.
- `[DataType(DataType.Date)]`: The DataType attribute specifies the type of the data (Date). With this attribute:
  - The user is not required to enter time information in the date field.
  - Only the date is displayed, not time information.

DataAnnotations are covered in a later tutorial.

Build the project to verify there are no compilation errors.

Scaffold the movie model

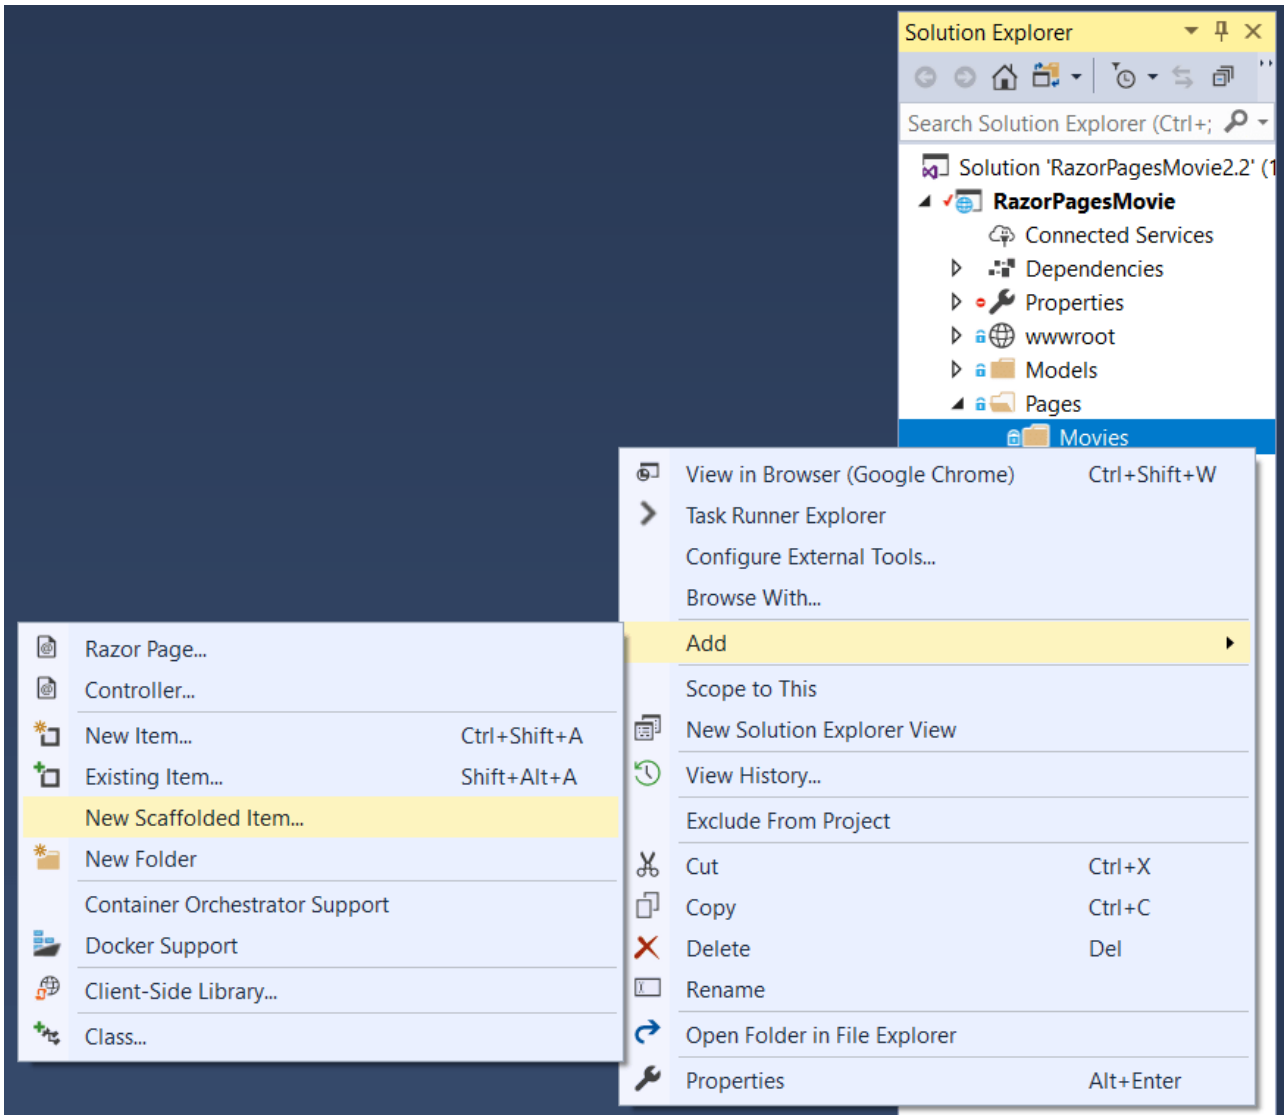
In this section, the movie model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the movie model.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

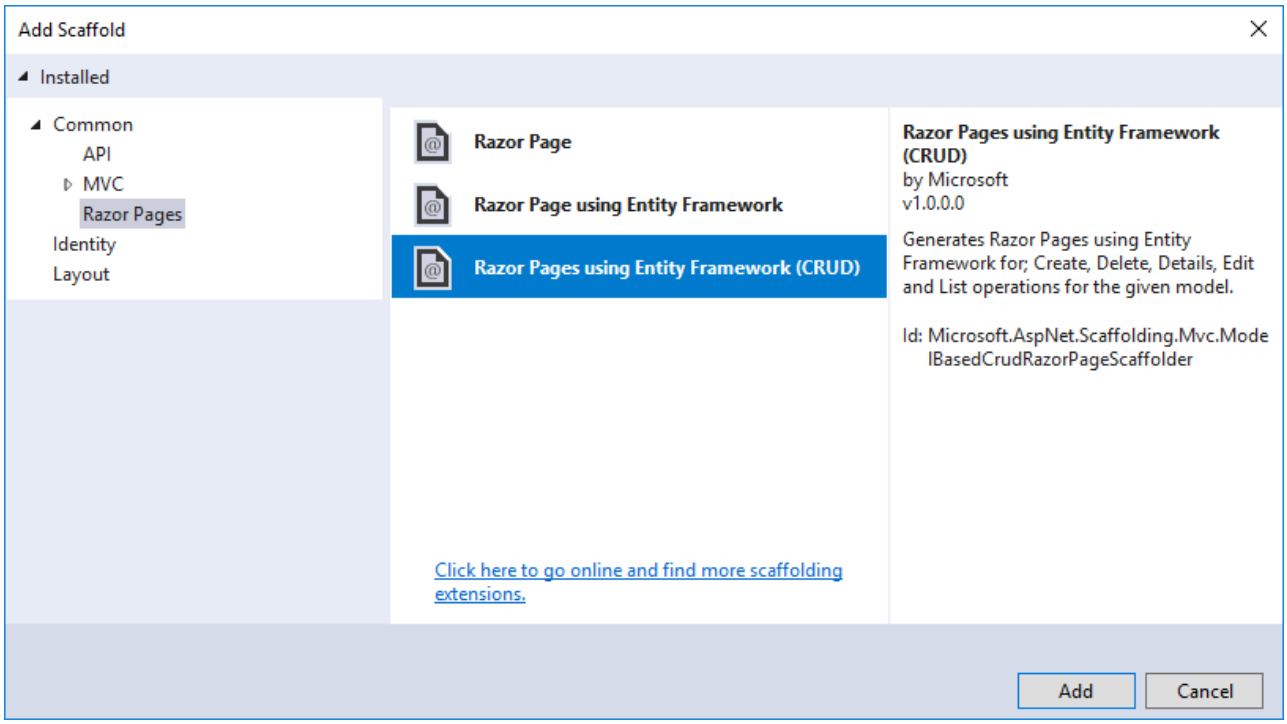
Create a *Pages/Movies* folder:

- Right click on the *Pages* folder > **Add** > **New Folder**.
- Name the folder *Movies*

Right click on the *Pages/Movies* folder > **Add** > **New Scaffolded Item**.

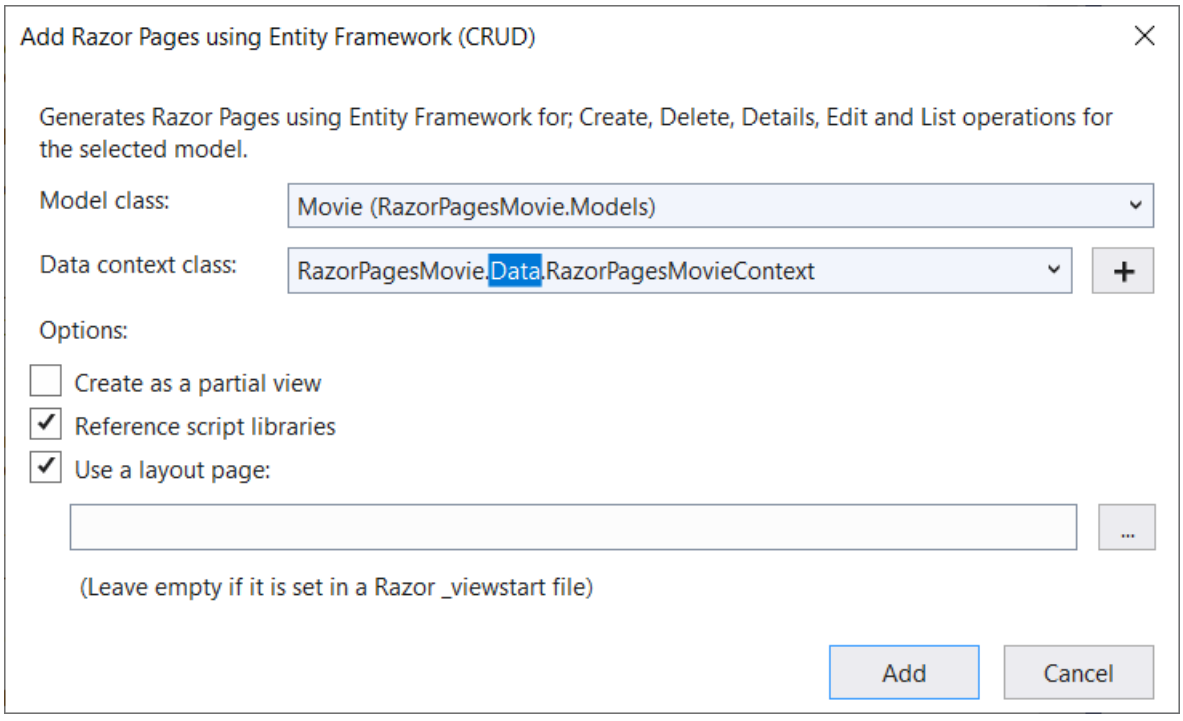


In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **Add**.



Complete the **Add Razor Pages using Entity Framework (CRUD)** dialog:

- In the **Model class** drop down, select **Movie (RazorPagesMovie.Models)**.
- In the **Data context class** row, select the **+** (plus) sign and change the generated name from RazorPagesMovie.**Models**.RazorPagesMovieContext to RazorPagesMovie.**Data**.RazorPagesMovieContext. This change is not required. It creates the database context class with the correct namespace.
- Select **Add**.



The *appsettings.json* file is updated with the connection string used to connect to a local database.

Files created

- Visual Studio
- Visual Studio for Mac
- Visual Studio Code

The scaffold process creates and updates the following files:

- *Pages/Movies*: Create, Delete, Details, Edit, and Index.
- *Data/RazorPagesMovieContext.cs*

Updated

- *Startup.cs*

The created and updated files are explained in the next section.

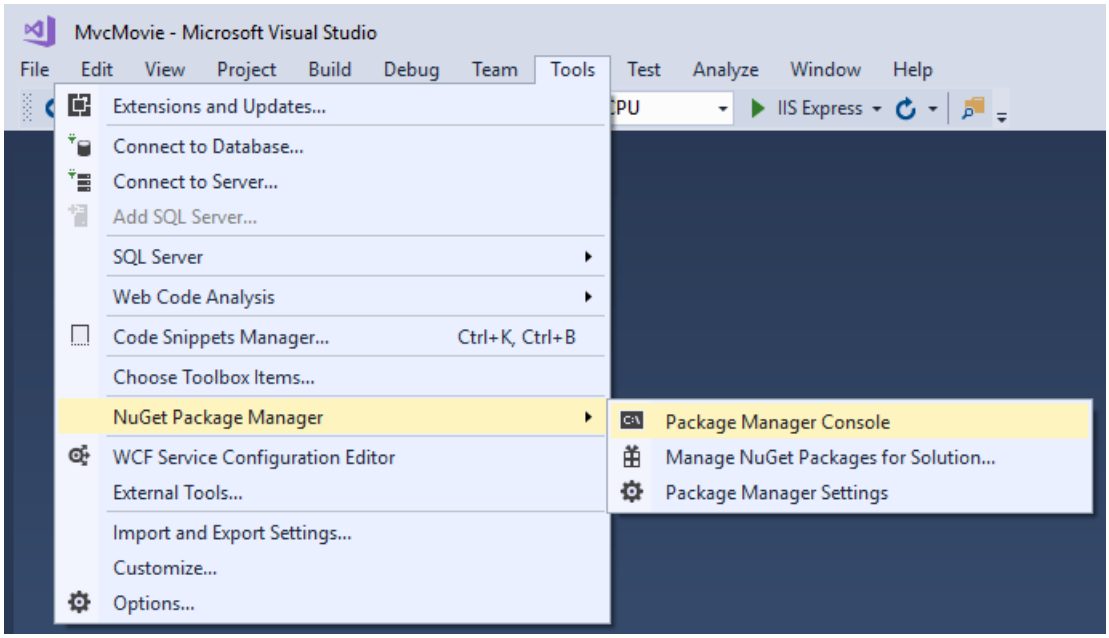
Initial migration

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

In this section, the Package Manager Console (PMC) is used to:

- Add an initial migration.
- Update the database with the initial migration.

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.



In the PMC, enter the following commands:

```
Add-Migration InitialCreate
Update-Database
```

The preceding commands generate the following warning: "No type was specified for the decimal column 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default precision and scale. Explicitly specify the SQL server column type that can accommodate all the values using 'HasColumnType()'."

You can ignore that warning, it will be fixed in a later tutorial.

The migrations command generates code to create the initial database schema. The schema is based on the model specified in `DbContext`. The `InitialCreate` argument is used to name the migrations. Any name can be used, but by convention a name is selected that describes the migration.

The `update` command runs the `Up` method in migrations that have not been applied. In this case, `update` runs the `Up` method in *Migrations/<time-stamp>_InitialCreate.cs* file, which creates the database.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection. Services (such as the EF Core DB context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a DB context instance is shown later in the tutorial.

The scaffolding tool automatically created a DB context and registered it with the dependency injection container.

Examine the `Startup.ConfigureServices` method. The highlighted line was added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddDbContext<RazorPagesMovieContext>(options =>
      options.UseSqlServer(Configuration.GetConnectionString("RazorPagesMovieContext")));
}
```

The `RazorPagesMovieContext` coordinates EF Core functionality (Create, Read, Update, Delete, etc.) for the `Movie` model. The data context (`RazorPagesMovieContext`) is derived from Microsoft.EntityFrameworkCore.DbContext. The data context specifies which entities are included in the data model.

```
using Microsoft.EntityFrameworkCore;

namespace RazorPagesMovie.Models
{
    public class RazorPagesMovieContext : DbContext
    {
        public RazorPagesMovieContext (DbContextOptions<RazorPagesMovieContext> options)
            : base(options)
        {
        }

        public DbSet<RazorPagesMovie.Models.Movie> Movie { get; set; }
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Test the app

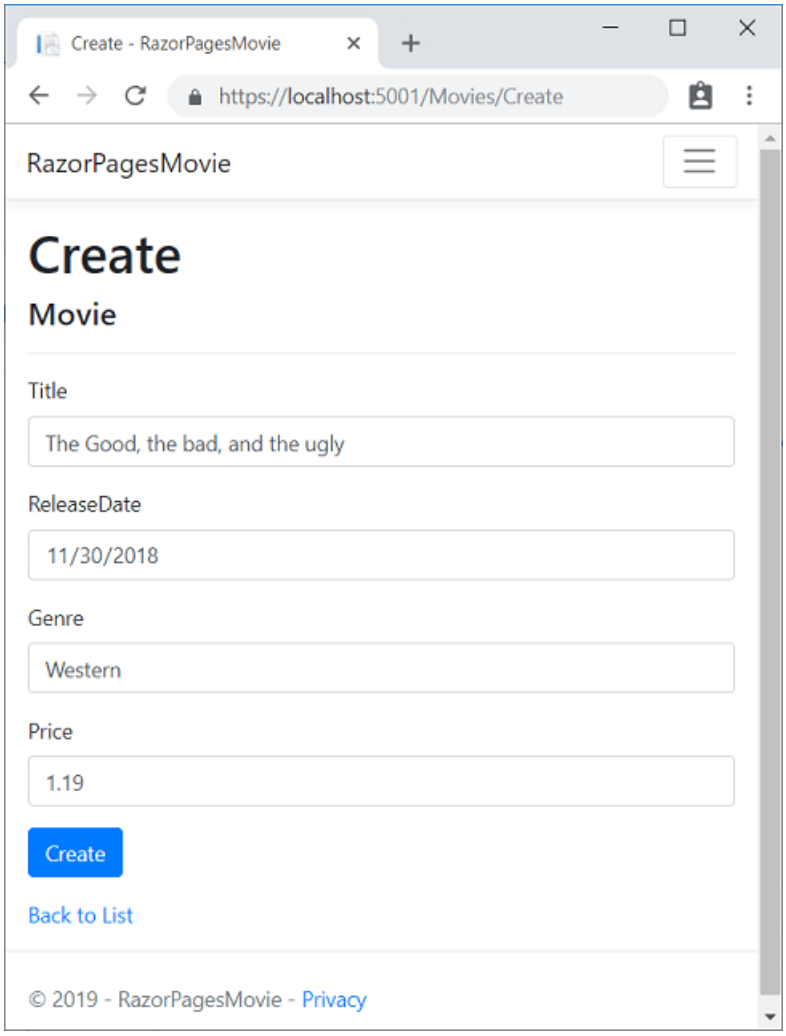
- Run the app and append `/Movies` to the URL in the browser (`http://localhost:port/movies`).

If you get the error:

```
SqlException: Cannot open database "RazorPagesMovieContext-GUID" requested by the login. The login failed.
Login failed for user 'User-name'.
```

You missed the migrations step.

- Test the **Create** link.



> **NOTE**
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

- Test the **Edit**, **Details**, and **Delete** links.

The next tutorial explains the files created by scaffolding.

Additional resources

PREVIOUS: GET STARTED
NEXT: SCAFFOLDED RAZOR PAGES

In this section, classes are added for managing movies in a cross-platform SQLite database. Apps created from an ASP.NET Core template use a SQLite database. The app's model classes are used with Entity Framework Core (EF Core) (SQLite EF Core Database Provider) to work with the database. EF Core is an object-relational mapping (ORM) framework that simplifies data access.

The model classes are known as POCO classes (from "plain-old CLR objects") because they don't have any dependency on EF Core. They define the properties of the data that are stored in the database.

View or download sample code (how to download).

View or download sample code (how to download).

Add a data model

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Right-click the **RazorPagesMovie** project > **Add** > **New Folder**. Name the folder *Models*.

Right click the *Models* folder. Select **Add** > **Class**. Name the class **Movie**.

Add the following properties to the `Movie` class:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace RazorPagesMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }

        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }
}
```

The `Movie` class contains:

- The `ID` field is required by the database for the primary key.
- `[DataType(DataType.Date)]`: The DataType attribute specifies the type of the data (Date). With this attribute:
  - The user is not required to enter time information in the date field.
  - Only the date is displayed, not time information.

DataAnnotations are covered in a later tutorial.

Build the project to verify there are no compilation errors.

Scaffold the movie model

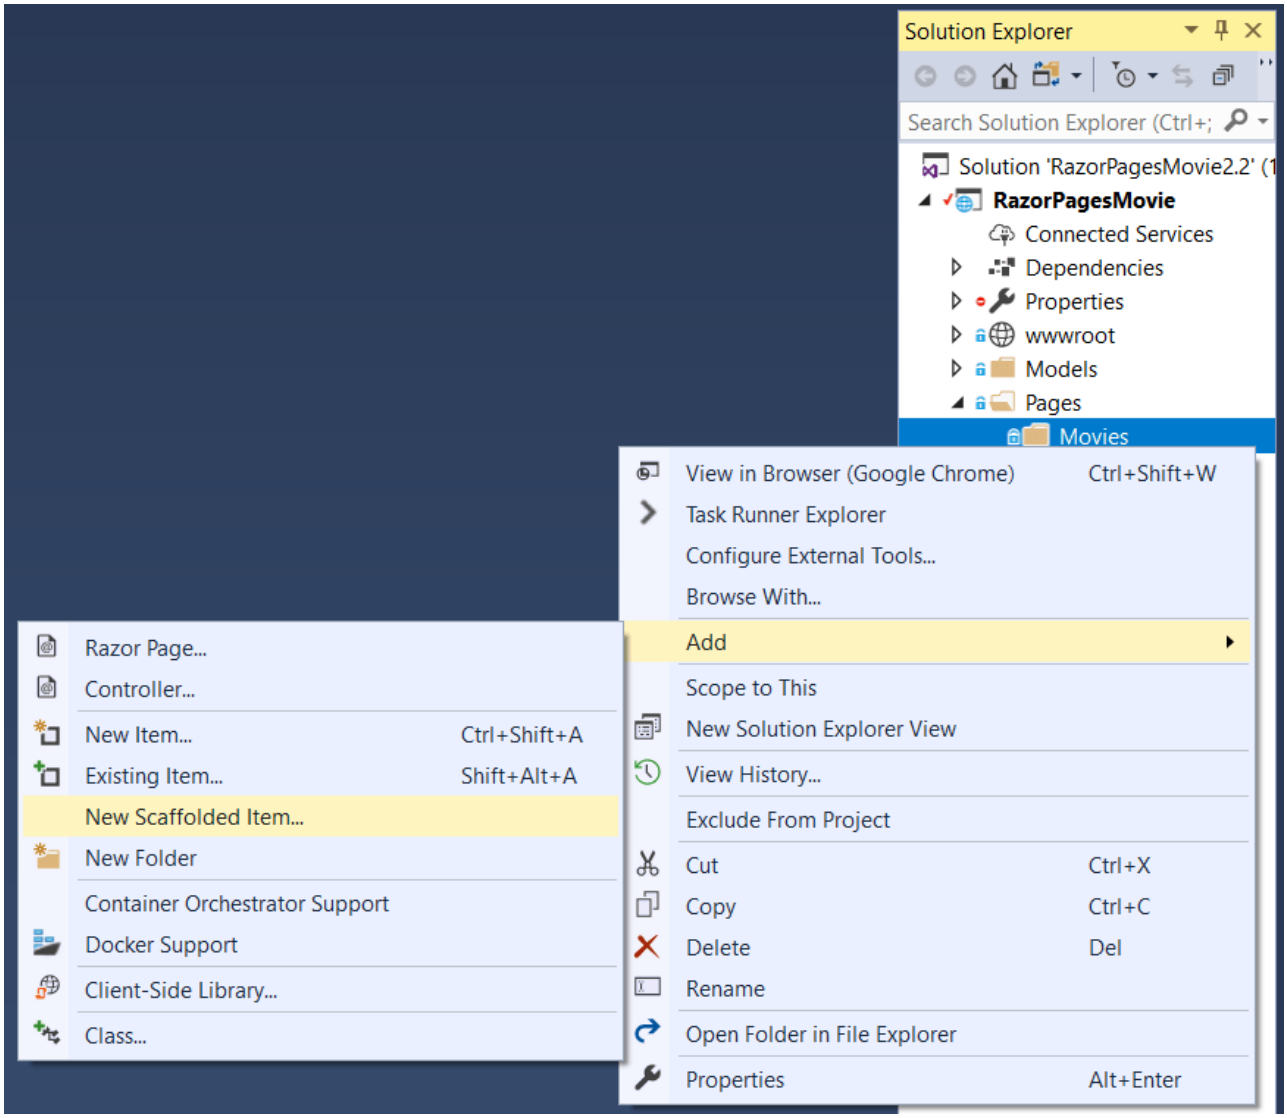
In this section, the movie model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the movie model.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

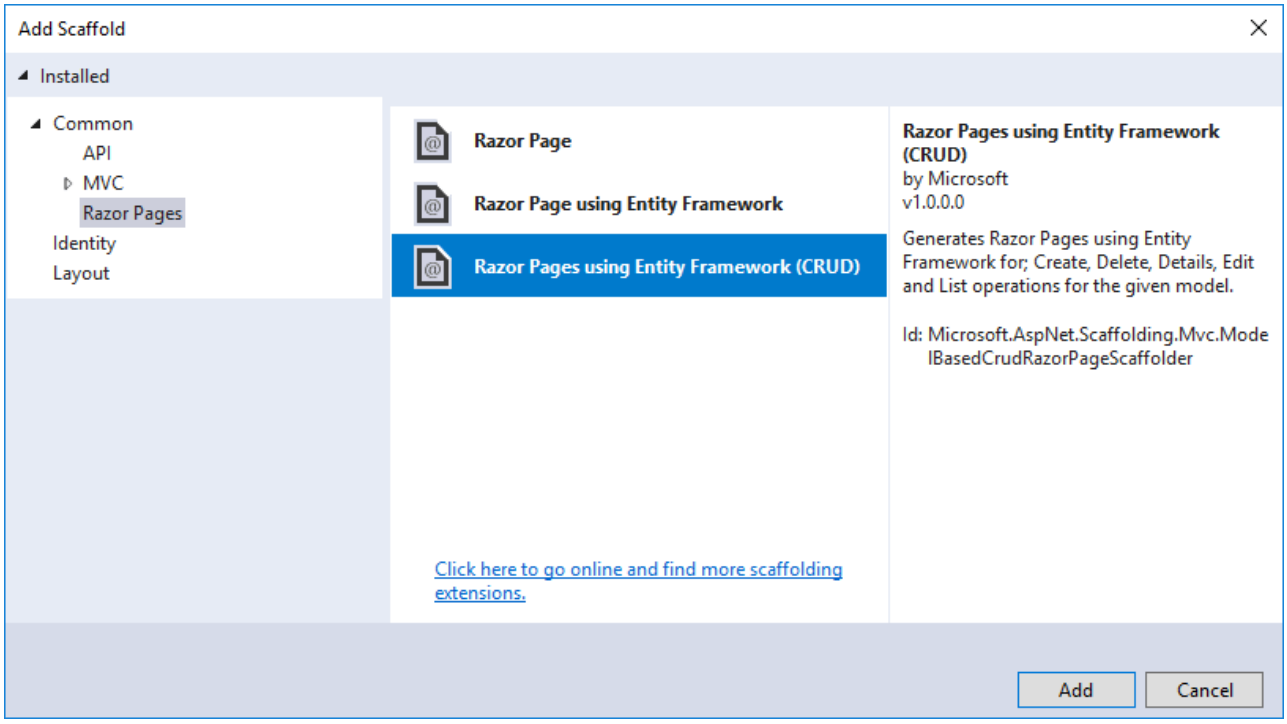
Create a *Pages/Movies* folder:

- Right click on the *Pages* folder > **Add** > **New Folder**.
- Name the folder *Movies*

Right click on the *Pages/Movies* folder > **Add** > **New Scaffolded Item**.

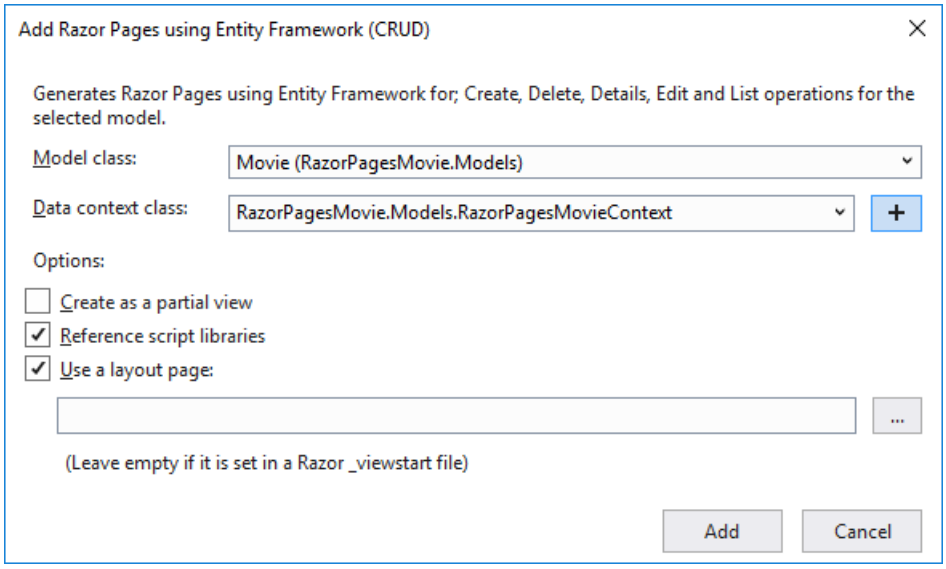


In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **Add**.



Complete the **Add Razor Pages using Entity Framework (CRUD)** dialog:

- In the **Model class** drop down, select **Movie (RazorPagesMovie.Models)**.
- In the **Data context class** row, select the **+** (plus) sign and accept the generated name **RazorPagesMovie.Models.RazorPagesMovieContext**.
- Select **Add**.



The *appsettings.json* file is updated with the connection string used to connect to a local database.

The scaffold process creates and updates the following files:

Files created

- *Pages/Movies*: Create, Delete, Details, Edit, and Index.
- *Data/RazorPagesMovieContext.cs*

File updated

- *Startup.cs*

The created and updated files are explained in the next section.

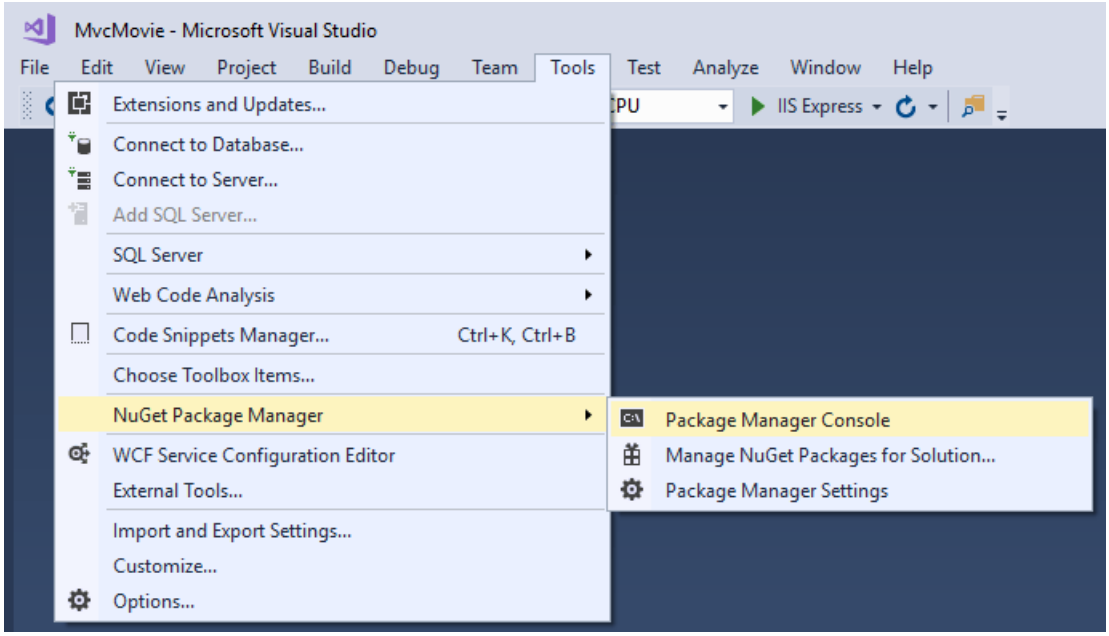
Initial migration

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

In this section, the Package Manager Console (PMC) is used to:

- Add an initial migration.
- Update the database with the initial migration.

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.



In the PMC, enter the following commands:

```
Add-Migration Initial
Update-Database
```

The `Add-Migration` command generates code to create the initial database schema. The schema is based on the model specified in the `DbContext` (In the *RazorPagesMovieContext.cs* file). The `InitialCreate` argument is used to name the migration. Any name can be used, but by convention a name that describes the migration is used. For more information, see Tutorial: Using the migrations feature - ASP.NET MVC with EF Core.

The `Update-Database` command runs the `Up` method in the *Migrations/<time-stamp>_InitialCreate.cs* file. The `Up` method creates the database.

> **NOTE**
>
> The preceding commands generate the following warning: "*No type was specified for the decimal column 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default precision and scale. Explicitly specify the SQL server column type that can accommodate all the values using 'HasColumnType()'.*" You can ignore that warning, it will be fixed in a later tutorial.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection. Services (such as the EF Core DB context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a DB context instance is shown later in the tutorial.

The scaffolding tool automatically created a DB context and registered it with the dependency injection container.

Examine the `Startup.ConfigureServices` method. The highlighted line was added by the scaffolder:

```
// This method gets called by the runtime.
// Use this method to add services to the container.
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for non-essential cookies is
        // needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddDbContext<RazorPagesMovieContext>(options =>
      options.UseSqlServer(
          Configuration.GetConnectionString("RazorPagesMovieContext")));
}
```

The `RazorPagesMovieContext` coordinates EF Core functionality (Create, Read, Update, Delete, etc.) for the `Movie` model. The data context (`RazorPagesMovieContext`) is derived from Microsoft.EntityFrameworkCore.DbContext. The data context specifies which entities are included in the data model.

```
using Microsoft.EntityFrameworkCore;

namespace RazorPagesMovie.Models
{
    public class RazorPagesMovieContext : DbContext
    {
        public RazorPagesMovieContext (DbContextOptions<RazorPagesMovieContext> options)
            : base(options)
        {
        }

        public DbSet<RazorPagesMovie.Models.Movie> Movie { get; set; }
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Test the app

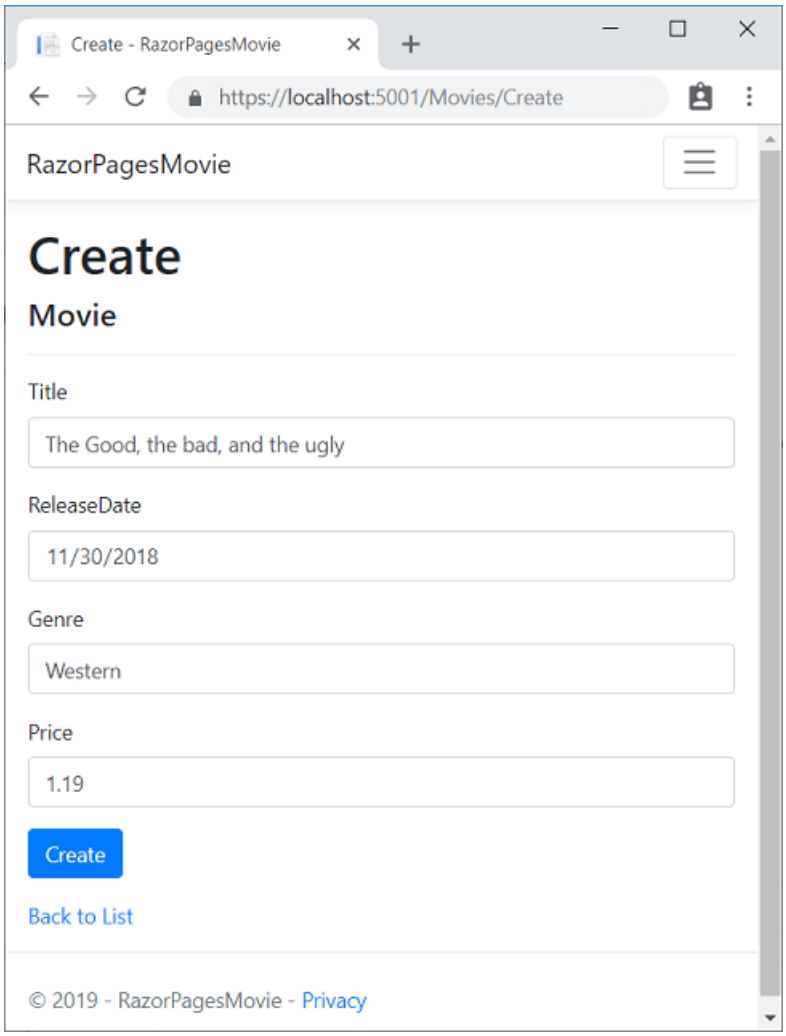
- Run the app and append `/Movies` to the URL in the browser (`http://localhost:port/movies`).

If you get the error:

```
SqlException: Cannot open database "RazorPagesMovieContext-GUID" requested by the login. The login failed.
Login failed for user 'User-name'.
```

You missed the migrations step.

- Test the **Create** link.



> **NOTE**
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

- Test the **Edit**, **Details**, and **Delete** links.

The next tutorial explains the files created by scaffolding.

Additional resources

PREVIOUS: GET STARTED
NEXT: SCAFFOLDED RAZOR PAGES

Part 3, scaffolded Razor Pages in ASP.NET Core

9/22/2020 • 16 minutes to read • Edit Online

By Rick Anderson

This tutorial examines the Razor Pages created by scaffolding in the previous tutorial.

View or download sample code (how to download).

View or download sample code (how to download).

The Create, Delete, Details, and Edit pages

Examine the *Pages/Movies/Index.cshtml.cs* Page Model:

```
// Unused usings removed.
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Models;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace RazorPagesMovie.Pages.Movies
{
    public class IndexModel : PageModel
    {
        private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

        public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
        {
            _context = context;
        }

        public IList<Movie> Movie { get;set; }

        public async Task OnGetAsync()
        {
            Movie = await _context.Movie.ToListAsync();
        }
    }
}
```

Razor Pages are derived from `PageModel`. By convention, the `PageModel`-derived class is called `<PageName>Model`. The constructor uses dependency injection to add the `RazorPagesMovieContext` to the page. All the scaffolded pages follow this pattern. See Asynchronous code for more information on asynchronous programming with Entity Framework.

When a request is made for the page, the `OnGetAsync` method returns a list of movies to the Razor Page. `OnGetAsync` or `OnGet` is called to initialize the state of the page. In this case, `OnGetAsync` gets a list of movies and displays them.

When `OnGet` returns `void` or `OnGetAsync` returns `Task`, no return statement is used. When the return type is `IActionResult` or `Task<IActionResult>`, a return statement must be provided. For example, the *Pages/Movies/Create.cshtml.cs* `OnPostAsync` method:

```
    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Movie.Add(Movie);
        await _context.SaveChangesAsync();

        return RedirectToPage("./Index");
    }
}
```

Examine the *Pages/Movies/Index.cshtml* Razor Page:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Razor can transition from HTML into C# or into Razor-specific markup. When an `@` symbol is followed by a Razor reserved keyword, it transitions into Razor-specific markup, otherwise it transitions into C#.

The @page directive

The `@page` Razor directive makes the file an MVC action, which means that it can handle requests. `@page` must be the first Razor directive on a page. `@page` is an example of transitioning into Razor-specific markup. See Razor syntax for more information.

Examine the lambda expression used in the following HTML Helper:

```
@Html.DisplayNameFor(model => model.Movie[0].Title)
```

The `DisplayNameFor` HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. The lambda expression is inspected rather than evaluated. That means there is no access violation when `model`, `model.Movie`, or `model.Movie[0]` is `null` or empty. When the lambda expression is evaluated (for example, with `@Html.DisplayFor(modelItem => item.Title)`), the model's property values are evaluated.

The @model directive

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel
```

The `@model` directive specifies the type of the model passed to the Razor Page. In the preceding example, the `@model` line makes the `PageModel`-derived class available to the Razor Page. The model is used in the `@Html.DisplayNameFor` and `@Html.DisplayFor` HTML Helpers on the page.

The layout page

Select the menu links (**RazorPagesMovie**, **Home**, and **Privacy**). Each page shows the same menu layout. The menu layout is implemented in the *Pages/Shared/_Layout.cshtml* file. Open the *Pages/Shared/_Layout.cshtml* file.

Layout templates allow the HTML container layout to be:

- Specified in one place.
- Applied in multiple pages in the site.

Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the page-specific views show up, *wrapped* in the layout page. For example, select the **Privacy** link and the *Pages/Privacy.cshtml* view is rendered inside the `RenderBody` method.

ViewData and layout

Consider the following markup from the *Pages/Movies/Index.cshtml* file:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}
```

The preceding highlighted markup is an example of Razor transitioning into C#. The `{` and `}` characters enclose a block of C# code.

The `PageModel` base class contains a `ViewData` dictionary property that can be used to pass data to a View. Objects are added to the `ViewData` dictionary using a key/value pattern. In the preceding sample, the `"Title"` property is added to the `ViewData` dictionary.

The `"Title"` property is used in the *Pages/Shared/_Layout.cshtml* file. The following markup shows the first few lines of the *_Layout.cshtml* file.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - RazorPagesMovie</title>

    @*Markup removed for brevity.*@
```

The line `@*Markup removed for brevity.*@` is a Razor comment. Unlike HTML comments (`<!-- -->`), Razor comments are not sent to the client.

Update the layout

Change the `<title>` element in the *Pages/Shared/_Layout.cshtml* file to display **Movie** rather than **RazorPagesMovie**.

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie</title>
```

Find the following anchor element in the *Pages/Shared/_Layout.cshtml* file.

```
<a class="navbar-brand" asp-area="" asp-page="/Index">RazorPagesMovie</a>
```

Replace the preceding element with the following markup:

```
<a class="navbar-brand" asp-page="/Movies/Index">RpMovie</a>
```

The preceding anchor element is a Tag Helper. In this case, it's the Anchor Tag Helper. The `asp-page="/Movies/Index"` Tag Helper attribute and value creates a link to the `/Movies/Index` Razor Page. The `asp-area` attribute value is empty, so the area isn't used in the link. See Areas for more information.

Save your changes, and test the app by clicking on the **RpMovie** link. See the _Layout.cshtml file in GitHub if you have any problems.

Test the other links (**Home**, **RpMovie**, **Create**, **Edit**, and **Delete**). Each page sets the title, which you can see in the browser tab. When you bookmark a page, the title is used for the bookmark.

> **NOTE**
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub issue 4076 for instructions on adding decimal comma.

The `Layout` property is set in the *Pages/_ViewStart.cshtml* file:

```
@{
    Layout = "_Layout";
}
```

The preceding markup sets the layout file to *Pages/Shared/_Layout.cshtml* for all Razor files under the *Pages* folder.

See Layout for more information.

The Create page model

Examine the *Pages/Movies/Create.cshtml.cs* page model:

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesMovie.Models;
using System;
using System.Threading.Tasks;

namespace RazorPagesMovie.Pages.Movies
{
    public class CreateModel : PageModel
    {
        private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

        public CreateModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            return Page();
        }

        [BindProperty]
        public Movie Movie { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _context.Movie.Add(Movie);
            await _context.SaveChangesAsync();

            return RedirectToPage("./Index");
        }
    }
}
```

The `OnGet` method initializes any state needed for the page. The Create page doesn't have any state to initialize, so `Page` is returned. Later in the tutorial, an example of `OnGet` initializing state is shown. The `Page` method creates a `PageResult` object that renders the *Create.cshtml* page.

The `Movie` property uses the `[BindProperty]` attribute to opt-in to model binding. When the Create form posts the form values, the ASP.NET Core runtime binds the posted values to the `Movie` model.

The `OnPostAsync` method is run when the page posts form data:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

If there are any model errors, the form is redisplayed, along with any form data posted. Most model errors can be caught on the client-side before the form is posted. An example of a model error is posting a value for the date field that cannot be converted to a date. Client-side validation and model validation are discussed later in the tutorial.

If there are no model errors, the data is saved, and the browser is redirected to the Index page.

The Create Razor Page

Examine the *Pages/Movies/Create.cshtml* Razor Page file:

```
@page
@model RazorPagesMovie.Pages.Movies.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h1>Create</h1>

<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Movie.Title" class="control-label"></label>
                <input asp-for="Movie.Title" class="form-control" />
                <span asp-validation-for="Movie.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.ReleaseDate" class="control-label"></label>
                <input asp-for="Movie.ReleaseDate" class="form-control" />
                <span asp-validation-for="Movie.ReleaseDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Genre" class="control-label"></label>
                <input asp-for="Movie.Genre" class="form-control" />
                <span asp-validation-for="Movie.Genre" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Price" class="control-label"></label>
                <input asp-for="Movie.Price" class="form-control" />
                <span asp-validation-for="Movie.Price" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

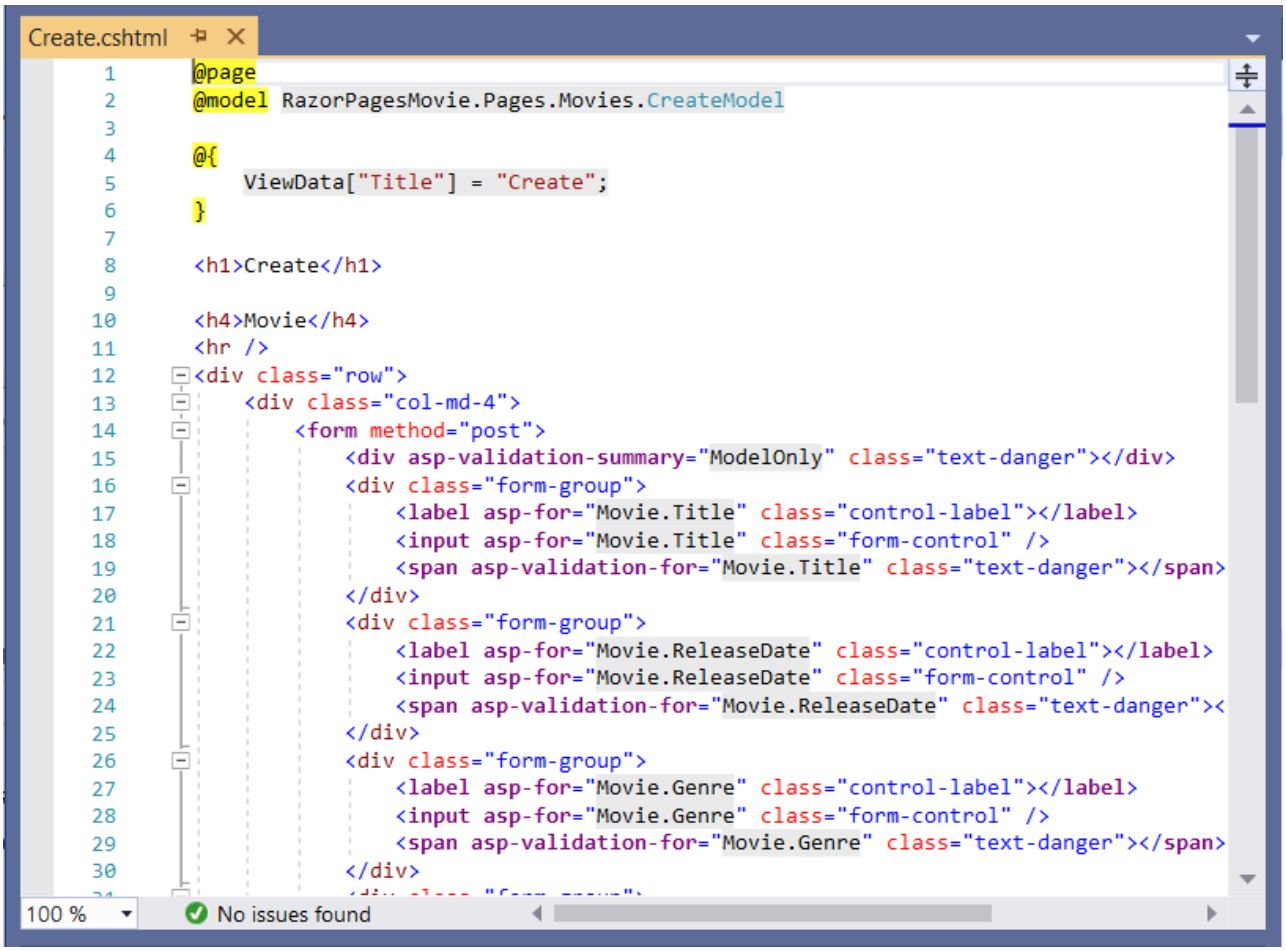
<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Visual Studio displays the following tags in a distinctive bold font used for Tag Helpers:

- `<form method="post">`
- `<div asp-validation-summary="ModelOnly" class="text-danger"></div>`
- `<label asp-for="Movie.Title" class="control-label"></label>`
- `<input asp-for="Movie.Title" class="form-control" />`
- `<span asp-validation-for="Movie.Title" class="text-danger"></span>`



The `<form method="post">` element is a Form Tag Helper. The Form Tag Helper automatically includes an antiforgery token.

The scaffolding engine creates Razor markup for each field in the model (except the ID) similar to the following:

```
<div asp-validation-summary="ModelOnly" class="text-danger"></div>
<div class="form-group">
    <label asp-for="Movie.Title" class="control-label"></label>
    <input asp-for="Movie.Title" class="form-control" />
    <span asp-validation-for="Movie.Title" class="text-danger"></span>
</div>
```

The Validation Tag Helpers (`<div asp-validation-summary` and `<span asp-validation-for`) display validation errors. Validation is covered in more detail later in this series.

The Label Tag Helper (`<label asp-for="Movie.Title" class="control-label"></label>`) generates the label caption and `for` attribute for the `Title` property.

The Input Tag Helper (`<input asp-for="Movie.Title" class="form-control">`) uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side.

For more information on Tag Helpers such as `<form method="post">`, see Tag Helpers in ASP.NET Core.

PREVIOUS: ADDING A MODEL
NEXT: DATABASE

By Rick Anderson

This tutorial examines the Razor Pages created by scaffolding in the previous tutorial.

View or download sample.

The Create, Delete, Details, and Edit pages

Examine the *Pages/Movies/Index.cshtml.cs* Page Model:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using RazorPagesMovie.Models;

namespace RazorPagesMovie.Pages.Movies
{
    public class IndexModel : PageModel
    {
        private readonly RazorPagesMovie.Models.RazorPagesMovieContext _context;

        public IndexModel(RazorPagesMovie.Models.RazorPagesMovieContext context)
        {
            _context = context;
        }

        public IList<Movie> Movie { get;set; }

        public async Task OnGetAsync()
        {
            Movie = await _context.Movie.ToListAsync();
        }
    }
}
```

Razor Pages are derived from `PageModel`. By convention, the `PageModel`-derived class is called `<PageName>Model`. The constructor uses dependency injection to add the `RazorPagesMovieContext` to the page. All the scaffolded pages follow this pattern. See Asynchronous code for more information on asynchronous programming with Entity Framework.

When a request is made for the page, the `OnGetAsync` method returns a list of movies to the Razor Page. `OnGetAsync` or `OnGet` is called on a Razor Page to initialize the state for the page. In this case, `OnGetAsync` gets a list of movies and displays them.

When `OnGet` returns `void` or `OnGetAsync` returns `Task`, no return method is used. When the return type is `IActionResult` or `Task<IActionResult>`, a return statement must be provided. For example, the *Pages/Movies/Create.cshtml.cs* `OnPostAsync` method:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

Examine the *Pages/Movies/Index.cshtml* Razor Page:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Razor can transition from HTML into C# or into Razor-specific markup. When an `@` symbol is followed by a Razor reserved keyword, it transitions into Razor-specific markup, otherwise it transitions into C#.

The `@page` Razor directive makes the file into an MVC action, which means that it can handle requests. `@page` must be the first Razor directive on a page. `@page` is an example of transitioning into Razor-specific markup. See Razor syntax for more information.

Examine the lambda expression used in the following HTML Helper:

```
@Html.DisplayNameFor(model => model.Movie[0].Title)
```

The `DisplayNameFor` HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. The lambda expression is inspected rather than evaluated. That means there is no access violation when `model`, `model.Movie`, or `model.Movie[0]` are `null` or empty. When the lambda expression is evaluated (for example, with `@Html.DisplayFor(modelItem => item.Title)`), the model's property values are evaluated.

The @model directive

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel
```

The `@model` directive specifies the type of the model passed to the Razor Page. In the preceding example, the `@model` line makes the `PageModel`-derived class available to the Razor Page. The model is used in the `@Html.DisplayNameFor` and `@Html.DisplayFor` HTML Helpers on the page.

The layout page

Select the menu links (**RazorPagesMovie**, **Home**, and **Privacy**). Each page shows the same menu layout. The menu layout is implemented in the *Pages/Shared/_Layout.cshtml* file. Open the *Pages/Shared/_Layout.cshtml* file.

Layout templates allow you to specify the HTML container layout of your site in one place and then apply it across multiple pages in your site. Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the page-specific views you create show up, *wrapped* in the layout page. For example, if you select the **Privacy** link, the **Pages/Privacy.cshtml** view is rendered inside the `RenderBody` method.

ViewData and layout

Consider the following code from the *Pages/Movies/Index.cshtml* file:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}
```

The preceding highlighted code is an example of Razor transitioning into C#. The `{` and `}` characters enclose a block of C# code.

The `PageModel` base class has a `ViewData` dictionary property that can be used to add data that you want to pass to a View. You add objects into the `ViewData` dictionary using a key/value pattern. In the preceding sample, the "Title" property is added to the `ViewData` dictionary.

The "Title" property is used in the *Pages/Shared/_Layout.cshtml* file. The following markup shows the first few lines of the *_Layout.cshtml* file.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - RazorPagesMovie</title>

    @*Markup removed for brevity.*@
```

The line `@*Markup removed for brevity.*@` is a Razor comment which doesn't appear in your layout file. Unlike

HTML comments (`<!-- -->`), Razor comments are not sent to the client.

Update the layout

Change the `<title>` element in the *Pages/Shared/_Layout.cshtml* file to display **Movie** rather than **RazorPagesMovie**.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie</title>
```

Find the following anchor element in the *Pages/Shared/_Layout.cshtml* file.

```
<a class="navbar-brand" asp-area="" asp-page="/Index">RazorPagesMovie</a>
```

Replace the preceding element with the following markup.

```
<a class="navbar-brand" asp-page="/Movies/Index">RpMovie</a>
```

The preceding anchor element is a Tag Helper. In this case, it's the Anchor Tag Helper. The `asp-page="/Movies/Index"` Tag Helper attribute and value creates a link to the `/Movies/Index` Razor Page. The `asp-area` attribute value is empty, so the area isn't used in the link. See Areas for more information.

Save your changes, and test the app by clicking on the **RpMovie** link. See the _Layout.cshtml file in GitHub if you have any problems.

Test the other links (**Home**, **RpMovie**, **Create**, **Edit**, and **Delete**). Each page sets the title, which you can see in the browser tab. When you bookmark a page, the title is used for the bookmark.

> **NOTE**
>
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. This GitHub issue 4076 for instructions on adding decimal comma.

The `Layout` property is set in the *Pages/_ViewStart.cshtml* file:

```
@{
    Layout = "_Layout";
}
```

The preceding markup sets the layout file to *Pages/Shared/_Layout.cshtml* for all Razor files under the *Pages* folder. See Layout for more information.

The Create page model

Examine the *Pages/Movies/Create.cshtml.cs* page model:

```
// Unused usings removed.
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesMovie.Models;
using System;
using System.Threading.Tasks;

namespace RazorPagesMovie.Pages.Movies
{
    public class CreateModel : PageModel
    {
        private readonly RazorPagesMovie.Models.RazorPagesMovieContext _context;

        public CreateModel(RazorPagesMovie.Models.RazorPagesMovieContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            return Page();
        }

        [BindProperty]
        public Movie Movie { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            _context.Movie.Add(Movie);
            await _context.SaveChangesAsync();

            return RedirectToPage("./Index");
        }
    }
}
```

The `OnGet` method initializes any state needed for the page. The Create page doesn't have any state to initialize, so `Page` is returned. Later in the tutorial you see `OnGet` method initialize state. The `Page` method creates a `PageResult` object that renders the *Create.cshtml* page.

The `Movie` property uses the `[BindProperty]` attribute to opt-in to model binding. When the Create form posts the form values, the ASP.NET Core runtime binds the posted values to the `Movie` model.

The `OnPostAsync` method is run when the page posts form data:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Movie.Add(Movie);
    await _context.SaveChangesAsync();

    return RedirectToPage("./Index");
}
```

If there are any model errors, the form is redisplayed, along with any form data posted. Most model errors can be caught on the client-side before the form is posted. An example of a model error is posting a value for the date field that cannot be converted to a date. Client-side validation and model validation are discussed later in the tutorial.

If there are no model errors, the data is saved, and the browser is redirected to the Index page.

The Create Razor Page

Examine the *Pages/Movies/Create.cshtml* Razor Page file:

```
@page
@model RazorPagesMovie.Pages.Movies.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h1>Create</h1>

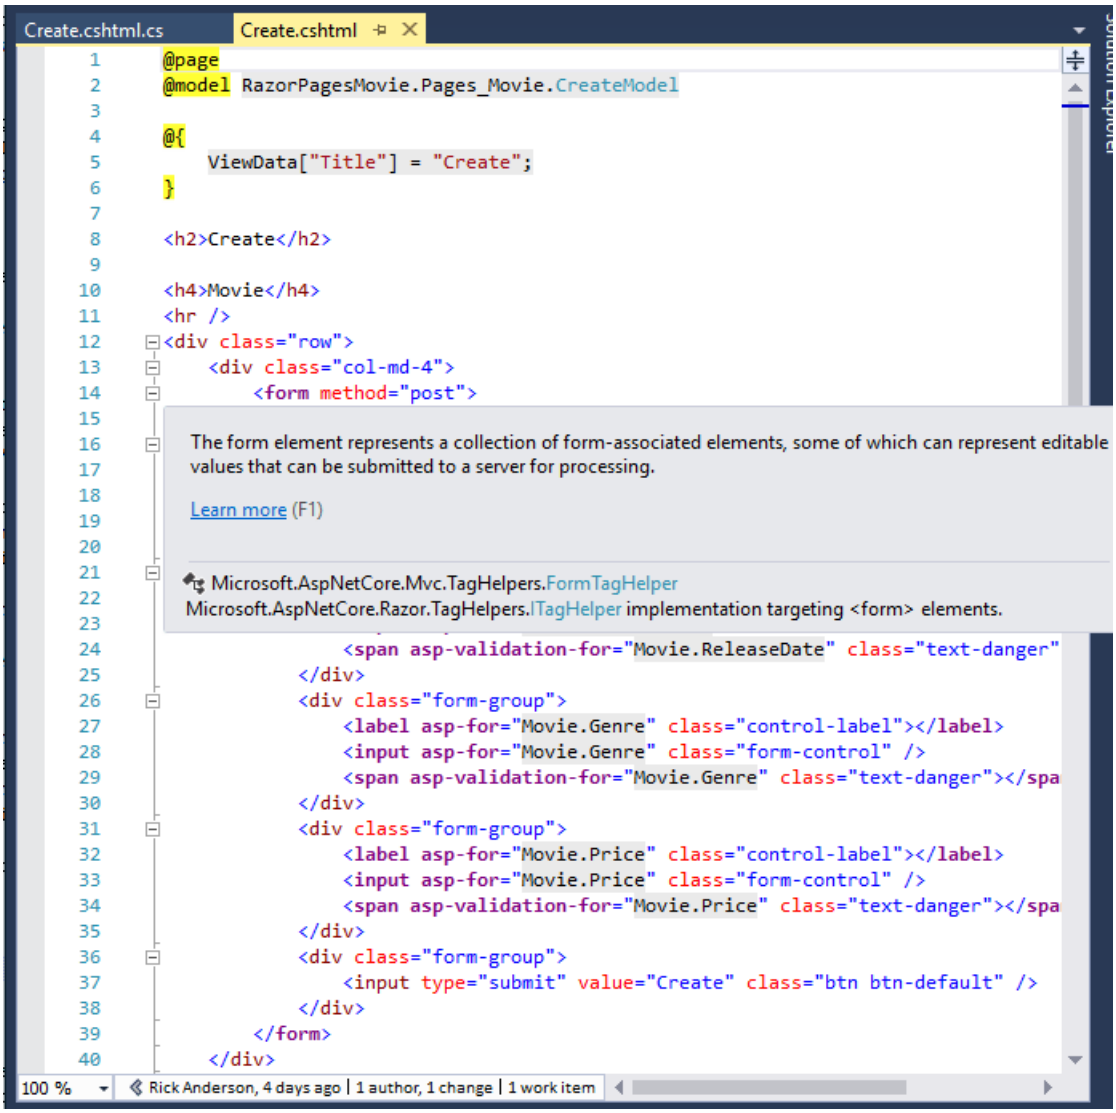
<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Movie.Title" class="control-label"></label>
                <input asp-for="Movie.Title" class="form-control" />
                <span asp-validation-for="Movie.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.ReleaseDate" class="control-label"></label>
                <input asp-for="Movie.ReleaseDate" class="form-control" />
                <span asp-validation-for="Movie.ReleaseDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Genre" class="control-label"></label>
                <input asp-for="Movie.Genre" class="form-control" />
                <span asp-validation-for="Movie.Genre" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Movie.Price" class="control-label"></label>
                <input asp-for="Movie.Price" class="form-control" />
                <span asp-validation-for="Movie.Price" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Visual Studio displays the `<form method="post">` tag in a distinctive bold font used for Tag Helpers:



The `<form method="post">` element is a Form Tag Helper. The Form Tag Helper automatically includes an antiforgery token.

The scaffolding engine creates Razor markup for each field in the model (except the ID) similar to the following:

```
<div asp-validation-summary="ModelOnly" class="text-danger"></div>
<div class="form-group">
    <label asp-for="Movie.Title" class="control-label"></label>
    <input asp-for="Movie.Title" class="form-control" />
    <span asp-validation-for="Movie.Title" class="text-danger"></span>
</div>
```

The Validation Tag Helpers (`<div asp-validation-summary` and `<span asp-validation-for`) display validation errors. Validation is covered in more detail later in this series.

The Label Tag Helper (`<label asp-for="Movie.Title" class="control-label"></label>`) generates the label caption and `for` attribute for the `Title` property.

The Input Tag Helper (`<input asp-for="Movie.Title" class="form-control">`) uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side.

PREVIOUS: ADDING A MODEL

NEXT: DATABASE

Part 4, with a database and ASP.NET Core

9/22/2020 • 12 minutes to read • Edit Online

By Rick Anderson and Joe Audette

View or download sample code (how to download).

View or download sample code (how to download).

The `RazorPagesMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to database records. The database context is registered with the Dependency Injection container in the `ConfigureServices` method in *Startup.cs*:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddDbContext<RazorPagesMovieContext>(options =>
      options.UseSqlServer(Configuration.GetConnectionString("RazorPagesMovieContext")));
}
```

The ASP.NET Core Configuration system reads the `ConnectionString`. For local development, it gets the connection string from the *appsettings.json* file.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

The name value for the database (`Database={Database name}`) will be different for your generated code. The name value is arbitrary.

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "RazorPagesMovieContext": "Server=(localdb)\\mssqllocaldb;Database=RazorPagesMovieContext-
bc;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

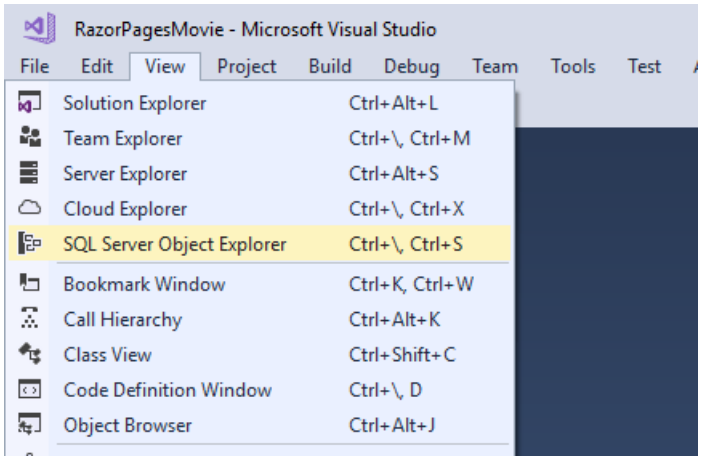
When the app is deployed to a test or production server, an environment variable can be used to set the connection string to a real database server. See Configuration for more information.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

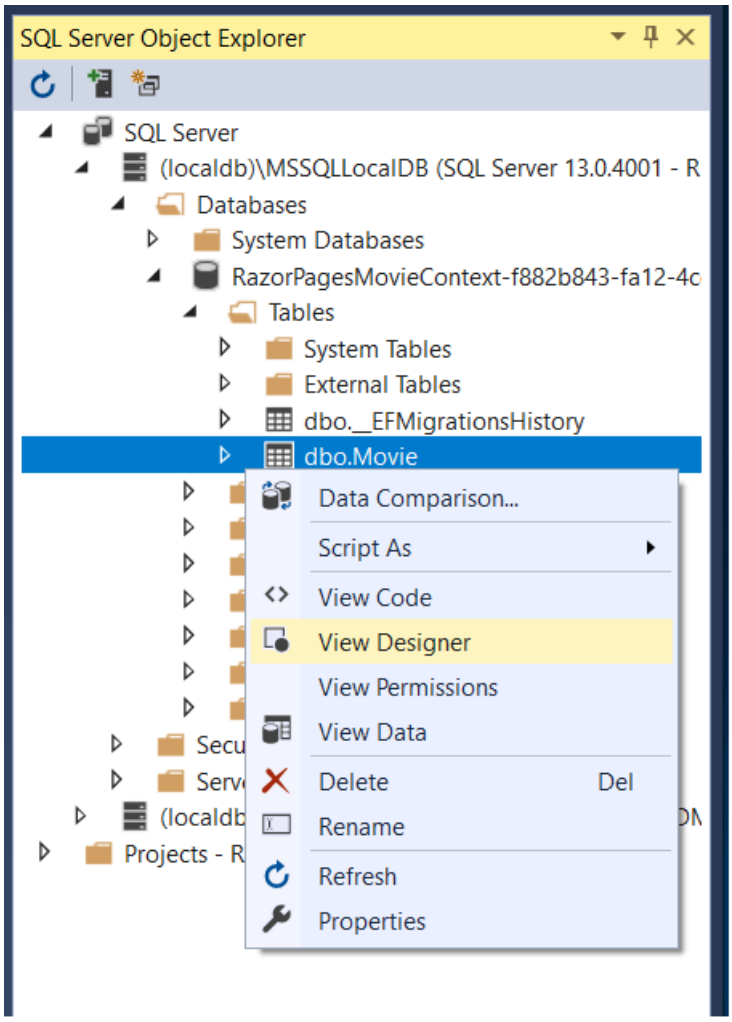
SQL Server Express LocalDB

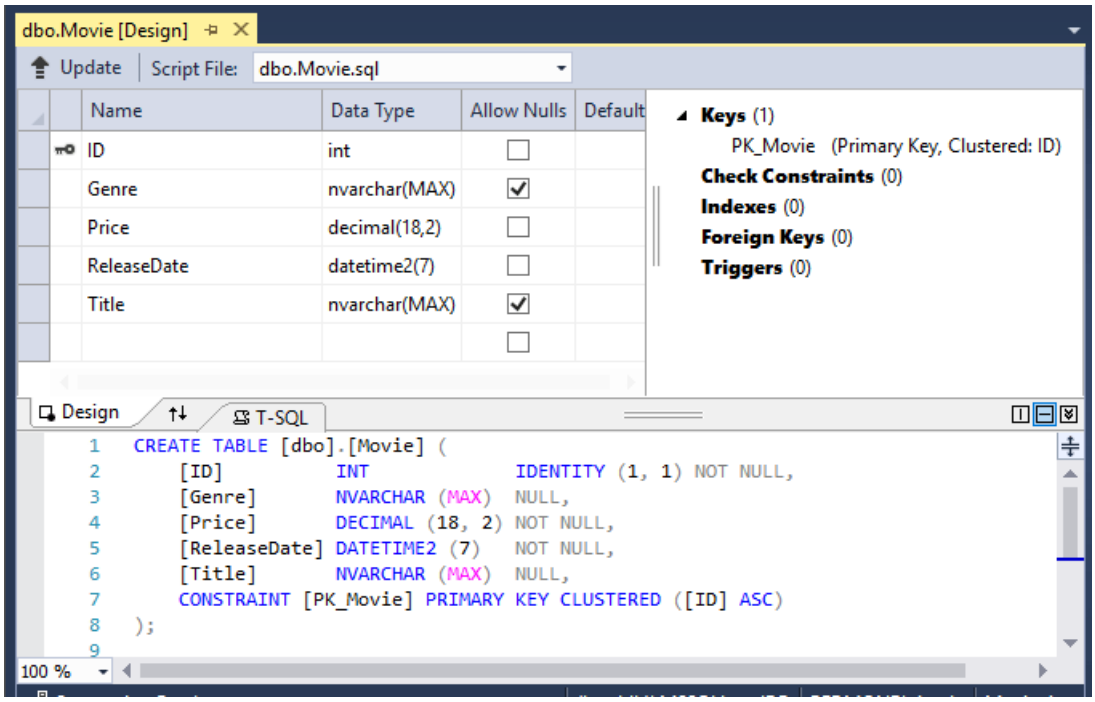
LocalDB is a lightweight version of the SQL Server Express database engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates `*.mdf` files in the `C:\Users\<user>\` directory.

- From the **View** menu, open **SQL Server Object Explorer** (SSOX).



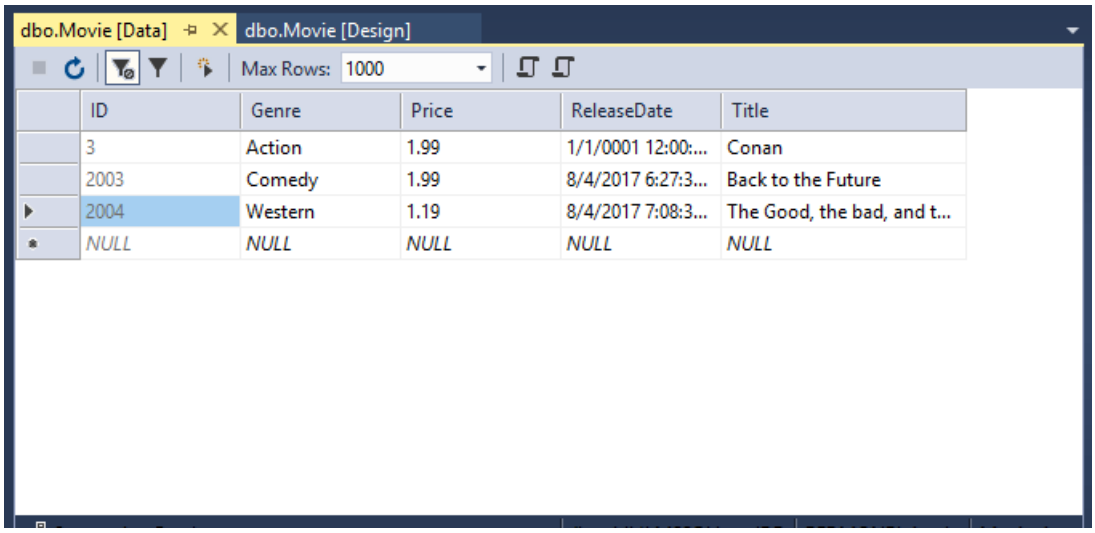
- Right click on the `Movie` table and select **View Designer**:





Note the key icon next to `ID`. By default, EF creates a property named `ID` for the primary key.

- Right click on the `Movie` table and select **View Data**:



Seed the database

Create a new class named `SeedData` in the *Models* folder with the following code:

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using RazorPagesMovie.Data;
using System;
using System.Linq;

namespace RazorPagesMovie.Models
{
    public static class SeedData
    {
        public static void Initialize(IServiceProvider serviceProvider)
        {
            using (var context = new RazorPagesMovieContext(
                serviceProvider.GetRequiredService<
                    DbContextOptions<RazorPagesMovieContext>>()))
            {
                // Look for any movies.
                if (context.Movie.Any())
                {
                    return;   // DB has been seeded
                }

                context.Movie.AddRange(
                    new Movie
                    {
                        Title = "When Harry Met Sally",
                        ReleaseDate = DateTime.Parse("1989-2-12"),
                        Genre = "Romantic Comedy",
                        Price = 7.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters ",
                        ReleaseDate = DateTime.Parse("1984-3-13"),
                        Genre = "Comedy",
                        Price = 8.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters 2",
                        ReleaseDate = DateTime.Parse("1986-2-23"),
                        Genre = "Comedy",
                        Price = 9.99M
                    },

                    new Movie
                    {
                        Title = "Rio Bravo",
                        ReleaseDate = DateTime.Parse("1959-4-15"),
                        Genre = "Western",
                        Price = 3.99M
                    }
                );
                context.SaveChanges();
            }
        }
    }
}
```

If there are any movies in the DB, the seed initializer returns and no movies are added.

```
if (context.Movie.Any())
{
    return;   // DB has been seeded.
}
```

Add the seed initializer

In *Program.cs*, modify the `Main` method to do the following:

- Get a DB context instance from the dependency injection container.
- Call the seed method, passing to it the context.
- Dispose the context when the seed method completes.

The following code shows the updated *Program.cs* file.

```
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using RazorPagesMovie.Models;
using System;

namespace RazorPagesMovie
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    SeedData.Initialize(services);
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred seeding the DB.");
                }
            }

            host.Run();

        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

The following exception occurs when `Update-Database` has not been run:

```
SqlException: Cannot open database "RazorPagesMovieContext-" requested by the login. The login failed.
Login failed for user 'user name'.
```

Test the app

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Delete all the records in the DB. You can do this with the delete links in the browser or from SSOX
- Force the app to initialize (call the methods in the `Startup` class) so the seed method runs. To force initialization, IIS Express must be stopped and restarted. You can do this with any of the following approaches:
  - Right click the IIS Express system tray icon in the notification area and tap **Exit** or **Stop Site**:

  - If you were running VS in non-debug mode, press F5 to run in debug mode.
  - If you were running VS in debug mode, stop the debugger and press F5.

The next tutorial will improve the presentation of the data.

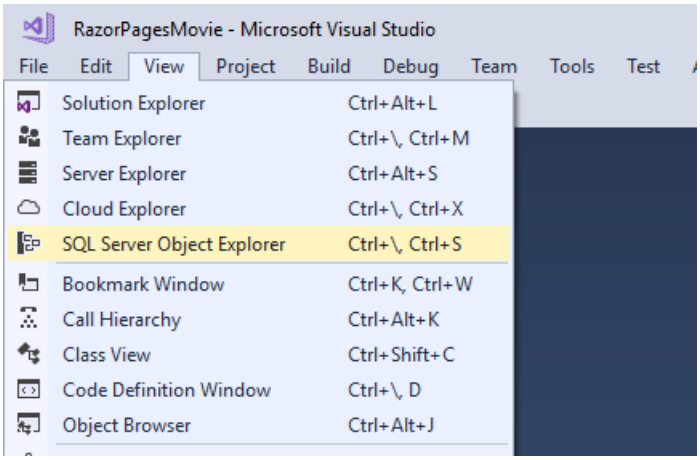
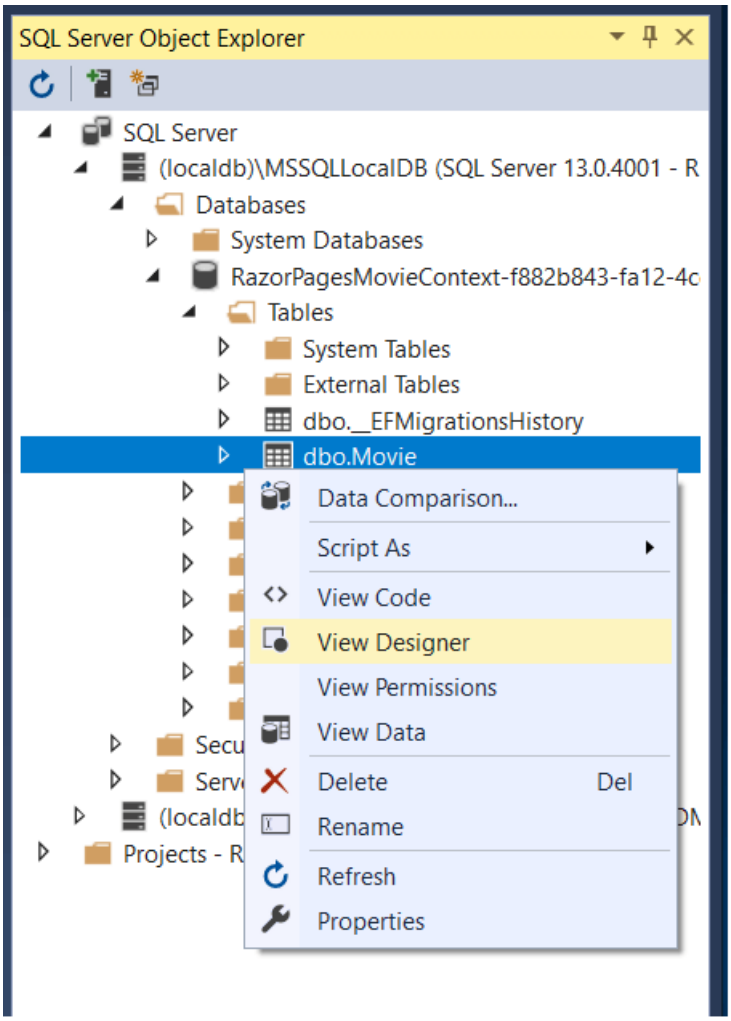
SQL Server Express LocalDB

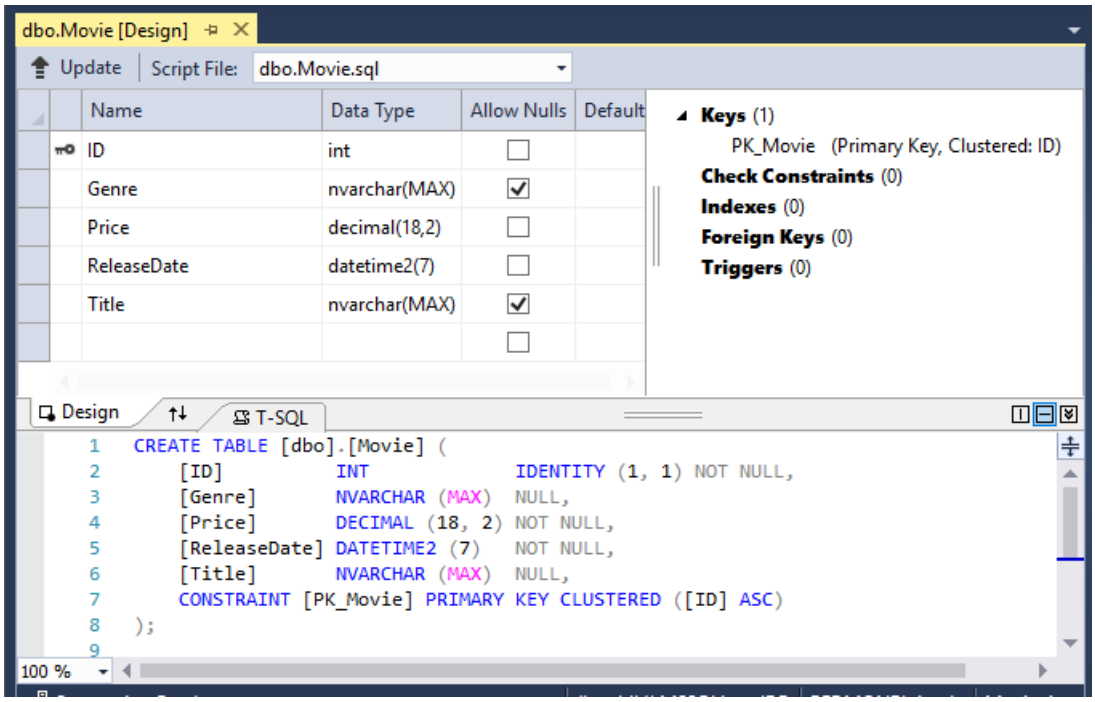
LocalDB is a lightweight version of the SQL Server Express database engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates `*.mdf` files in the `C:/Users/<user/>` directory.

- From the **View** menu, open **SQL Server Object Explorer** (SSOX).



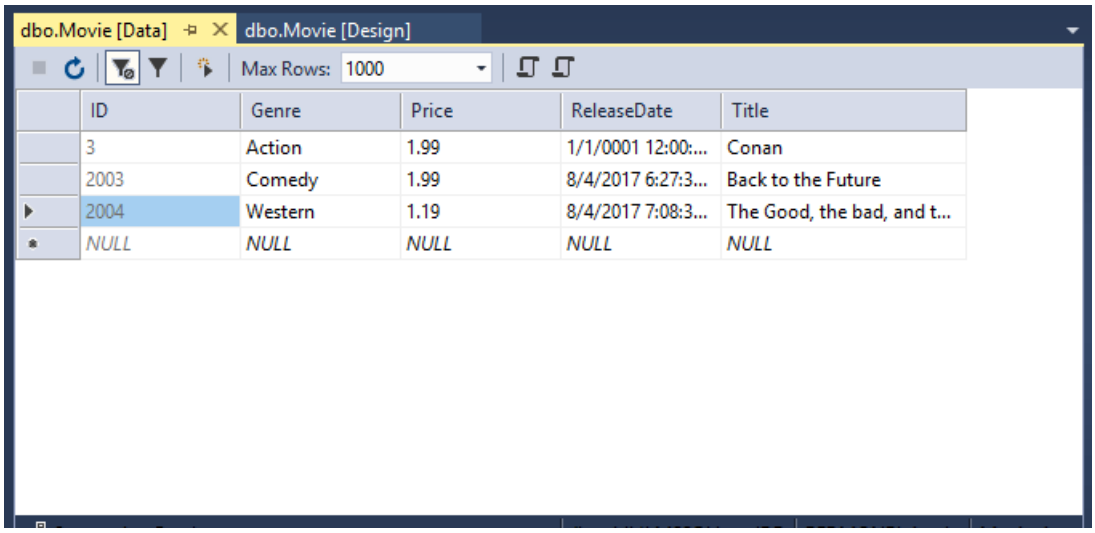
- Right click on the `Movie` table and select **View Designer**:





Note the key icon next to `ID`. By default, EF creates a property named `ID` for the primary key.

- Right click on the `Movie` table and select **View Data**:



Seed the database

Create a new class named `SeedData` in the *Models* folder with the following code:

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using System;
using System.Linq;

namespace RazorPagesMovie.Models
{
    public static class SeedData
    {
        public static void Initialize(IServiceProvider serviceProvider)
        {
            using (var context = new RazorPagesMovieContext(
                serviceProvider.GetRequiredService<
                    DbContextOptions<RazorPagesMovieContext>>()))
            {
                // Look for any movies.
                if (context.Movie.Any())
                {
                    return;   // DB has been seeded
                }

                context.Movie.AddRange(
                    new Movie
                    {
                        Title = "When Harry Met Sally",
                        ReleaseDate = DateTime.Parse("1989-2-12"),
                        Genre = "Romantic Comedy",
                        Price = 7.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters ",
                        ReleaseDate = DateTime.Parse("1984-3-13"),
                        Genre = "Comedy",
                        Price = 8.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters 2",
                        ReleaseDate = DateTime.Parse("1986-2-23"),
                        Genre = "Comedy",
                        Price = 9.99M
                    },

                    new Movie
                    {
                        Title = "Rio Bravo",
                        ReleaseDate = DateTime.Parse("1959-4-15"),
                        Genre = "Western",
                        Price = 3.99M
                    }
                );
                context.SaveChanges();
            }
        }
    }
}
```

If there are any movies in the DB, the seed initializer returns and no movies are added.

```
if (context.Movie.Any())
{
    return;   // DB has been seeded.
}
```

Add the seed initializer

In *Program.cs*, modify the `Main` method to do the following:

- Get a DB context instance from the dependency injection container.
- Call the seed method, passing to it the context.
- Dispose the context when the seed method completes.

The following code shows the updated *Program.cs* file.

```
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Logging;
using RazorPagesMovie.Models;
using System;
using Microsoft.EntityFrameworkCore;

namespace RazorPagesMovie
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateWebHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context=services.
                        GetRequiredService<RazorPagesMovieContext>();
                    context.Database.Migrate();
                    SeedData.Initialize(services);
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred seeding the DB.");
                }
            }

            host.Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();
    }
}
```

A production app would not call `Database.Migrate`. It's added to the preceding code to prevent the following exception when `Update-Database` has not been run:

SqlException: Cannot open database "RazorPagesMovieContext-21" requested by the login. The login failed. Login failed for user 'user name'.

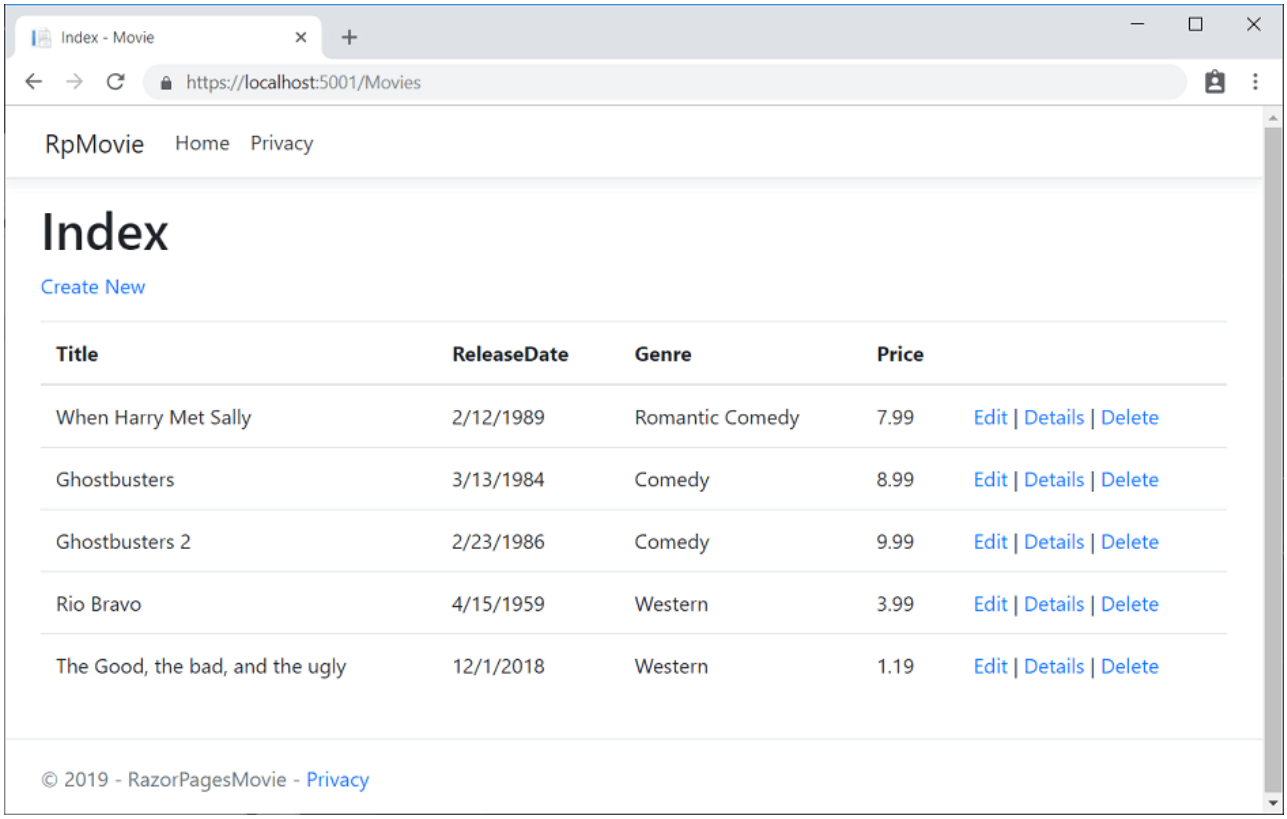
Test the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Delete all the records in the DB. You can do this with the delete links in the browser or from SSOX
- Force the app to initialize (call the methods in the `Startup` class) so the seed method runs. To force initialization, IIS Express must be stopped and restarted. You can do this with any of the following approaches:
  - Right-click the IIS Express system tray icon in the notification area and tap **Exit** or **Stop Site**:

  - If you were running VS in non-debug mode, press F5 to run in debug mode.
  - If you were running VS in debug mode, stop the debugger and press F5.

The app shows the seeded data:



The next tutorial will clean up the presentation of the data.

PREVIOUS: SCAFFOLDED RAZOR PAGES

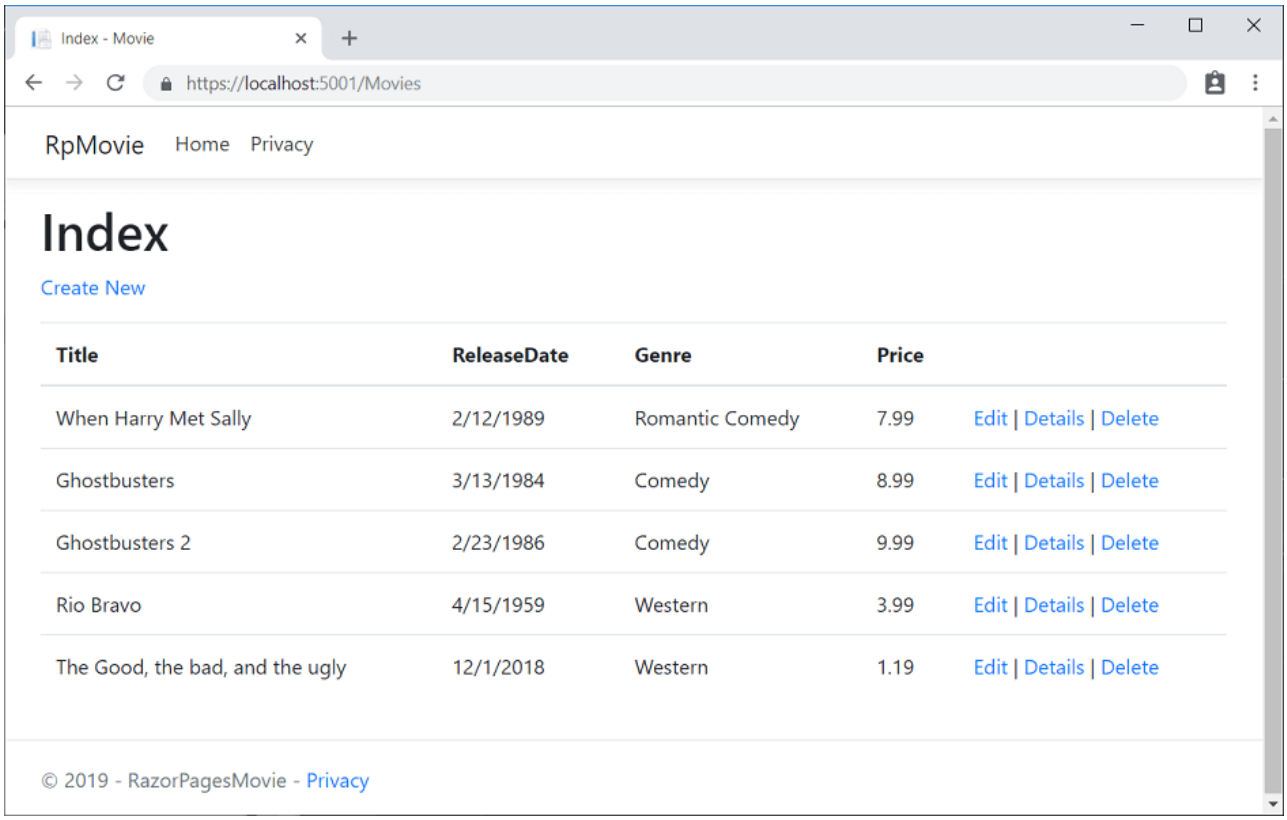
NEXT: UPDATING THE PAGES

Part 5, update the generated pages in an ASP.NET Core app

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

The scaffolded movie app has a good start, but the presentation isn't ideal. **ReleaseDate** should be **Release Date** (two words).



Update the generated code

Open the *Models/Movie.cs* file and add the highlighted lines shown in the following code:

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }

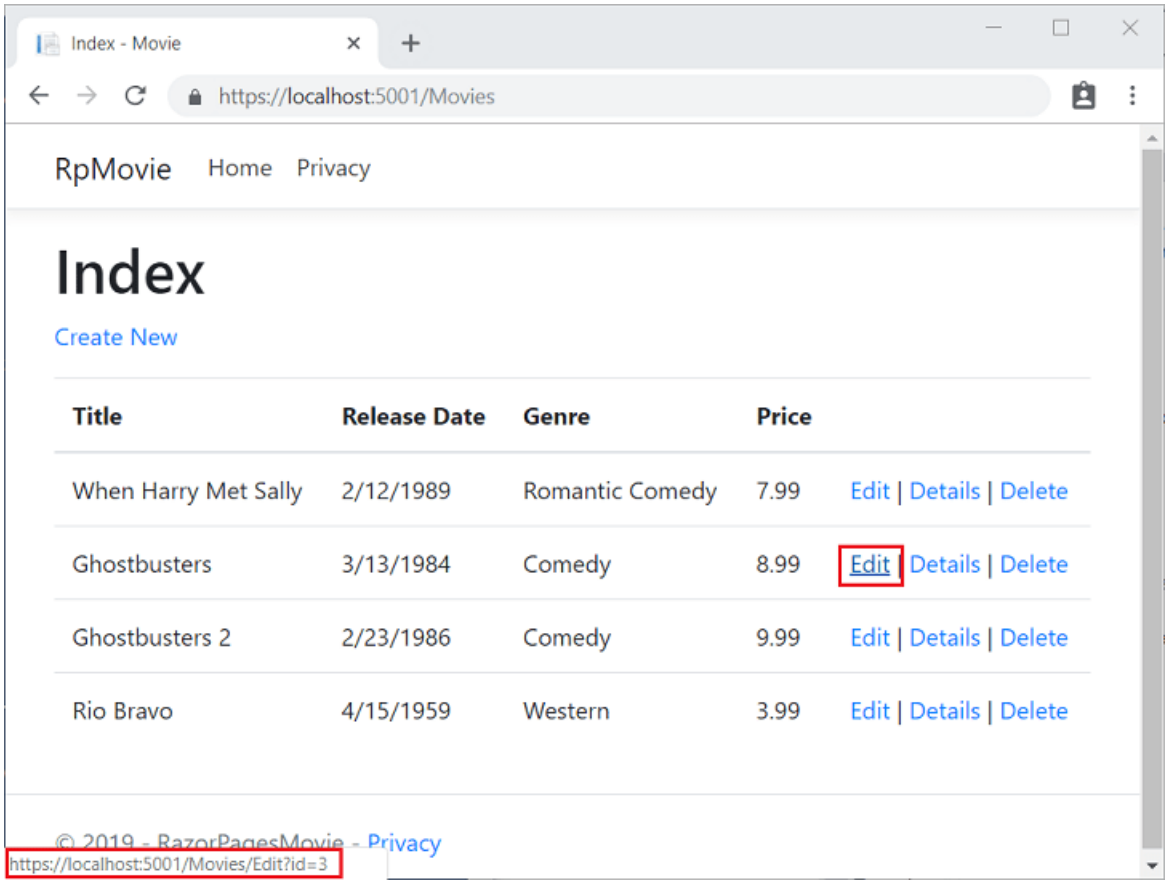
        [Display(Name = "Release Date")]
        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }

        [Column(TypeName = "decimal(18, 2)")]
        public decimal Price { get; set; }
    }
}
```

The `[Column(TypeName = "decimal(18, 2)")]` data annotation enables Entity Framework Core to correctly map `Price` to currency in the database. For more information, see Data Types.

DataAnnotations is covered in the next tutorial. The Display attribute specifies what to display for the name of a field (in this case "Release Date" instead of "ReleaseDate"). The DataType attribute specifies the type of the data (Date), so the time information stored in the field isn't displayed.

Browse to Pages/Movies and hover over an **Edit** link to see the target URL.



The **Edit**, **Details**, and **Delete** links are generated by the Anchor Tag Helper in the *Pages/Movies/Index.cshtml* file.

```
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. In the preceding code, the `AnchorTagHelper` dynamically generates the HTML `href` attribute value from the Razor Page (the route is relative), the `asp-page`, and the route id (`asp-route-id`). See URL generation for Pages for more information.

Use **View Source** from your favorite browser to examine the generated markup. A portion of the generated HTML is shown below:

```
<td>
  <a href="/Movies/Edit?id=1">Edit</a> |
  <a href="/Movies/Details?id=1">Details</a> |
  <a href="/Movies/Delete?id=1">Delete</a>
</td>
```

The dynamically-generated links pass the movie ID with a query string (for example, the `?id=1` in `https://localhost:5001/Movies/Details?id=1`).

Add route template

Update the Edit, Details, and Delete Razor Pages to use the "{id:int}" route template. Change the page directive for each of these pages from `@page` to `@page "{id:int}"`. Run the app and then view source. The generated HTML adds the ID to the path portion of the URL:

```
<td>
  <a href="/Movies/Edit/1">Edit</a> |
  <a href="/Movies/Details/1">Details</a> |
  <a href="/Movies/Delete/1">Delete</a>
</td>
```

A request to the page with the "{id:int}" route template that does **not** include the integer will return an HTTP 404 (not found) error. For example, `http://localhost:5000/Movies/Details` will return a 404 error. To make the ID optional, append `?` to the route constraint:

```
@page "{id:int?}"
```

To test the behavior of `@page "{id:int?}"`:

- Set the page directive in *Pages/Movies/Details.cshtml* to `@page "{id:int?}"`.
- Set a break point in `public async Task<IActionResult> OnGetAsync(int? id)` (in *Pages/Movies/Details.cshtml.cs*).
- Navigate to `https://localhost:5001/Movies/Details/`.

With the `@page "{id:int}"` directive, the break point is never hit. The routing engine returns HTTP 404. Using `@page "{id:int?}"`, the `OnGetAsync` method returns `NotFound` (HTTP 404).

Review concurrency exception handling

Review the `OnPostAsync` method in the *Pages/Movies/Edit.cshtml.cs* file:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Attach(Movie).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!MovieExists(Movie.ID))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return RedirectToPage("./Index");
}

private bool MovieExists(int id)
{
    return _context.Movie.Any(e => e.ID == id);
}
```

The previous code detects concurrency exceptions when the one client deletes the movie and the other client posts changes to the movie.

To test the `catch` block:

- Set a breakpoint on `catch (DbUpdateConcurrencyException)`
- Select **Edit** for a movie, make changes, but don't enter **Save**.
- In another browser window, select the **Delete** link for the same movie, and then delete the movie.
- In the previous browser window, post changes to the movie.

Production code may want to detect concurrency conflicts. See Handle concurrency conflicts for more information.

Posting and binding review

Examine the *Pages/Movies/Edit.cshtml.cs* file:

```
public class EditModel : PageModel
{
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public EditModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Movie Movie { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Movie = await _context.Movie.FirstOrDefaultAsync(m => m.ID == id);

        if (Movie == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Attach(Movie).State = EntityState.Modified;

        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(Movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }

        return RedirectToPage("./Index");
    }

    private bool MovieExists(int id)
    {
        return _context.Movie.Any(e => e.ID == id);
    }
```

When an HTTP GET request is made to the Movies/Edit page (for example, `http://localhost:5000/Movies/Edit/2`):

- The `OnGetAsync` method fetches the movie from the database and returns the `Page` method.
- The `Page` method renders the *Pages/Movies/Edit.cshtml* Razor Page. The *Pages/Movies/Edit.cshtml* file contains

the model directive (`@model RazorPagesMovie.Pages.Movies.EditModel`), which makes the movie model available on the page.

- The Edit form is displayed with the values from the movie.

When the Movies/Edit page is posted:

- The form values on the page are bound to the `Movie` property. The `[BindProperty]` attribute enables Model binding.

```
[BindProperty]
public Movie Movie { get; set; }
```

- If there are errors in the model state (for example, `ReleaseDate` cannot be converted to a date), the form is redisplayed with the submitted values.
- If there are no model errors, the movie is saved.

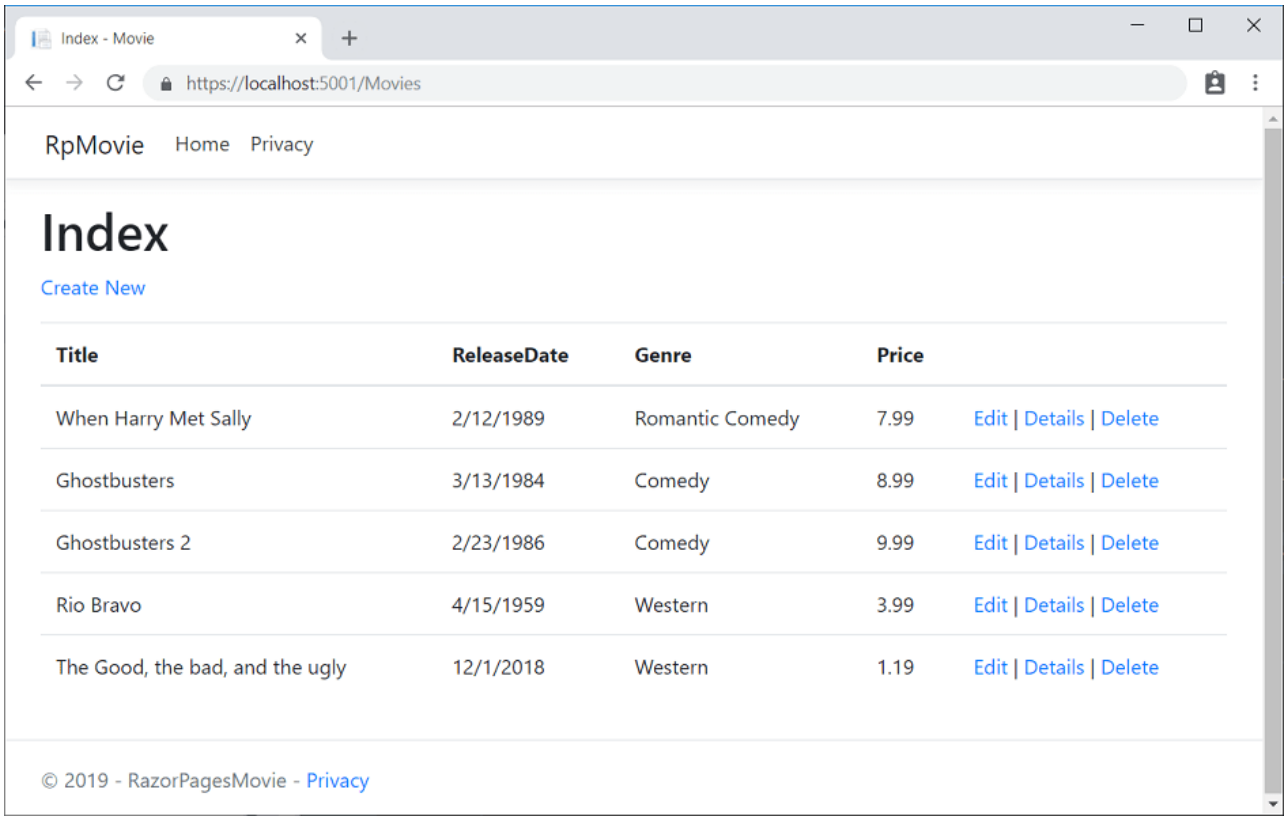
The HTTP GET methods in the Index, Create, and Delete Razor pages follow a similar pattern. The HTTP POST `OnPostAsync` method in the Create Razor Page follows a similar pattern to the `OnPostAsync` method in the Edit Razor Page.

Additional resources

PREVIOUS: WORKING WITH A DATABASE

NEXT: ADD SEARCH

The scaffolded movie app has a good start, but the presentation isn't ideal. **ReleaseDate** should be **Release Date** (two words).



Update the generated code

Open the *Models/Movie.cs* file and add the highlighted lines shown in the following code:

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace RazorPagesMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }

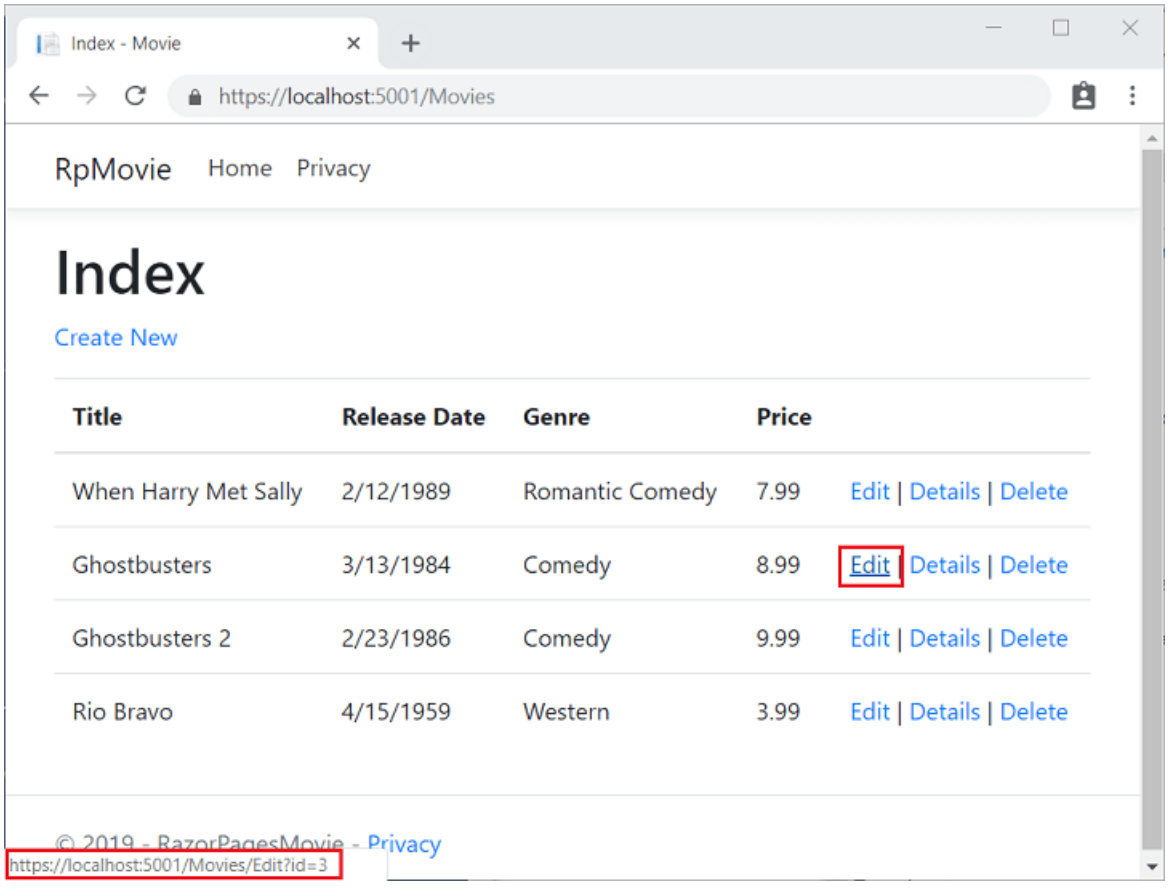
        [Display(Name = "Release Date")]
        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }

        [Column(TypeName = "decimal(18, 2)")]
        public decimal Price { get; set; }
    }
}
```

The `[Column(TypeName = "decimal(18, 2)")]` data annotation enables Entity Framework Core to correctly map `Price` to currency in the database. For more information, see Data Types.

DataAnnotations is covered in the next tutorial. The Display attribute specifies what to display for the name of a field (in this case "Release Date" instead of "ReleaseDate"). The DataType attribute specifies the type of the data (Date), so the time information stored in the field isn't displayed.

Browse to Pages/Movies and hover over an **Edit** link to see the target URL.



The **Edit**, **Details**, and **Delete** links are generated by the Anchor Tag Helper in the *Pages/Movies/Index.cshtml* file.

```
@foreach (var item in Model.Movie) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. In the preceding code, the `AnchorTagHelper` dynamically generates the HTML `href` attribute value from the Razor Page (the route is relative), the `asp-page`, and the route id (`asp-route-id`). See URL generation for Pages for more information.

Use **View Source** from your favorite browser to examine the generated markup. A portion of the generated HTML is shown below:

```
<td>
  <a href="/Movies/Edit?id=1">Edit</a> |
  <a href="/Movies/Details?id=1">Details</a> |
  <a href="/Movies/Delete?id=1">Delete</a>
</td>
```

The dynamically-generated links pass the movie ID with a query string (for example, the `?id=1` in `https://localhost:5001/Movies/Details?id=1`).

Update the Edit, Details, and Delete Razor Pages to use the "{id:int}" route template. Change the page directive for each of these pages from `@page` to `@page "{id:int}"`. Run the app and then view source. The generated HTML adds the ID to the path portion of the URL:

```
<td>
  <a href="/Movies/Edit/1">Edit</a> |
  <a href="/Movies/Details/1">Details</a> |
  <a href="/Movies/Delete/1">Delete</a>
</td>
```

A request to the page with the "{id:int}" route template that does **not** include the integer will return an HTTP 404 (not found) error. For example, `http://localhost:5000/Movies/Details` will return a 404 error. To make the ID optional, append `?` to the route constraint:

```
@page "{id:int?}"
```

To test the behavior of `@page "{id:int?}"`:

- Set the page directive in *Pages/Movies/Details.cshtml* to `@page "{id:int?}"`.
- Set a break point in `public async Task<IActionResult> OnGetAsync(int? id)` (in *Pages/Movies/Details.cshtml.cs*).
- Navigate to `https://localhost:5001/Movies/Details/`.

With the `@page "{id:int}"` directive, the break point is never hit. The routing engine returns HTTP 404. Using `@page "{id:int?}"`, the `OnGetAsync` method returns `NotFound` (HTTP 404).

Review concurrency exception handling

Review the `OnPostAsync` method in the *Pages/Movies/Edit.cshtml.cs* file:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    _context.Attach(Movie).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!MovieExists(Movie.ID))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return RedirectToPage("./Index");
}

private bool MovieExists(int id)
{
    return _context.Movie.Any(e => e.ID == id);
}
```

The previous code detects concurrency exceptions when the one client deletes the movie and the other client posts changes to the movie.

To test the `catch` block:

- Set a breakpoint on `catch (DbUpdateConcurrencyException)`
- Select **Edit** for a movie, make changes, but don't enter **Save**.
- In another browser window, select the **Delete** link for the same movie, and then delete the movie.
- In the previous browser window, post changes to the movie.

Production code may want to detect concurrency conflicts. See Handle concurrency conflicts for more information.

Posting and binding review

Examine the *Pages/Movies/Edit.cshtml.cs* file:

```
public class EditModel : PageModel
{
    private readonly RazorPagesMovieContext _context;

    public EditModel(RazorPagesMovieContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Movie Movie { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Movie = await _context.Movie.SingleOrDefaultAsync(m => m.ID == id);

        if (Movie == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Attach(Movie).State = EntityState.Modified;

        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!_context.Movie.Any(e => e.ID == Movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }

        return RedirectToPage("./Index");
    }
}
```

When an HTTP GET request is made to the Movies/Edit page (for example, `http://localhost:5000/Movies/Edit/2`):

- The `OnGetAsync` method fetches the movie from the database and returns the `Page` method.
- The `Page` method renders the *Pages/Movies/Edit.cshtml* Razor Page. The *Pages/Movies/Edit.cshtml* file contains the model directive (`@model RazorPagesMovie.Pages.Movies.EditModel`), which makes the movie model available on the page.
- The Edit form is displayed with the values from the movie.

When the Movies/Edit page is posted:

- The form values on the page are bound to the `Movie` property. The `[BindProperty]` attribute enables Model binding.

```
[BindProperty]
public Movie Movie { get; set; }
```

- If there are errors in the model state (for example, `ReleaseDate` cannot be converted to a date), the form is displayed with the submitted values.
- If there are no model errors, the movie is saved.

The HTTP GET methods in the Index, Create, and Delete Razor pages follow a similar pattern. The HTTP POST `OnPostAsync` method in the Create Razor Page follows a similar pattern to the `OnPostAsync` method in the Edit Razor Page.

Search is added in the next tutorial.

- YouTube version of this tutorial

PREVIOUS: WORKING WITH A DATABASE

NEXT: ADD SEARCH

Part 6, add search to ASP.NET Core Razor Pages

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

View or download sample code (how to download).

View or download sample code (how to download).

In the following sections, searching movies by *genre* or *name* is added.

Add the following highlighted properties to *Pages/Movies/Index.cshtml.cs*:

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovie.Data.RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovie.Data.RazorPagesMovieContext context)
    {
        _context = context;
    }

    public IList<Movie> Movie { get; set; }
    [BindProperty(SupportsGet = true)]
    public string SearchString { get; set; }
    // Requires using Microsoft.AspNetCore.Mvc.Rendering;
    public SelectList Genres { get; set; }
    [BindProperty(SupportsGet = true)]
    public string MovieGenre { get; set; }
```

- `SearchString`: contains the text users enter in the search text box. `SearchString` has the `[BindProperty]` attribute. `[BindProperty]` binds form values and query strings with the same name as the property. `(SupportsGet = true)` is required for binding on GET requests.
- `Genres`: contains the list of genres. `Genres` allows the user to select a genre from the list. `SelectList` requires `using Microsoft.AspNetCore.Mvc.Rendering;`
- `MovieGenre`: contains the specific genre the user selects (for example, "Western").
- `Genres` and `MovieGenre` are used later in this tutorial.

WARNING

For security reasons, you must opt in to binding `GET` request data to page model properties. Verify user input before mapping it to properties. Opting into `GET` binding is useful when addressing scenarios that rely on query string or route values.

To bind a property on `GET` requests, set the `[BindProperty]` attribute's `SupportsGet` property to `true`:

```
[BindProperty(SupportsGet = true)]
```

For more information, see ASP.NET Core Community Standup: Bind on GET discussion (YouTube).

Update the Index page's `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    var movies = from m in _context.Movie
                 select m;
    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    Movie = await movies.ToListAsync();
}
```

The first line of the `OnGetAsync` method creates a LINQ query to select the movies:

```
// using System.Linq;
var movies = from m in _context.Movie
             select m;
```

The query is *only* defined at this point, it has **not** been run against the database.

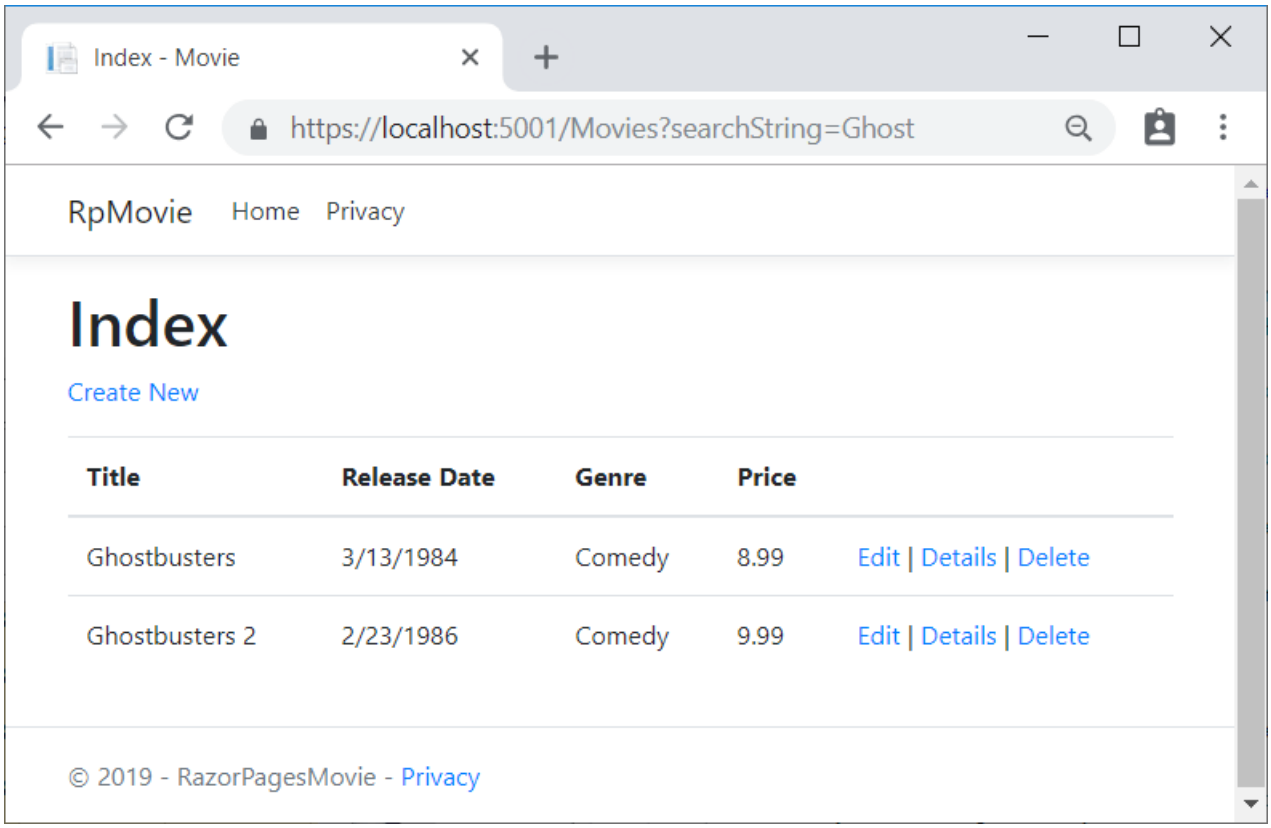
If the `SearchString` property is not null or empty, the movies query is modified to filter on the search string:

```
if (!string.IsNullOrEmpty(SearchString))
{
    movies = movies.Where(s => s.Title.Contains(SearchString));
}
```

The `s => s.Title.Contains()` code is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains` (used in the preceding code). LINQ queries are not executed when they're defined or when they're modified by calling a method (such as `Where`, `Contains` or `OrderBy`). Rather, query execution is deferred. That means the evaluation of an expression is delayed until its realized value is iterated over or the `ToListAsync` method is called. See Query Execution for more information.

> **NOTE**
>
> The Contains method is run on the database, not in the C# code. The case sensitivity on the query depends on the database and the collation. On SQL Server, `Contains` maps to SQL LIKE, which is case insensitive. In SQLite, with the default collation, it's case sensitive.

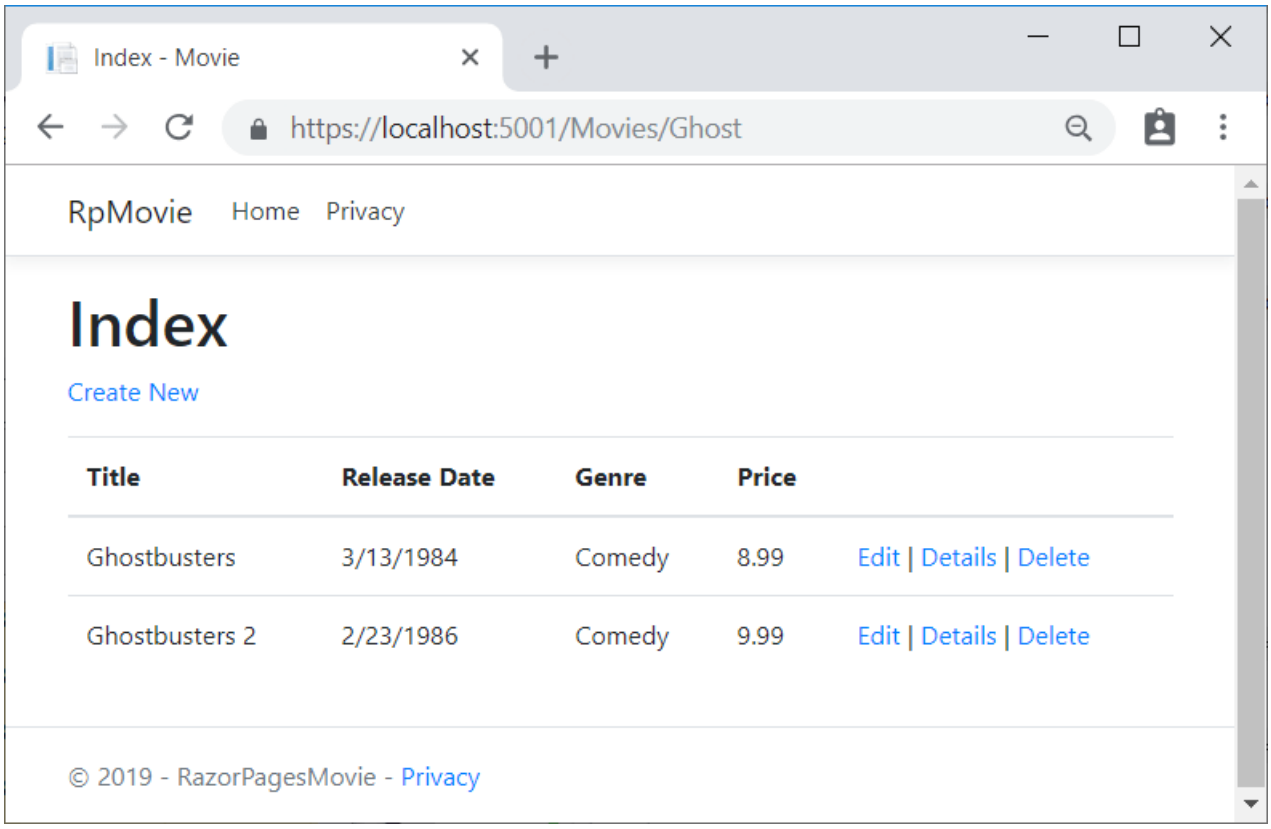
Navigate to the Movies page and append a query string such as `?searchString=Ghost` to the URL (for example, `https://localhost:5001/Movies?searchString=Ghost`). The filtered movies are displayed.



If the following route template is added to the Index page, the search string can be passed as a URL segment (for example, `https://localhost:5001/Movies/Ghost`).

```
@page "{searchString?}"
```

The preceding route constraint allows searching the title as route data (a URL segment) instead of as a query string value. The `?` in `"{searchString?}"` means this is an optional route parameter.



The ASP.NET Core runtime uses model binding to set the value of the `SearchString` property from the query string

(`?searchString=Ghost`) or route data (`https://localhost:5001/Movies/Ghost`). Model binding is not case sensitive.

However, you can't expect users to modify the URL to search for a movie. In this step, UI is added to filter movies. If you added the route constraint `"{searchString?}"`, remove it.

Open the *Pages/Movies/Index.cshtml* file, and add the `<form>` markup highlighted in the following code:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

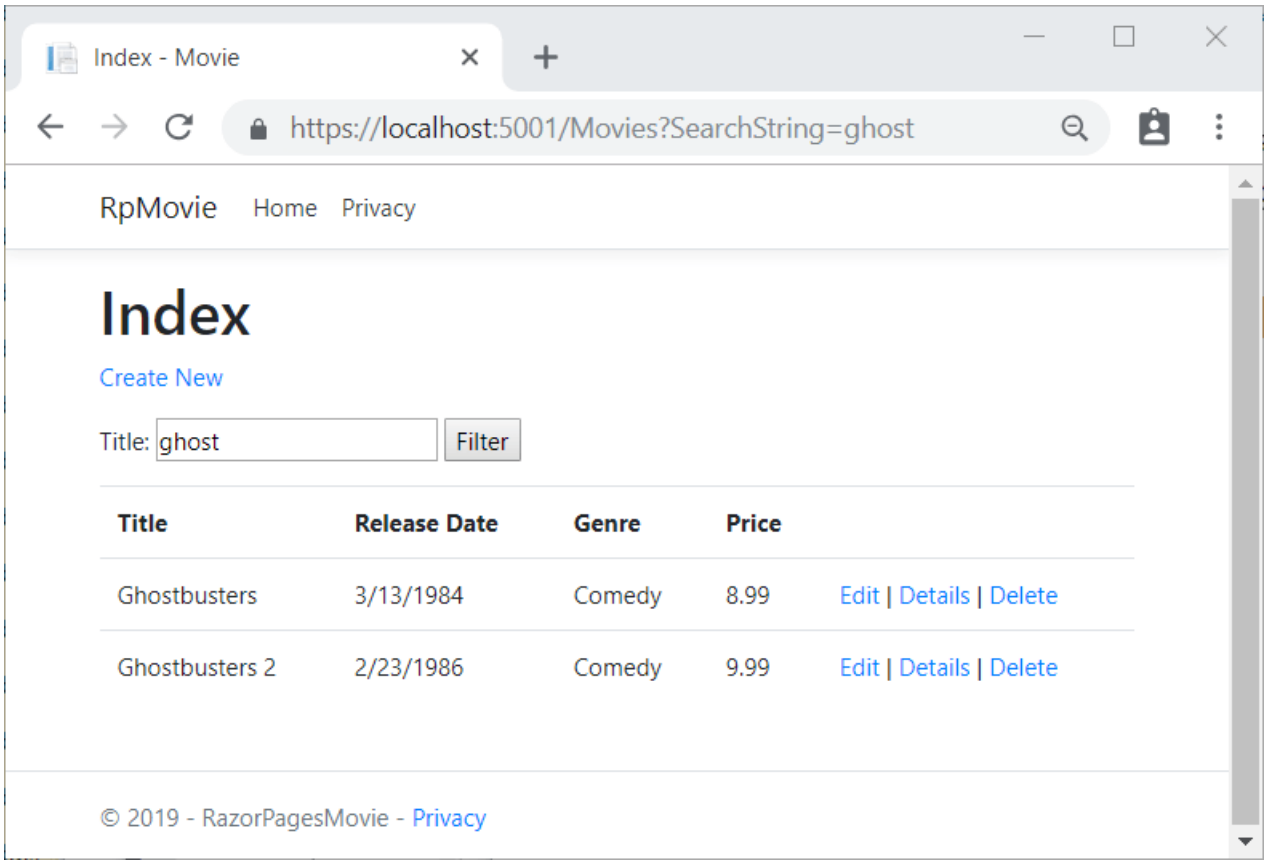
<form>
    <p>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    @*Markup removed for brevity.*@
```

The HTML `<form>` tag uses the following Tag Helpers:

- Form Tag Helper. When the form is submitted, the filter string is sent to the *Pages/Movies/Index* page via query string.
- Input Tag Helper

Save the changes and test the filter.



Search by genre

Update the `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    // Use LINQ to get list of genres.
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;

    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    if (!string.IsNullOrEmpty(MovieGenre))
    {
        movies = movies.Where(x => x.Genre == MovieGenre);
    }
    Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
    Movie = await movies.ToListAsync();
}
```

The following code is a LINQ query that retrieves all the genres from the database.

```
// Use LINQ to get list of genres.
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres.

```
Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
```

Add search by genre to the Razor Page

Update *Index.cshtml* as follows:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    @*Markup removed for brevity.*@
```

Test the app by searching by genre, by movie title, and by both.

Additional resources

- YouTube version of this tutorial

PREVIOUS: UPDATING THE PAGES

NEXT: ADDING A NEW FIELD

View or download sample code (how to download).

View or download sample code (how to download).

In the following sections, searching movies by *genre* or *name* is added.

Add the following highlighted properties to *Pages/Movies/Index.cshtml.cs*:

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovie.Models.RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovie.Models.RazorPagesMovieContext context)
    {
        _context = context;
    }

    public IList<Movie> Movie { get; set; }
    [BindProperty(SupportsGet = true)]
    public string SearchString { get; set; }
    // Requires using Microsoft.AspNetCore.Mvc.Rendering;
    public SelectList Genres { get; set; }
    [BindProperty(SupportsGet = true)]
    public string MovieGenre { get; set; }
```

- `SearchString`: contains the text users enter in the search text box. `SearchString` has the `[BindProperty]` attribute. `[BindProperty]` binds form values and query strings with the same name as the property. `(SupportsGet = true)` is required for binding on GET requests.
- `Genres`: contains the list of genres. `Genres` allows the user to select a genre from the list. `SelectList` requires `using Microsoft.AspNetCore.Mvc.Rendering;`
- `MovieGenre`: contains the specific genre the user selects (for example, "Western").
- `Genres` and `MovieGenre` are used later in this tutorial.

WARNING

For security reasons, you must opt in to binding `GET` request data to page model properties. Verify user input before mapping it to properties. Opting into `GET` binding is useful when addressing scenarios that rely on query string or route values.

To bind a property on `GET` requests, set the `[BindProperty]` attribute's `SupportsGet` property to `true`:

```
[BindProperty(SupportsGet = true)]
```

For more information, see ASP.NET Core Community Standup: Bind on GET discussion (YouTube).

Update the Index page's `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    var movies = from m in _context.Movie
                 select m;
    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    Movie = await movies.ToListAsync();
}
```

The first line of the `OnGetAsync` method creates a LINQ query to select the movies:

```
// using System.Linq;
var movies = from m in _context.Movie
             select m;
```

The query is *only* defined at this point, it has **not** been run against the database.

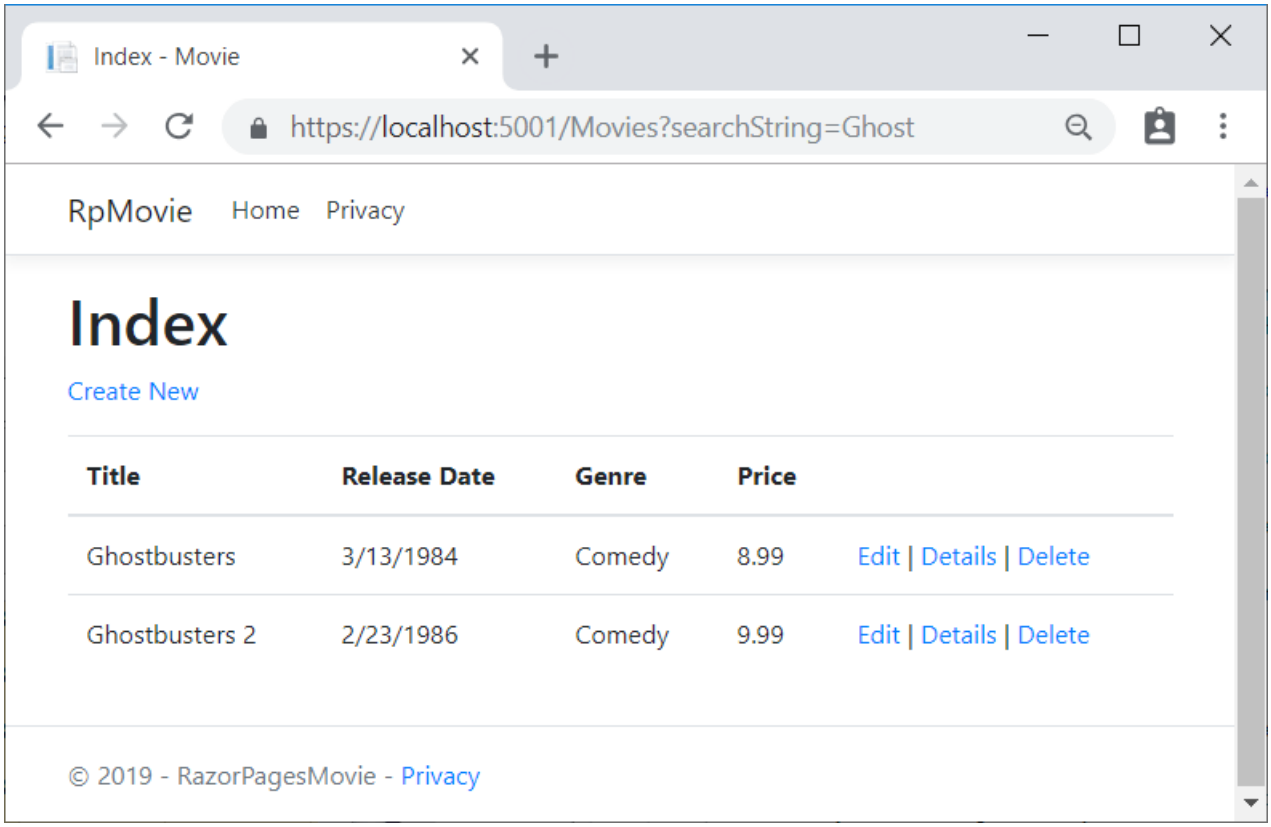
If the `SearchString` property is not null or empty, the movies query is modified to filter on the search string:

```
if (!string.IsNullOrEmpty(SearchString))
{
    movies = movies.Where(s => s.Title.Contains(SearchString));
}
```

The `s => s.Title.Contains()` code is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains` (used in the preceding code). LINQ queries are not executed when they're defined or when they're modified by calling a method (such as `Where`, `Contains` or `OrderBy`). Rather, query execution is deferred. That means the evaluation of an expression is delayed until its realized value is iterated over or the `ToListAsync` method is called. See Query Execution for more information.

Note: The Contains method is run on the database, not in the C# code. The case sensitivity on the query depends on the database and the collation. On SQL Server, `Contains` maps to SQL LIKE, which is case insensitive. In SQLite, with the default collation, it's case sensitive.

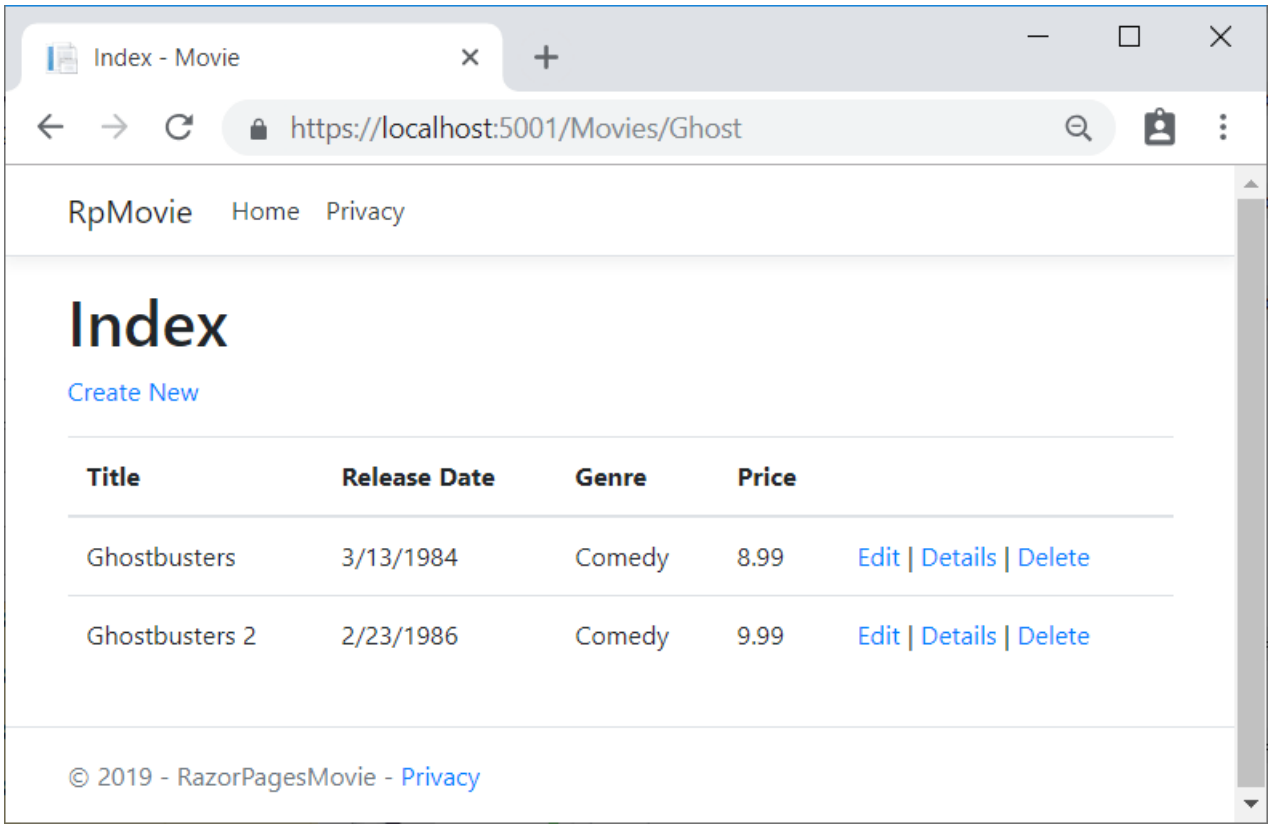
Navigate to the Movies page and append a query string such as `?searchString=Ghost` to the URL (for example, `https://localhost:5001/Movies?searchString=Ghost`). The filtered movies are displayed.



If the following route template is added to the Index page, the search string can be passed as a URL segment (for example, `https://localhost:5001/Movies/Ghost`).

```
@page "{searchString?}"
```

The preceding route constraint allows searching the title as route data (a URL segment) instead of as a query string value. The `?` in `"{searchString?}"` means this is an optional route parameter.



The ASP.NET Core runtime uses model binding to set the value of the `SearchString` property from the query string (`?searchString=Ghost`) or route data (`https://localhost:5001/Movies/Ghost`). Model binding is not case sensitive.

However, you can't expect users to modify the URL to search for a movie. In this step, UI is added to filter movies. If you added the route constraint `"{searchString?}"`, remove it.

Open the *Pages/Movies/Index.cshtml* file, and add the `<form>` markup highlighted in the following code:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

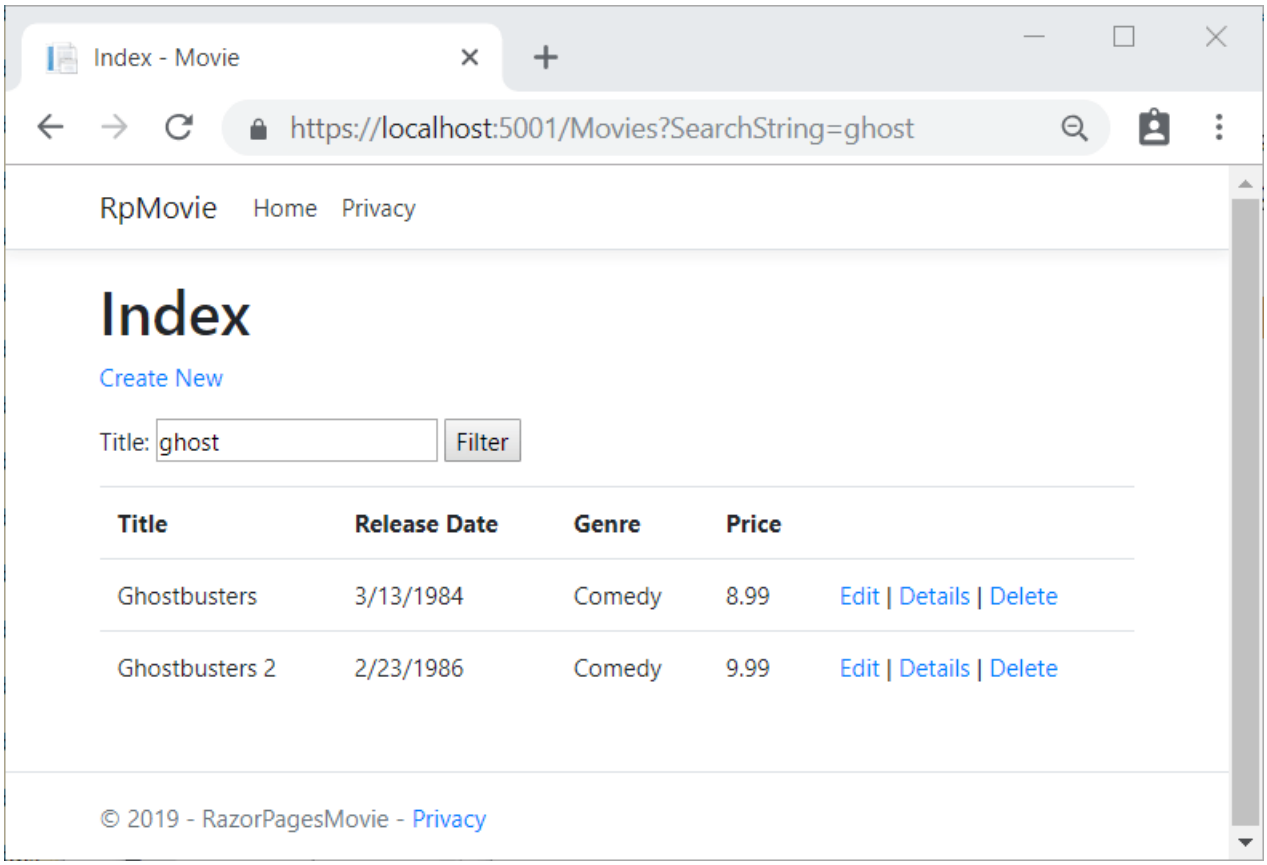
<form>
    <p>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    @*Markup removed for brevity.*@
```

The HTML `<form>` tag uses the following Tag Helpers:

- Form Tag Helper. When the form is submitted, the filter string is sent to the *Pages/Movies/Index* page via query string.
- Input Tag Helper

Save the changes and test the filter.



Search by genre

Update the `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    // Use LINQ to get list of genres.
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;

    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(SearchString))
    {
        movies = movies.Where(s => s.Title.Contains(SearchString));
    }

    if (!string.IsNullOrEmpty(MovieGenre))
    {
        movies = movies.Where(x => x.Genre == MovieGenre);
    }
    Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
    Movie = await movies.ToListAsync();
}
```

The following code is a LINQ query that retrieves all the genres from the database.

```
// Use LINQ to get list of genres.
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres.

```
Genres = new SelectList(await genreQuery.Distinct().ToListAsync());
```

Add search by genre to the Razor Page

Update *Index.cshtml* as follows:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    @*Markup removed for brevity.*@
```

Test the app by searching by genre, by movie title, and by both. The preceding code uses the Select Tag Helper and Option Tag Helper.

PREVIOUS: UPDATING THE PAGES

NEXT: ADDING A NEW FIELD

Part 7, add a new field to a Razor Page in ASP.NET Core

9/22/2020 • 10 minutes to read • Edit Online

By Rick Anderson

View or download sample code (how to download).

View or download sample code (how to download).

In this section Entity Framework Code First Migrations is used to:

- Add a new field to the model.
- Migrate the new field schema change to the database.

When using EF Code First to automatically create a database, Code First:

- Adds an `__EFMigrationsHistory` table to the database to track whether the schema of the database is in sync with the model classes it was generated from.
- If the model classes aren't in sync with the DB, EF throws an exception.

Automatic verification of schema/model in sync makes it easier to find inconsistent database/code issues.

Adding a Rating Property to the Movie Model

Open the *Models/Movie.cs* file and add a `Rating` property:

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string Rating { get; set; }
}
```

Build the app.

Edit *Pages/Movies/Index.cshtml*, and add a `Rating` field:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
```

```
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">

    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Rating)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movie)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Rating)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Update the following pages:

- Add the `Rating` field to the Delete and Details pages.

- Update Create.cshtml with a `Rating` field.
- Add the `Rating` field to the Edit Page.

The app won't work until the DB is updated to include the new field. Running the app without updating the database throws a `SqlException`:

```
SqlException: Invalid column name 'Rating'.
```

The `SqlException` exception is caused by the updated Movie model class being different than the schema of the Movie table of the database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database using the new model class schema. This approach is convenient early in the development cycle; it allows you to quickly evolve the model and database schema together. The downside is that you lose existing data in the database. Don't use this approach on a production database! Dropping the DB on schema changes and using an initializer to automatically seed the database with test data is often a productive way to develop an app.
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.
3. Use Code First Migrations to update the database schema.

For this tutorial, use Code First Migrations.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but you'll want to make this change for each `new Movie` block.

```
context.Movie.AddRange(
    new Movie
    {
        Title = "When Harry Met Sally",
        ReleaseDate = DateTime.Parse("1989-2-12"),
        Genre = "Romantic Comedy",
        Price = 7.99M,
        Rating = "R"
    },
```

See the completed SeedData.cs file.

Build the solution.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Add a migration for the rating field

From the **Tools** menu, select **NuGet Package Manager > Package Manager Console**. In the PMC, enter the following commands:

```
Add-Migration Rating
Update-Database
```

The `Add-Migration` command tells the framework to:

- Compare the `Movie` model with the `Movie` DB schema.
- Create code to migrate the DB schema to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

The `Update-Database` command tells the framework to apply the schema changes to the database and to preserve existing data.

If you delete all the records in the DB, the initializer will seed the DB and include the `Rating` field. You can do this with the delete links in the browser or from Sql Server Object Explorer (SSOX).

Another option is to delete the database and use migrations to re-create the database. To delete the database in SSOX:

- Select the database in SSOX.
- Right click on the database, and select *Delete*.
- Check **Close existing connections**.
- Select **OK**.
- In the PMC, update the database:

```
Update-Database
```

Run the app and verify you can create/edit/display movies with a `Rating` field. If the database isn't seeded, set a break point in the `SeedData.Initialize` method.

Automatic verification of schema/model in sync makes it easier to find inconsistent database/code issues.

Adding a Rating Property to the Movie Model

Open the *Models/Movie.cs* file and add a `Rating` property:

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string Rating { get; set; }
}
```

Build the app.

Edit *Pages/Movies/Index.cshtml*, and add a `Rating` field:

```
@page
@model RazorPagesMovie.Pages.Movies.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form>
    <p>
        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>
        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">

    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Price)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movie[0].Rating)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movie)
```

```
        {
        <tr><td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Rating)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
        }
    </tbody>
</table>
```

Update the following pages:

- Add the `Rating` field to the Delete and Details pages.
- Update Create.cshtml with a `Rating` field.
- Add the `Rating` field to the Edit Page.

The app won't work until the DB is updated to include the new field. If run now, the app throws a `SqlException`:

```
SqlException: Invalid column name 'Rating'.
```

This error is caused by the updated Movie model class being different than the schema of the Movie table of the database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database using the new model class schema. This approach is convenient early in the development cycle; it allows you to quickly evolve the model and database schema together. The downside is that you lose existing data in the database. Don't use this approach on a production database! Dropping the DB on schema changes and using an initializer to automatically seed the database with test data is often a productive way to develop an app.
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.
3. Use Code First Migrations to update the database schema.

For this tutorial, use Code First Migrations.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but you'll want to make this change for each `new Movie` block.

```
context.Movie.AddRange(
    new Movie
    {
        Title = "When Harry Met Sally",
        ReleaseDate = DateTime.Parse("1989-2-12"),
        Genre = "Romantic Comedy",
        Price = 7.99M,
        Rating = "R"
    },
```

See the completed SeedData.cs file.

Build the solution.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Add a migration for the rating field

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**. In the PMC, enter the following commands:

```
Add-Migration Rating
Update-Database
```

The `Add-Migration` command tells the framework to:

- Compare the `Movie` model with the `Movie` DB schema.
- Create code to migrate the DB schema to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

The `Update-Database` command tells the framework to apply the schema changes to the database.

If you delete all the records in the DB, the initializer will seed the DB and include the `Rating` field. You can do this with the delete links in the browser or from Sql Server Object Explorer (SSOX).

Another option is to delete the database and use migrations to re-create the database. To delete the database in SSOX:

- Select the database in SSOX.
- Right click on the database, and select *Delete*.
- Check **Close existing connections**.
- Select **OK**.
- In the PMC, update the database:

  ```
  Update-Database
  ```

Run the app and verify you can create/edit/display movies with a `Rating` field. If the database isn't seeded, set a break point in the `SeedData.Initialize` method.

PREVIOUS: ADDING SEARCH

NEXT: ADDING VALIDATION

Part 8, add validation to an ASP.NET Core Razor Page

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

In this section, validation logic is added to the `Movie` model. The validation rules are enforced any time a user creates or edits a movie.

Validation

A key tenet of software development is called DRY ("**D**on't **R**epeat **Y**ourself"). Razor Pages encourages development where functionality is specified once, and it's reflected throughout the app. DRY can help:

- Reduce the amount of code in an app.
- Make the code less error prone, and easier to test and maintain.

The validation support provided by Razor Pages and Entity Framework is a good example of the DRY principle. Validation rules are declaratively specified in one place (in the model class), and the rules are enforced everywhere in the app.

Add validation rules to the movie model

The DataAnnotations namespace provides a set of built-in validation attributes that are applied declaratively to a class or property. DataAnnotations also contains formatting attributes like `DataType` that help with formatting and don't provide any validation.

Update the `Movie` class to take advantage of the built-in `Required`, `StringLength`, `RegularExpression`, and `Range` validation attributes.

```
public class Movie
{
    public int ID { get; set; }

    [StringLength(60, MinimumLength = 3)]
    [Required]
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
    [Required]
    [StringLength(30)]
    public string Genre { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
    [StringLength(5)]
    [Required]
    public string Rating { get; set; }
}
```

The validation attributes specify behavior that you want to enforce on the model properties they're applied to:

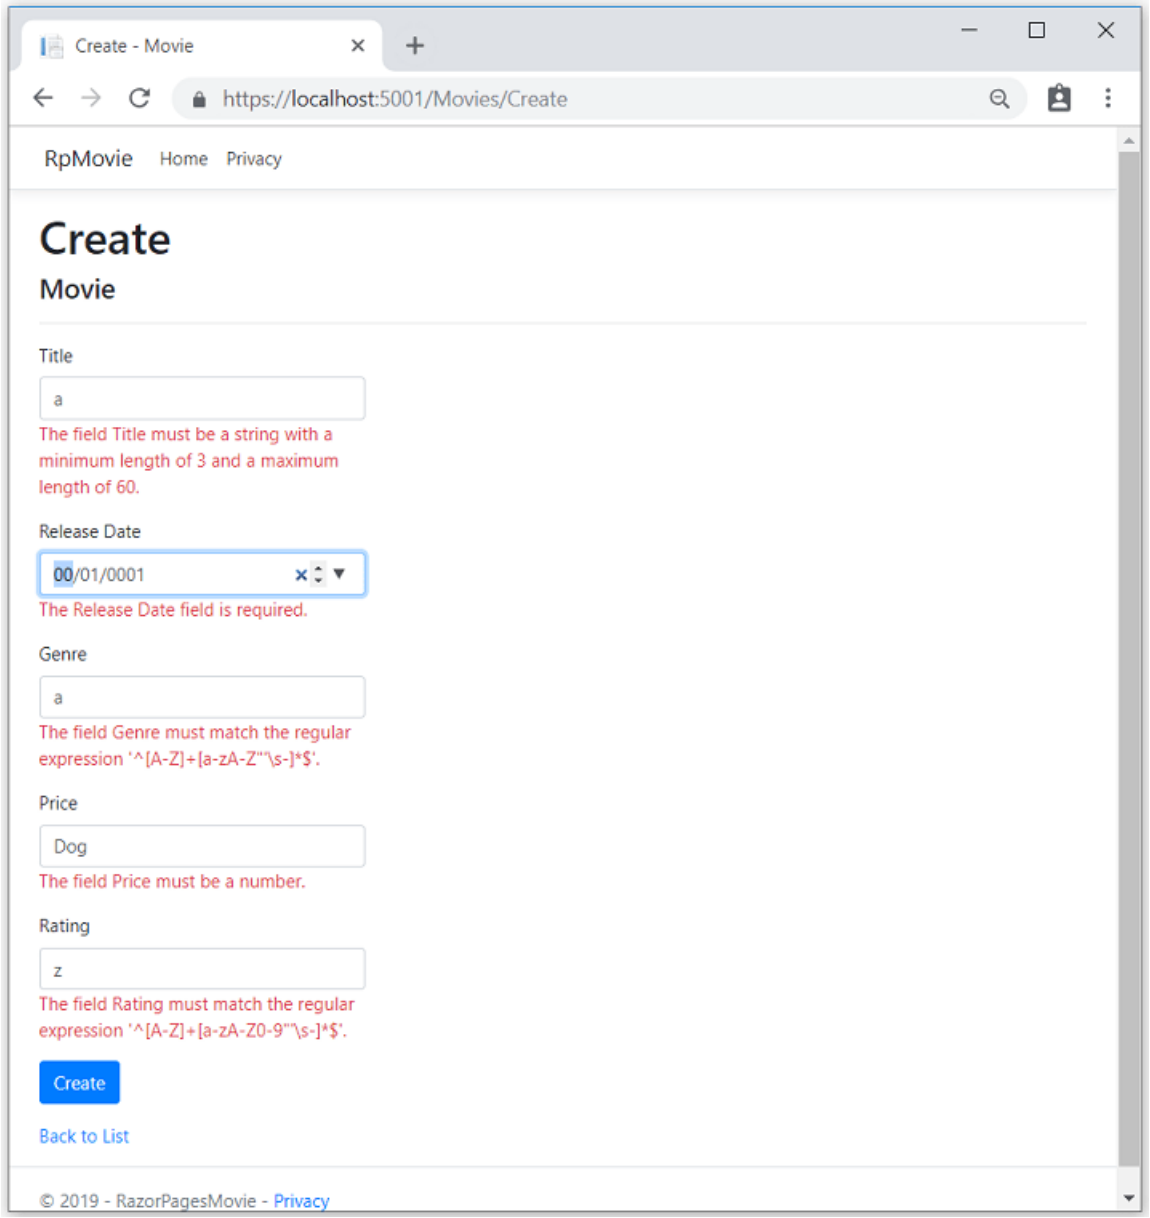
- The `Required` and `MinimumLength` attributes indicate that a property must have a value; but nothing prevents a user from entering white space to satisfy this validation.
- The `RegularExpression` attribute is used to limit what characters can be input. In the preceding code, "Genre":
  - Must only use letters.
  - The first letter is required to be uppercase. White space, numbers, and special characters are not allowed.
- The `RegularExpression` "Rating":
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a "Genre".
- The `Range` attribute constrains a value to within a specified range.
- The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length.
- Value types (such as `decimal`, `int`, `float`, `DateTime`) are inherently required and don't need the `[Required]` attribute.

Having validation rules automatically enforced by ASP.NET Core helps make your app more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Validation Error UI in Razor Pages

Run the app and navigate to Pages/Movies.

Select the **Create New** link. Complete the form with some invalid values. When jQuery client-side validation detects the error, it displays an error message.



> **NOTE**
> You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub issue 4076 for instructions on adding decimal comma.

Notice how the form has automatically rendered a validation error message in each field containing an invalid value. The errors are enforced both client-side (using JavaScript and jQuery) and server-side (when a user has JavaScript disabled).

A significant benefit is that **no** code changes were necessary in the Create or Edit pages. Once DataAnnotations were applied to the model, the validation UI was enabled. The Razor Pages created in this tutorial automatically picked up the validation rules (using validation attributes on the properties of the `Movie` model class). Test validation using the Edit page, the same validation is applied.

The form data isn't posted to the server until there are no client-side validation errors. Verify form data isn't posted by one or more of the following approaches:

- Put a break point in the `OnPostAsync` method. Submit the form (select **Create** or **Save**). The break point is never hit.
- Use the Fiddler tool.

- Use the browser developer tools to monitor network traffic.

Server-side validation

When JavaScript is disabled in the browser, submitting the form with errors will post to the server.

Optional, test server-side validation:

- Disable JavaScript in the browser. You can disable JavaScript using browser's developer tools. If you can't disable JavaScript in the browser, try another browser.
- Set a break point in the `OnPostAsync` method of the Create or Edit page.
- Submit a form with invalid data.
- Verify the model state is invalid:

```
if (!ModelState.IsValid)
{
    return Page();
}
```

Alternatively, you can Disable client-side validation on the server.

The following code shows a portion of the *Create.cshtml* page scaffolded earlier in the tutorial. It's used by the Create and Edit pages to display the initial form and to redisplay the form in the event of an error.

```
<form method="post">
    <div asp-validation-summary="ModelOnly" class="text-danger"></div>
    <div class="form-group">
        <label asp-for="Movie.Title" class="control-label"></label>
        <input asp-for="Movie.Title" class="form-control" />
        <span asp-validation-for="Movie.Title" class="text-danger"></span>
    </div>
```

The Input Tag Helper uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client-side. The Validation Tag Helper displays validation errors. See Validation for more information.

The Create and Edit pages have no validation rules in them. The validation rules and the error strings are specified only in the `Movie` class. These validation rules are automatically applied to Razor Pages that edit the `Movie` model.

When validation logic needs to change, it's done only in the model. Validation is applied consistently throughout the application (validation logic is defined in one place). Validation in one place helps keep the code clean, and makes it easier to maintain and update.

Using DataType Attributes

Examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. The `DataType` attribute is applied to the `ReleaseDate` and `Price` properties.

```
[Display(Name = "Release Date")]
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[Range(1, 100)]
[DataType(DataType.Currency)]
public decimal Price { get; set; }
```

The `DataType` attributes only provide hints for the view engine to format the data (and supplies attributes such as `<a>` for URL's and `<a href="mailto:EmailAddress.com">` for email). Use the `RegularExpression` attribute to validate the format of the data. The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type. `DataType` attributes are not validation attributes. In the sample application, only the date is displayed, without time.

The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`. A date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attributes emit HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers consume. The `DataType` attributes do **not** provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's `CultureInfo`.

The `[Column(TypeName = "decimal(18, 2)")]` data annotation is required so Entity Framework Core can correctly map `Price` to currency in the database. For more information, see Data Types.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
public DateTime ReleaseDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the formatting should be applied when the value is displayed for editing. You might not want that behavior for some fields. For example, in currency values, you probably don't want the currency symbol in the edit UI.

The `DisplayFormat` attribute can be used by itself, but it's generally a good idea to use the `DataType` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with DisplayFormat:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.)
- By default, the browser will render data using the correct format based on your locale.
- The `DataType` attribute can enable the ASP.NET Core framework to choose the right field template to render the data. The `DisplayFormat`, if used by itself, uses the string template.

Note: jQuery validation doesn't work with the `Range` attribute and `DateTime`. For example, the following code will always display a client-side validation error, even when the date is in the specified range:

```
[Range(typeof(DateTime), "1/1/1966", "1/1/2020")]
```

It's generally not a good practice to compile hard dates in your models, so using the `Range` attribute and `DateTime` is discouraged.

The following code shows combining attributes on one line:

```
public class Movie
{
    public int ID { get; set; }

    [StringLength(60, MinimumLength = 3)]
    public string Title { get; set; }

    [Display(Name = "Release Date"), DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z]*$"), Required, StringLength(30)]
    public string Genre { get; set; }

    [Range(1, 100), DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$"), StringLength(5)]
    public string Rating { get; set; }
}
```

Get started with Razor Pages and EF Core shows advanced EF Core operations with Razor Pages.

Apply migrations

The DataAnnotations applied to the class changes the schema. For example, the DataAnnotations applied to the `Title` field:

```
[StringLength(60, MinimumLength = 3)]
[Required]
public string Title { get; set; }
```

- Limits the characters to 60.
- Doesn't allow a `null` value.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

The `Movie` table currently has the following schema:

```
CREATE TABLE [dbo].[Movie] (
    [ID]          INT             IDENTITY (1, 1) NOT NULL,
    [Title]       NVARCHAR (MAX)  NULL,
    [ReleaseDate] DATETIME2 (7)   NOT NULL,
    [Genre]       NVARCHAR (MAX)  NULL,
    [Price]       DECIMAL (18, 2) NOT NULL,
    [Rating]      NVARCHAR (MAX)  NULL,
    CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([ID] ASC)
);
```

The preceding schema changes don't cause EF to throw an exception. However, create a migration so the schema is consistent with the model.

From the **Tools** menu, select **NuGet Package Manager > Package Manager Console**. In the PMC, enter the following commands:

```
Add-Migration New_DataAnnotations
Update-Database
```

`Update-Database` runs the `Up` methods of the `New_DataAnnotations` class. Examine the `Up` method:

```
public partial class New_DataAnnotations : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.AlterColumn<string>(
            name: "Title",
            table: "Movie",
            maxLength: 60,
            nullable: false,
            oldClrType: typeof(string),
            oldNullable: true);

        migrationBuilder.AlterColumn<string>(
            name: "Rating",
            table: "Movie",
            maxLength: 5,
            nullable: false,
            oldClrType: typeof(string),
            oldNullable: true);

        migrationBuilder.AlterColumn<string>(
            name: "Genre",
            table: "Movie",
            maxLength: 30,
            nullable: false,
            oldClrType: typeof(string),
            oldNullable: true);
    }
```

The updated `Movie` table has the following schema:

```
CREATE TABLE [dbo].[Movie] (
    [ID]          INT             IDENTITY (1, 1) NOT NULL,
    [Title]       NVARCHAR (60)   NOT NULL,
    [ReleaseDate] DATETIME2 (7)   NOT NULL,
    [Genre]       NVARCHAR (30)   NOT NULL,
    [Price]       DECIMAL (18, 2) NOT NULL,
    [Rating]      NVARCHAR (5)    NOT NULL,
    CONSTRAINT [PK_Movie] PRIMARY KEY CLUSTERED ([ID] ASC)
);
```

Publish to Azure

For information on deploying to Azure, see Tutorial: Build an ASP.NET Core app in Azure with SQL Database.

Thanks for completing this introduction to Razor Pages. Get started with Razor Pages and EF Core is an excellent follow up to this tutorial.

Create a web app with ASP.NET Core MVC

9/22/2020 • 2 minutes to read • Edit Online

This tutorial teaches ASP.NET Core MVC web development with controllers and views. If you're new to ASP.NET Core web development, consider the Razor Pages version of this tutorial, which provides an easier starting point.

The tutorial series includes the following:

1. Get started
2. Add a controller
3. Add a view
4. Add a model
5. Work with SQL Server LocalDB
6. Controller methods and views
7. Add search
8. Add a new field
9. Add validation
10. Examine the Details and Delete methods

Get started with ASP.NET Core MVC

9/22/2020 • 10 minutes to read • Edit Online

By Rick Anderson

This tutorial teaches ASP.NET Core MVC web development with controllers and views. If you're new to ASP.NET Core web development, consider the Razor Pages version of this tutorial, which provides an easier starting point.

This tutorial teaches the basics of building an ASP.NET Core MVC web app.

The app manages a database of movie titles. You learn how to:

- Create a web app.
- Add and scaffold a model.
- Work with a database.
- Add search and validation.

At the end, you have an app that can manage and display movie data.

View or download sample code (how to download).

Prerequisites

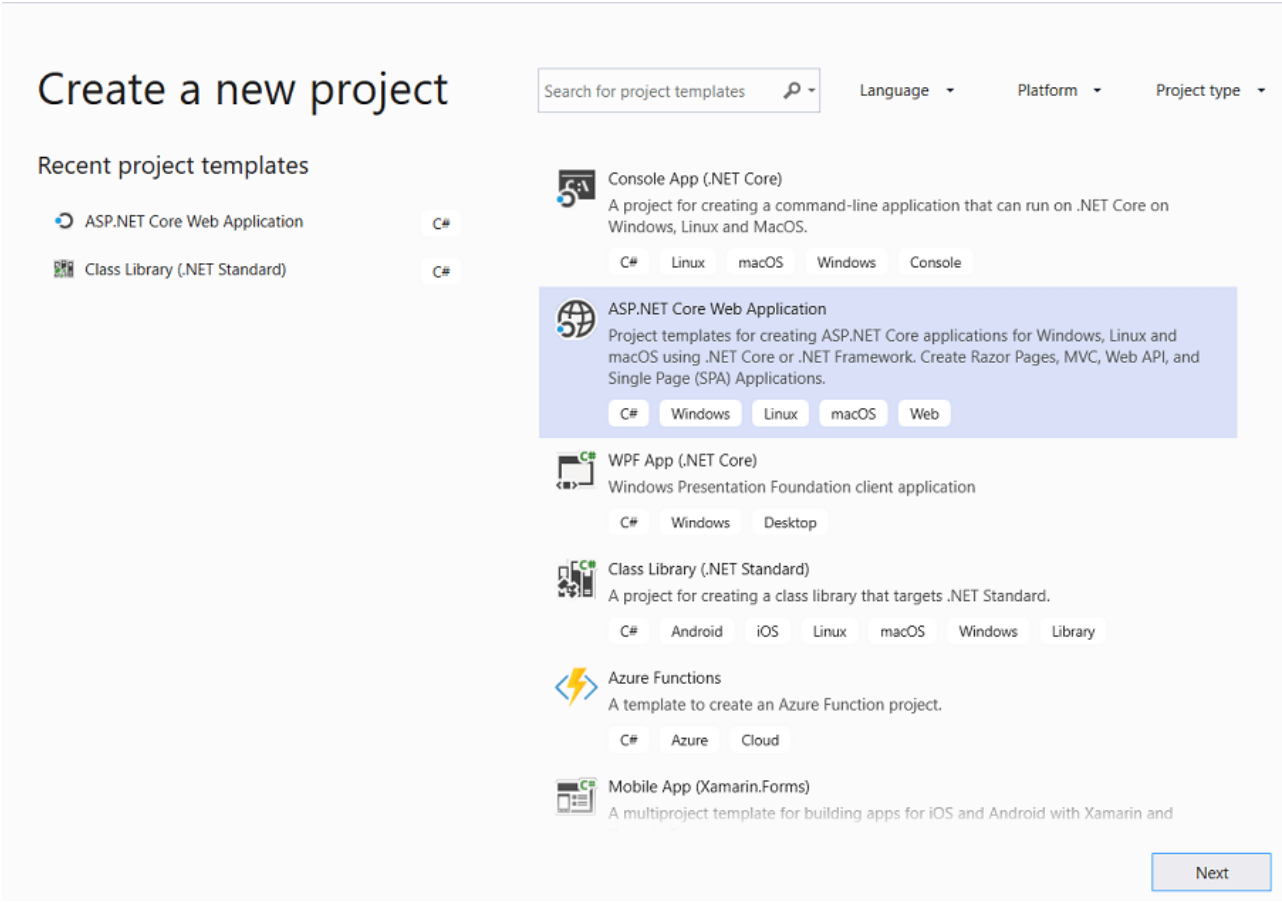
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

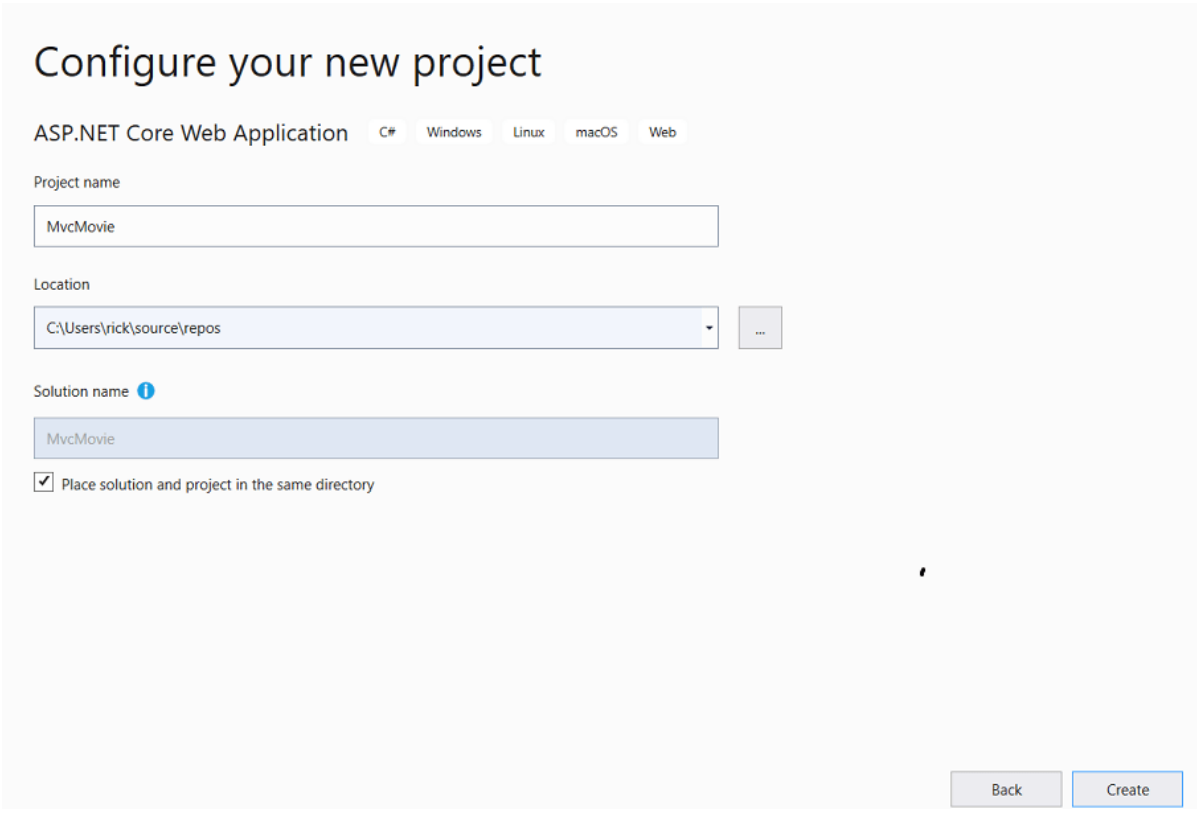
Create a web app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

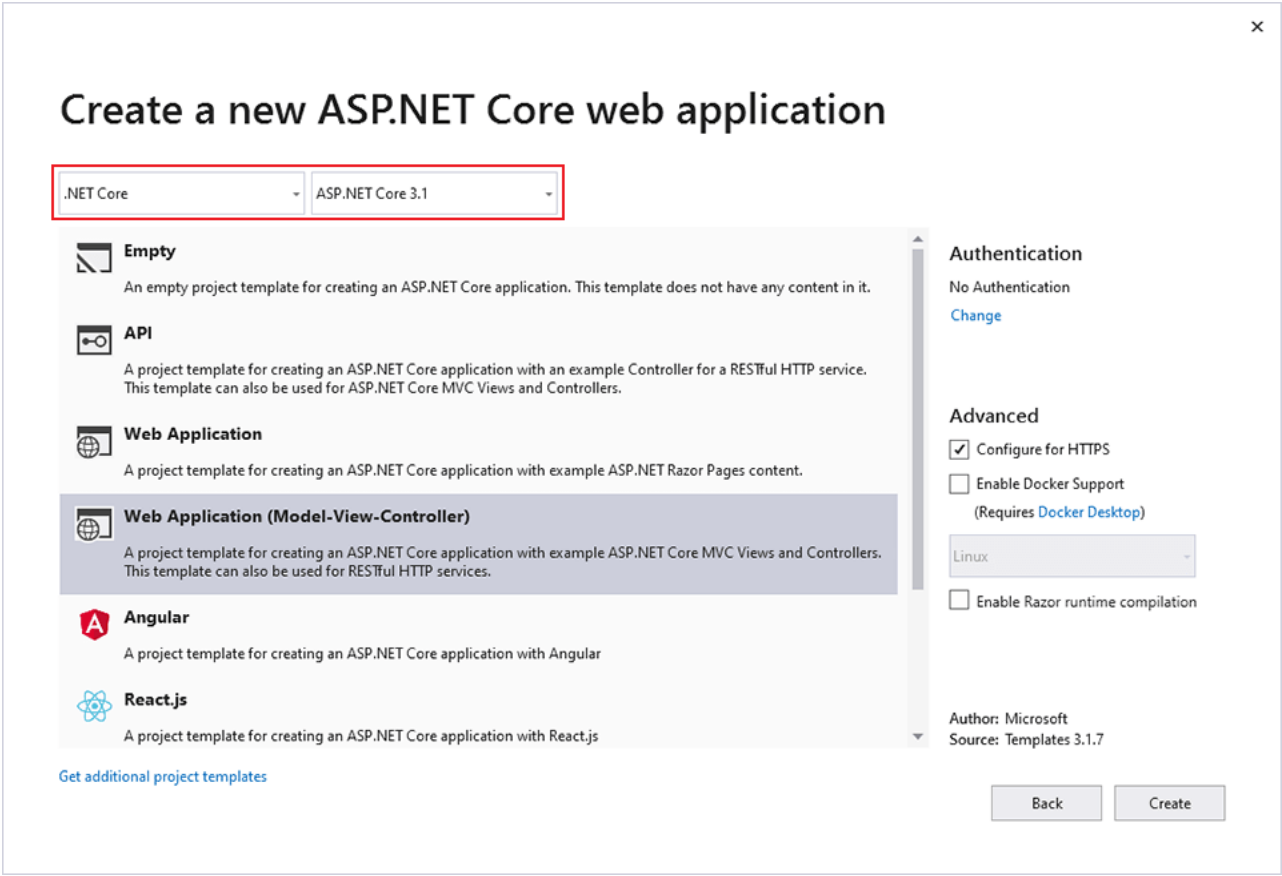
- From the Visual Studio select **Create a new project**.
- Select **ASP.NET Core Web Application** and then select **Next**.



- Name the project **MvcMovie** and select **Create**. It's important to name the project **MvcMovie** so when you copy code, the namespace will match.



- Select **Web Application(Model-View-Controller)**, and then select **Create**.



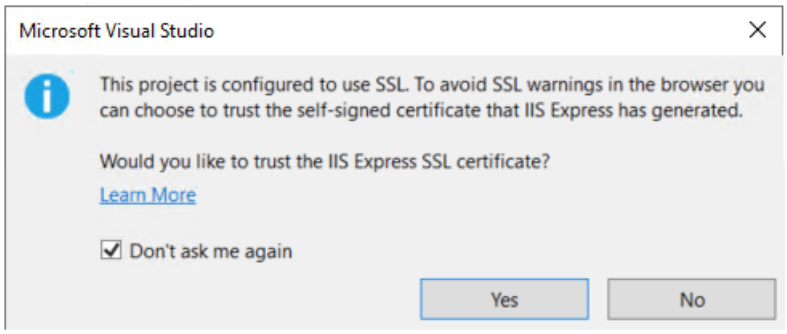
Visual Studio used the default template for the MVC project you just created. You have a working app right now by entering a project name and selecting a few options. This is a basic starter project.

Run the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

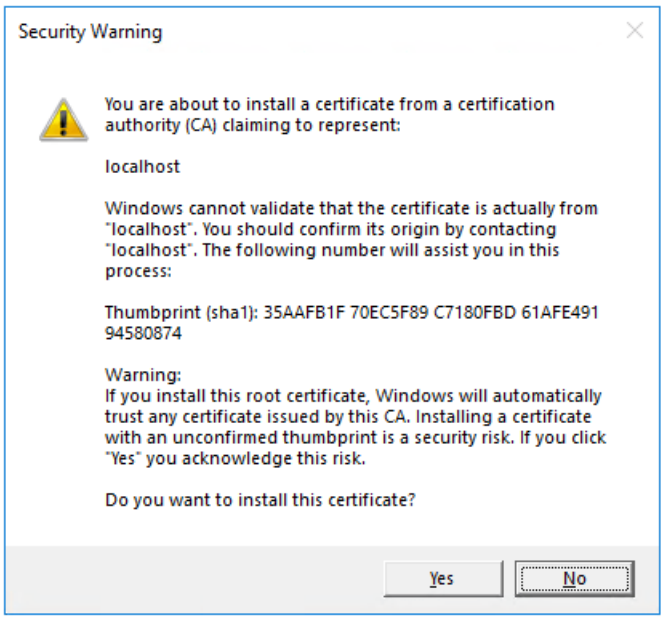
Select **Ctrl-F5** to run the app in non-debug mode.

Visual Studio displays the following dialog:



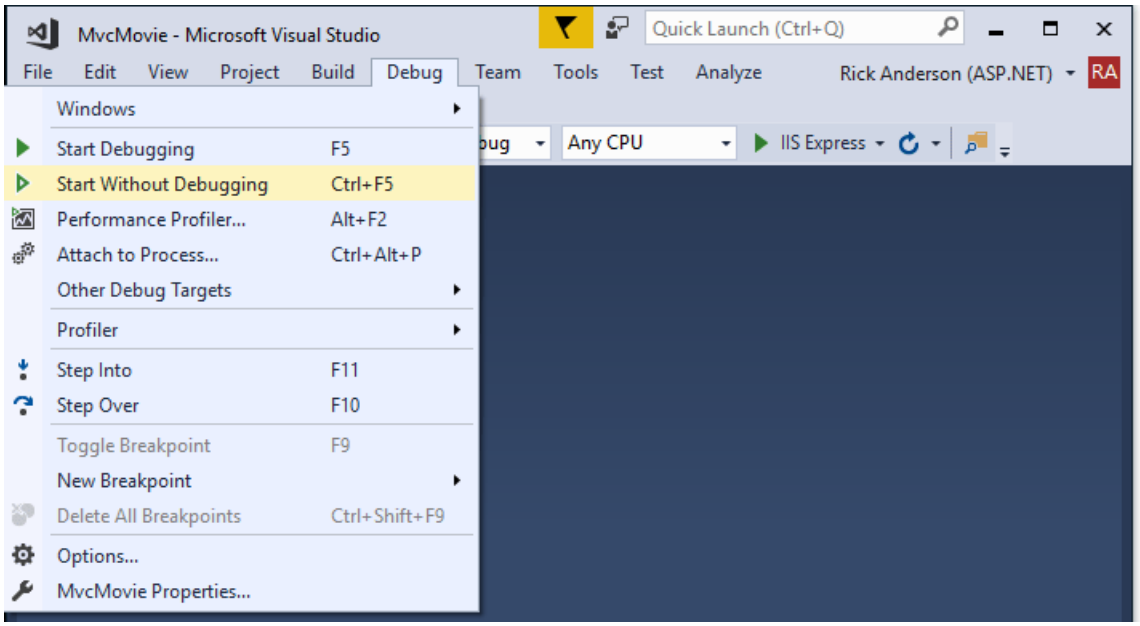
Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

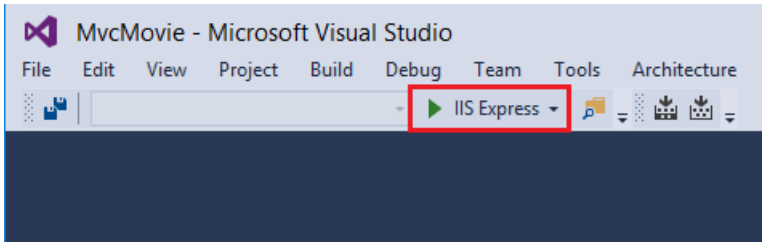


Select **Yes** if you agree to trust the development certificate.

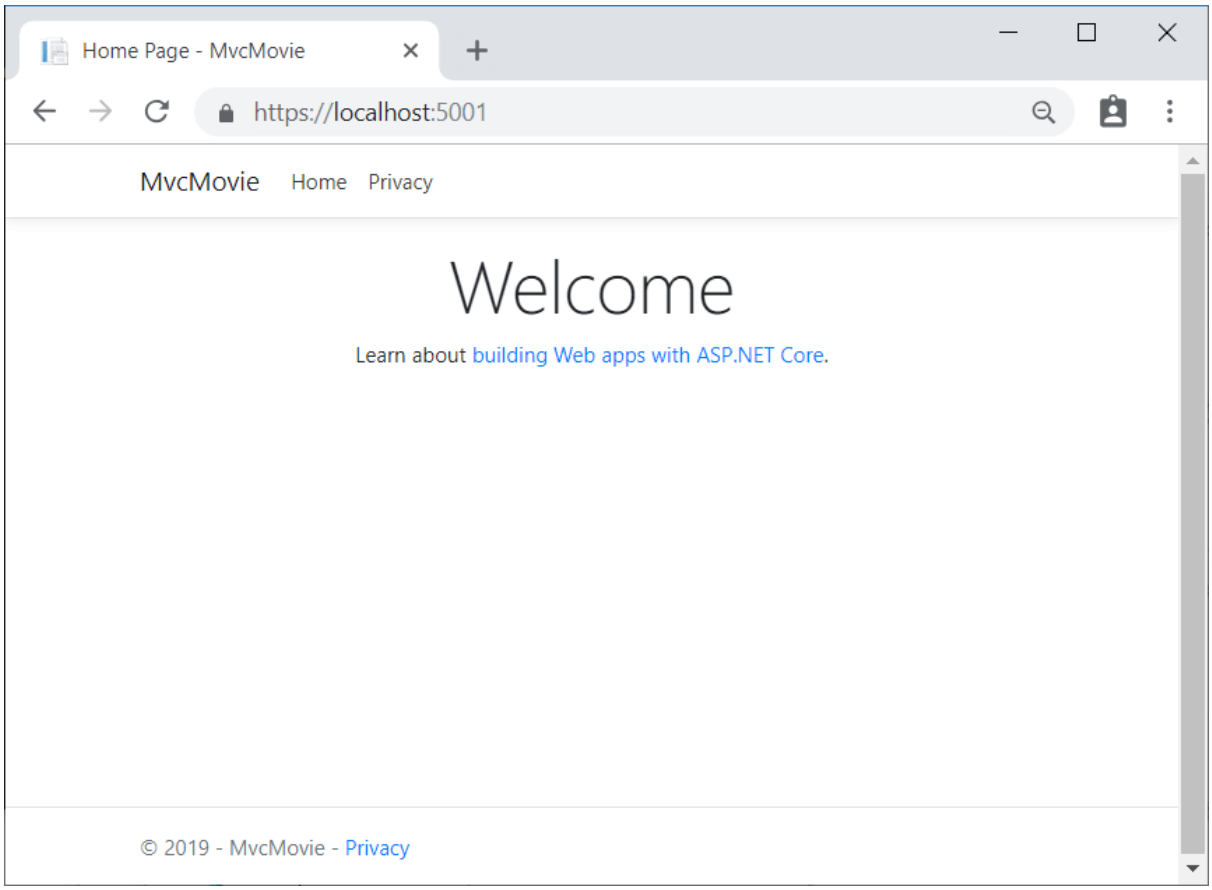
- Visual Studio starts IIS Express and runs the app. Notice that the address bar shows `localhost:port#` and not something like `example.com`. That's because `localhost` is the standard hostname for your local computer. When Visual Studio creates a web project, a random port is used for the web server.
- Launching the app with Ctrl+F5 (non-debug mode) allows you to make code changes, save the file, refresh the browser, and see the code changes. Many developers prefer to use non-debug mode to quickly launch the app and view changes.
- You can launch the app in debug or non-debug mode from the **Debug** menu item:



- You can debug the app by selecting the **IIS Express** button



The following image shows the app:



- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Visual Studio help

- Learn to debug C# code using Visual Studio
- Introduction to the Visual Studio IDE

In the next part of this tutorial, you learn about MVC and start writing some code.

NEXT

This tutorial teaches ASP.NET Core MVC web development with controllers and views. If you're new to ASP.NET Core web development, consider the Razor Pages version of this tutorial, which provides an easier starting point.

This tutorial teaches the basics of building an ASP.NET Core MVC web app.

The app manages a database of movie titles. You learn how to:

- Create a web app.
- Add and scaffold a model.
- Work with a database.
- Add search and validation.

At the end, you have an app that can manage and display movie data.

View or download sample code (how to download).

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

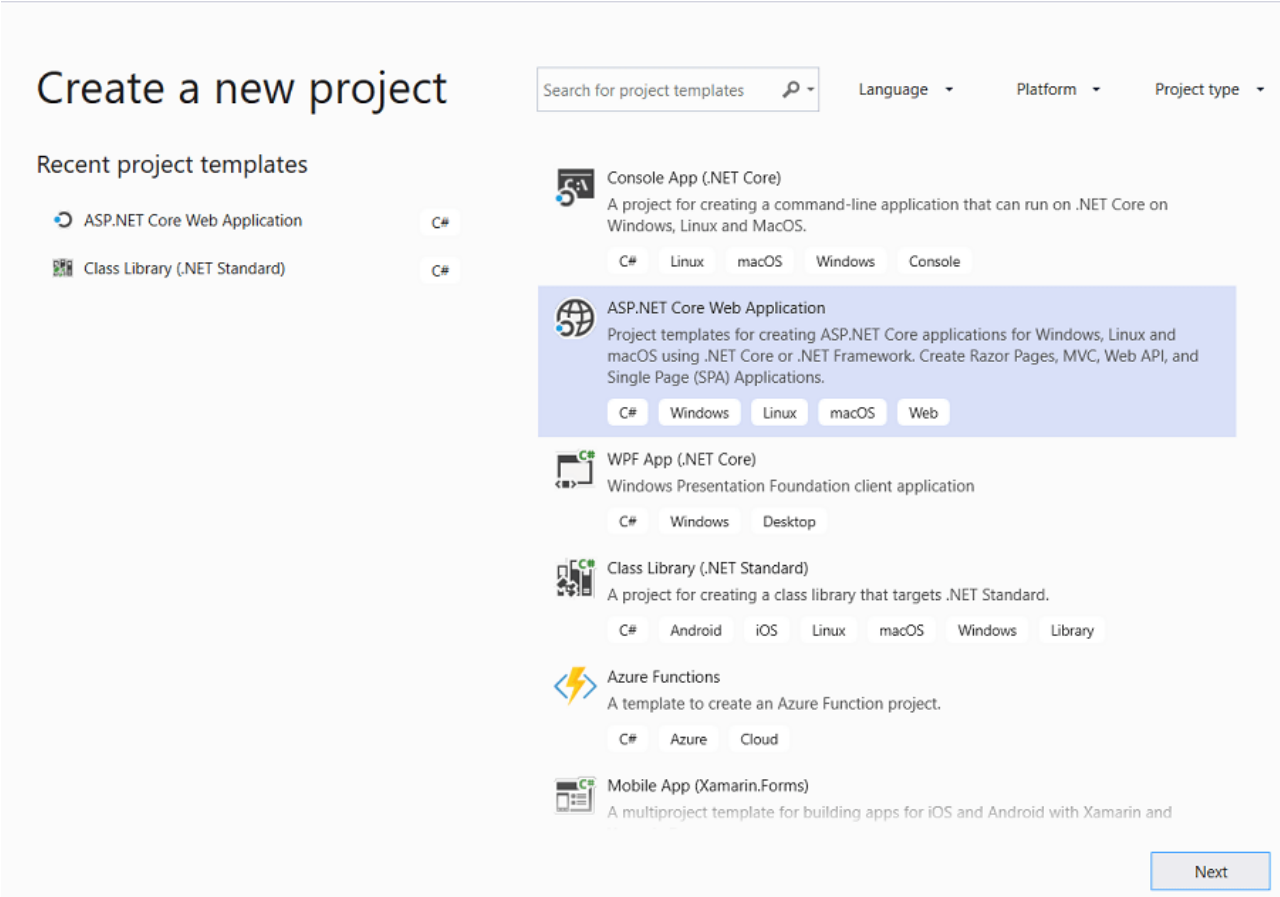
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

> **WARNING**
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

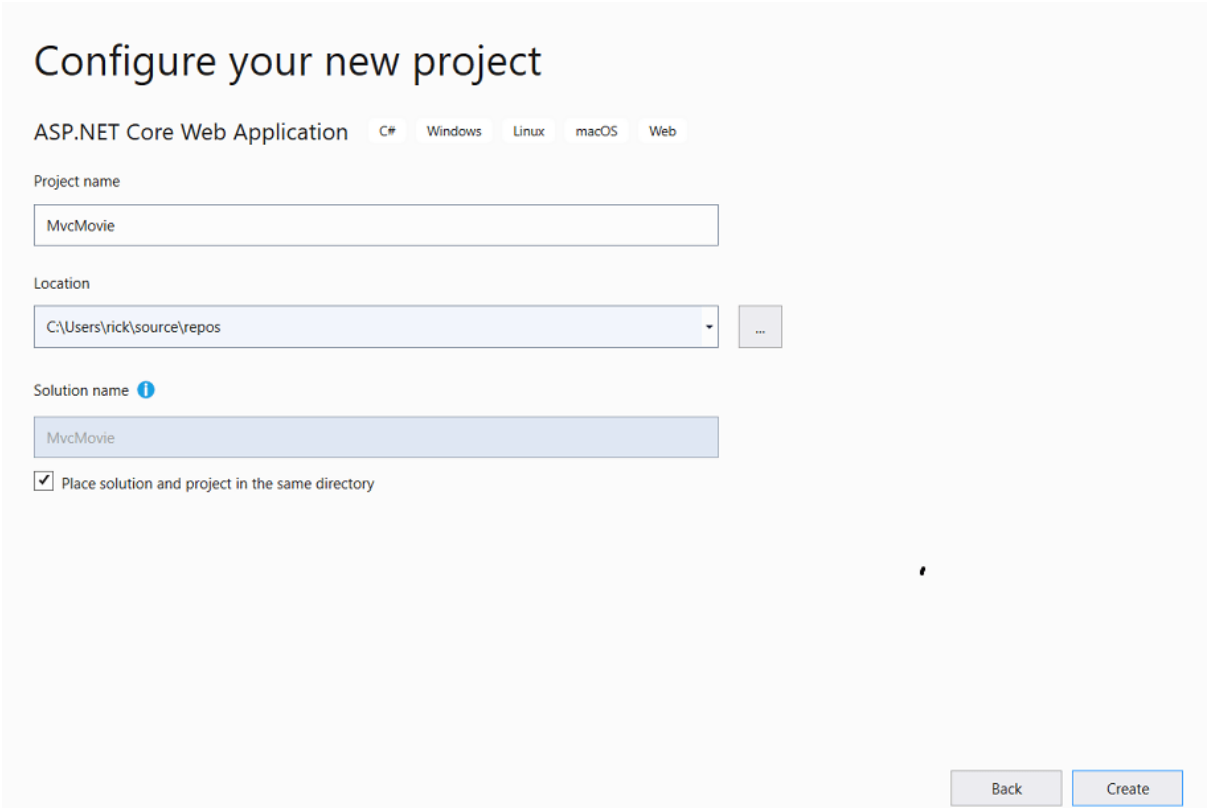
Create a web app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

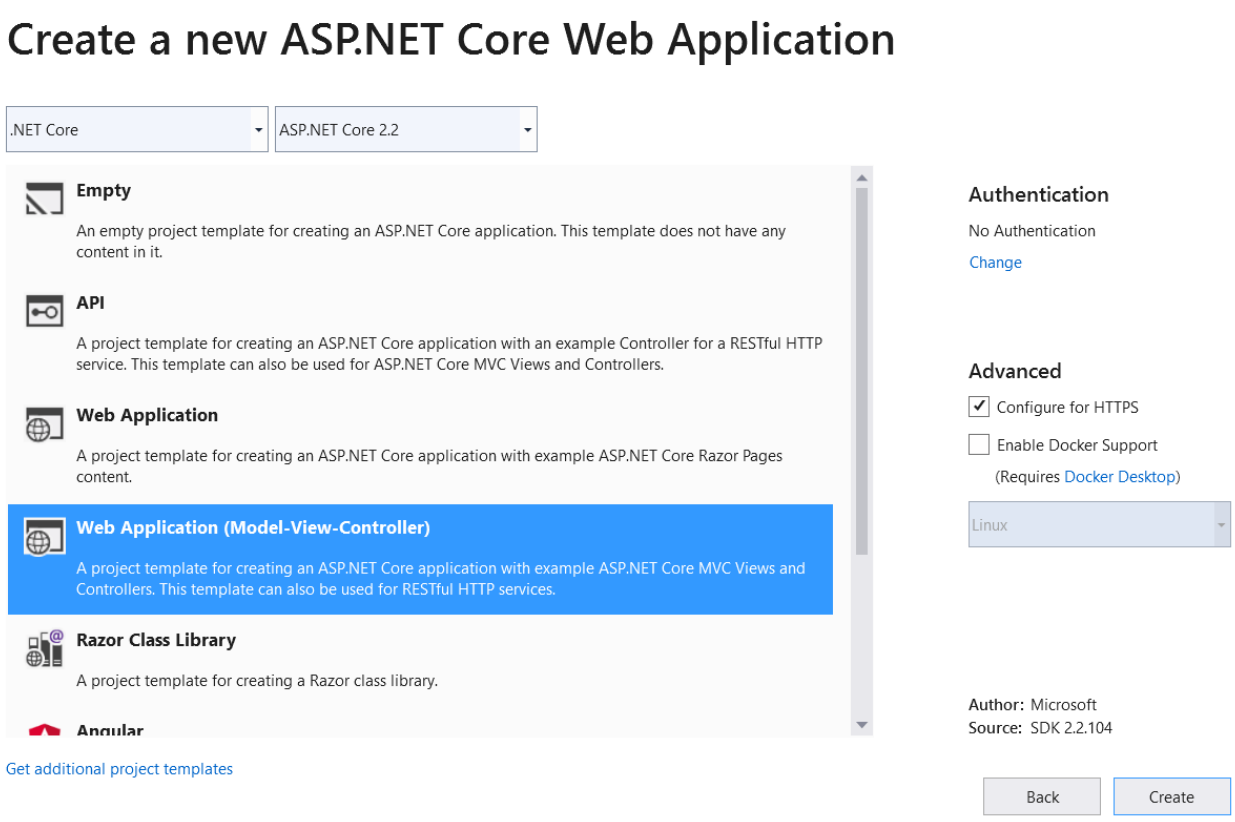
- From the Visual Studio select **Create a new project**.
- Select **ASP.NET Core Web Application** and then select **Next**.



- Name the project **MvcMovie** and select **Create**. It's important to name the project **MvcMovie** so when you copy code, the namespace will match.



- Select **Web Application(Model-View-Controller)**, and then select **Create**.



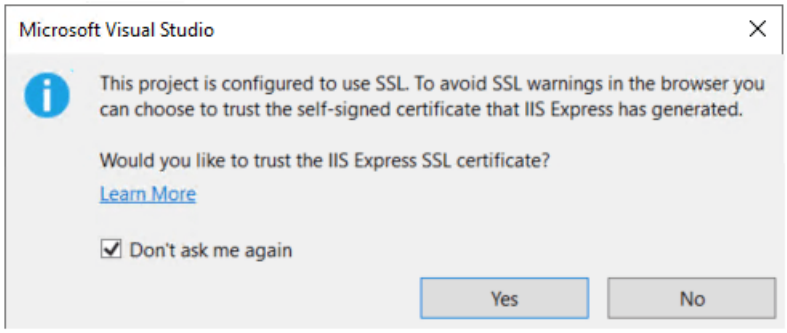
Visual Studio used the default template for the MVC project you just created. You have a working app right now by entering a project name and selecting a few options. This is a basic starter project, and it's a good place to start.

Run the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

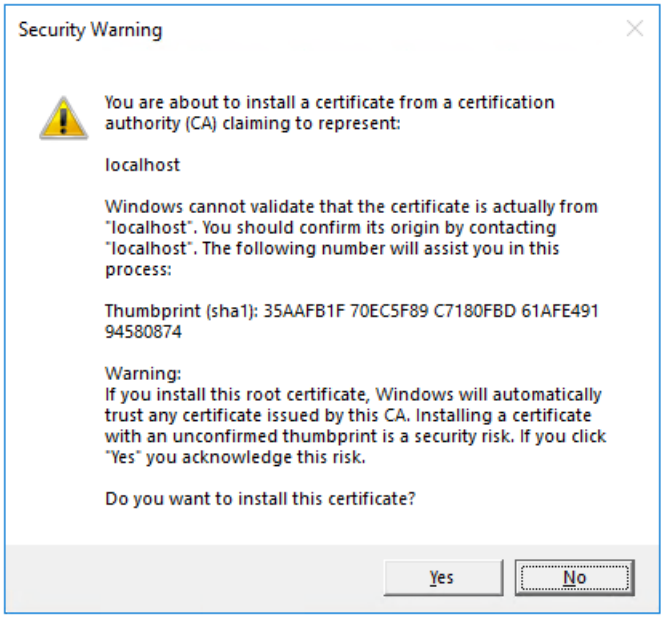
Select **Ctrl-F5** to run the app in non-debug mode.

Visual Studio displays the following dialog:



Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:



Select **Yes** if you agree to trust the development certificate.

Part 2, add a controller to an ASP.NET Core MVC app

9/22/2020 • 12 minutes to read • Edit Online

By Rick Anderson

The Model-View-Controller (MVC) architectural pattern separates an app into three main components: **M**odel, **V**iew, and **C**ontroller. The MVC pattern helps you create apps that are more testable and easier to update than traditional monolithic apps. MVC-based apps contain:

- **M**odels: Classes that represent the data of the app. The model classes use validation logic to enforce business rules for that data. Typically, model objects retrieve and store model state in a database. In this tutorial, a `Movie` model retrieves movie data from a database, provides it to the view or updates it. Updated data is written to a database.
- **V**iews: Views are the components that display the app's user interface (UI). Generally, this UI displays the model data.
- **C**ontrollers: Classes that handle browser requests. They retrieve model data and call view templates that return a response. In an MVC app, the view only displays information; the controller handles and responds to user input and interaction. For example, the controller handles route data and query-string values, and passes these values to the model. The model might use these values to query the database. For example, `https://localhost:5001/Home/Privacy` has route data of `Home` (the controller) and `Privacy` (the action method to call on the home controller). `https://localhost:5001/Movies/Edit/5` is a request to edit the movie with ID=5 using the movie controller. Route data is explained later in the tutorial.

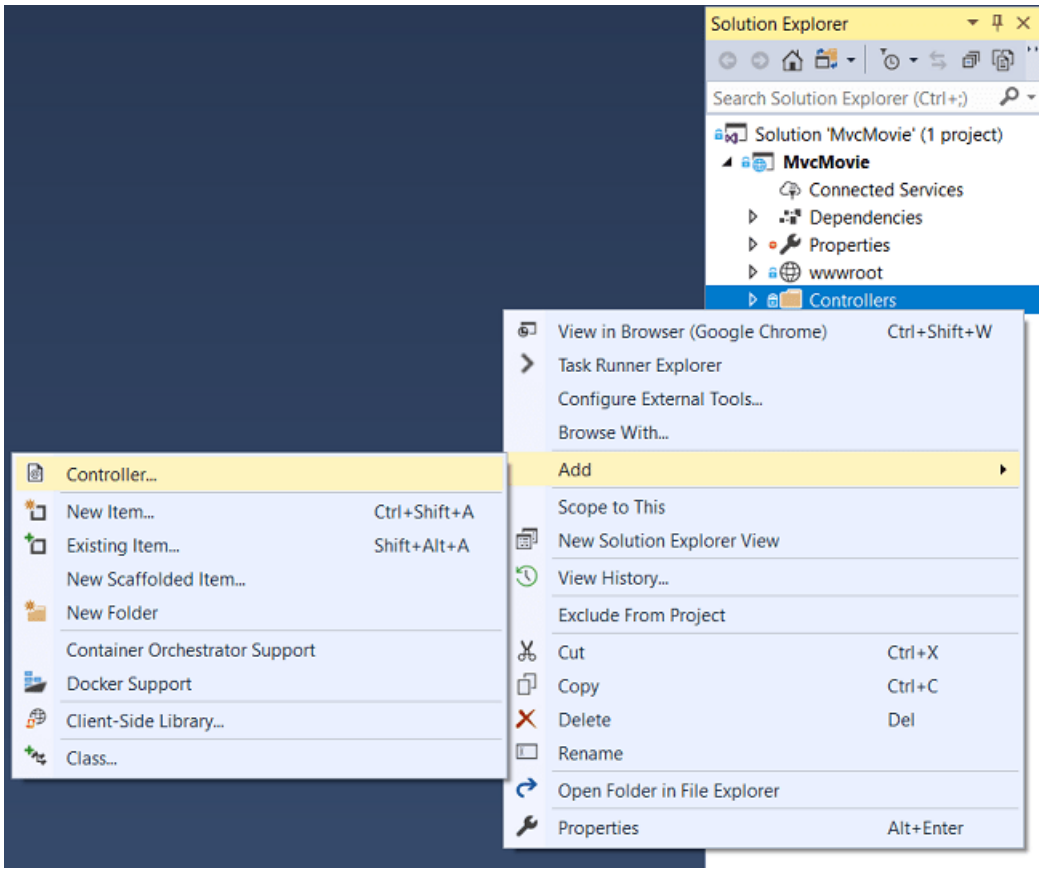
The MVC pattern helps you create apps that separate the different aspects of the app (input logic, business logic, and UI logic), while providing a loose coupling between these elements. The pattern specifies where each kind of logic should be located in the app. The UI logic belongs in the view. Input logic belongs in the controller. Business logic belongs in the model. This separation helps you manage complexity when you build an app, because it enables you to work on one aspect of the implementation at a time without impacting the code of another. For example, you can work on the view code without depending on the business logic code.

We cover these concepts in this tutorial series and show you how to use them to build a movie app. The MVC project contains folders for the *Controllers* and *Views*.

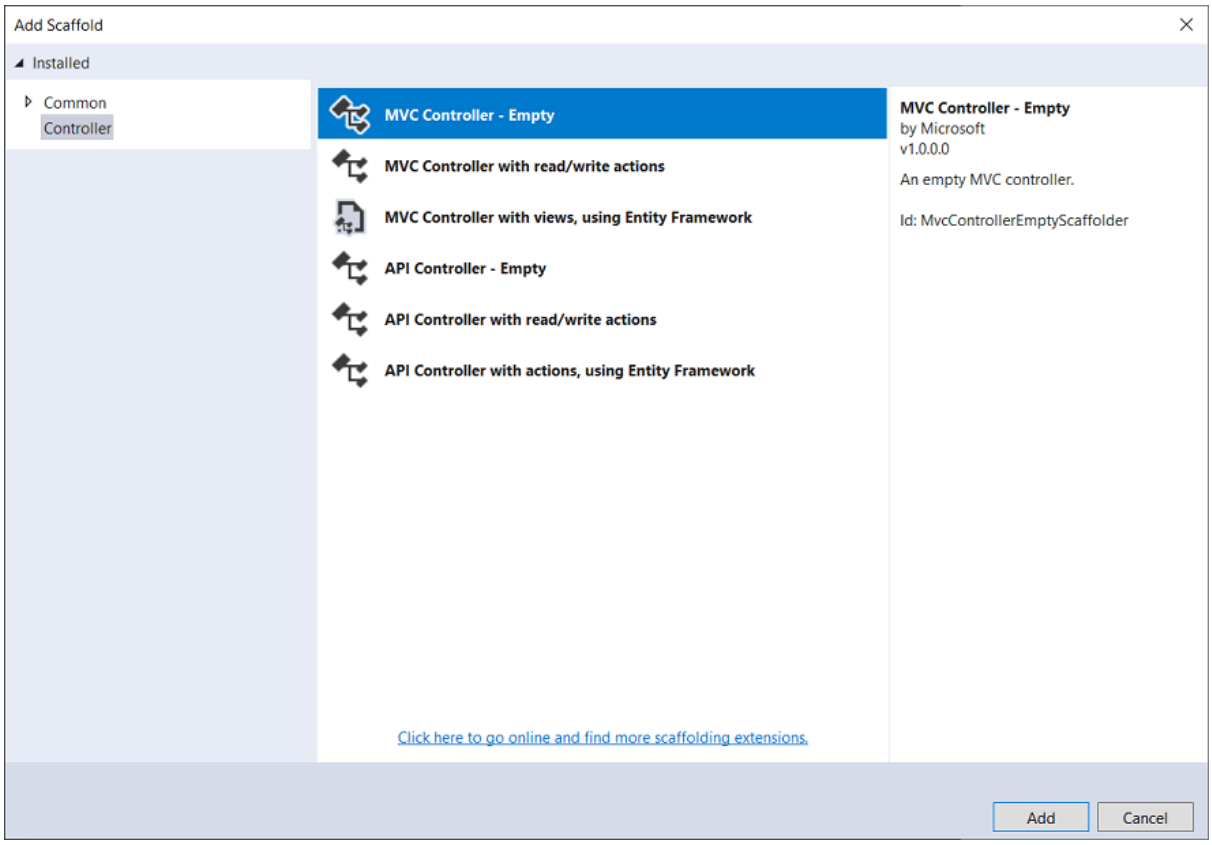
Add a controller

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click **Controllers** > **Add** > **Controller**



- In the **Add Scaffold** dialog box, select **Controller Class - Empty**



- In the **Add Empty MVC Controller dialog**, enter **HelloWorldController** and select **ADD**.

Replace the contents of *Controllers/HelloWorldController.cs* with the following:

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        //
        // GET: /HelloWorld/

        public string Index()
        {
            return "This is my default action...";
        }

        //
        // GET: /HelloWorld/Welcome/

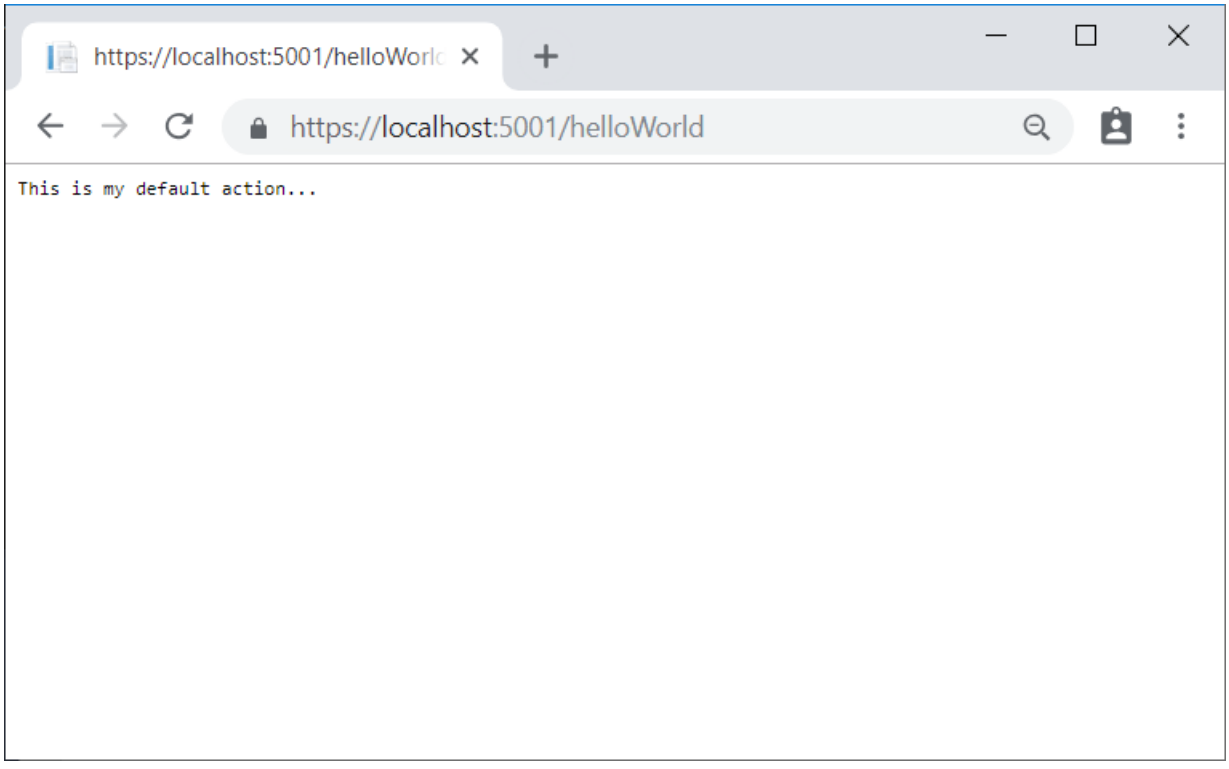
        public string Welcome()
        {
            return "This is the Welcome action method...";
        }
    }
}
```

Every `public` method in a controller is callable as an HTTP endpoint. In the sample above, both methods return a string. Note the comments preceding each method.

An HTTP endpoint is a targetable URL in the web application, such as `https://localhost:5001/HelloWorld`, and combines the protocol used: `HTTPS`, the network location of the web server (including the TCP port): `localhost:5001` and the target URI `HelloWorld`.

The first comment states this is an HTTP GET method that's invoked by appending `/HelloWorld/` to the base URL. The second comment specifies an HTTP GET method that's invoked by appending `/HelloWorld/Welcome/` to the URL. Later on in the tutorial the scaffolding engine is used to generate `HTTP POST` methods which update data.

Run the app in non-debug mode and append "HelloWorld" to the path in the address bar. The `Index` method returns a string.



MVC invokes controller classes (and the action methods within them) depending on the incoming URL. The default URL routing logic used by MVC uses a format like this to determine what code to invoke:

`/[Controller]/[ActionName]/[Parameters]`

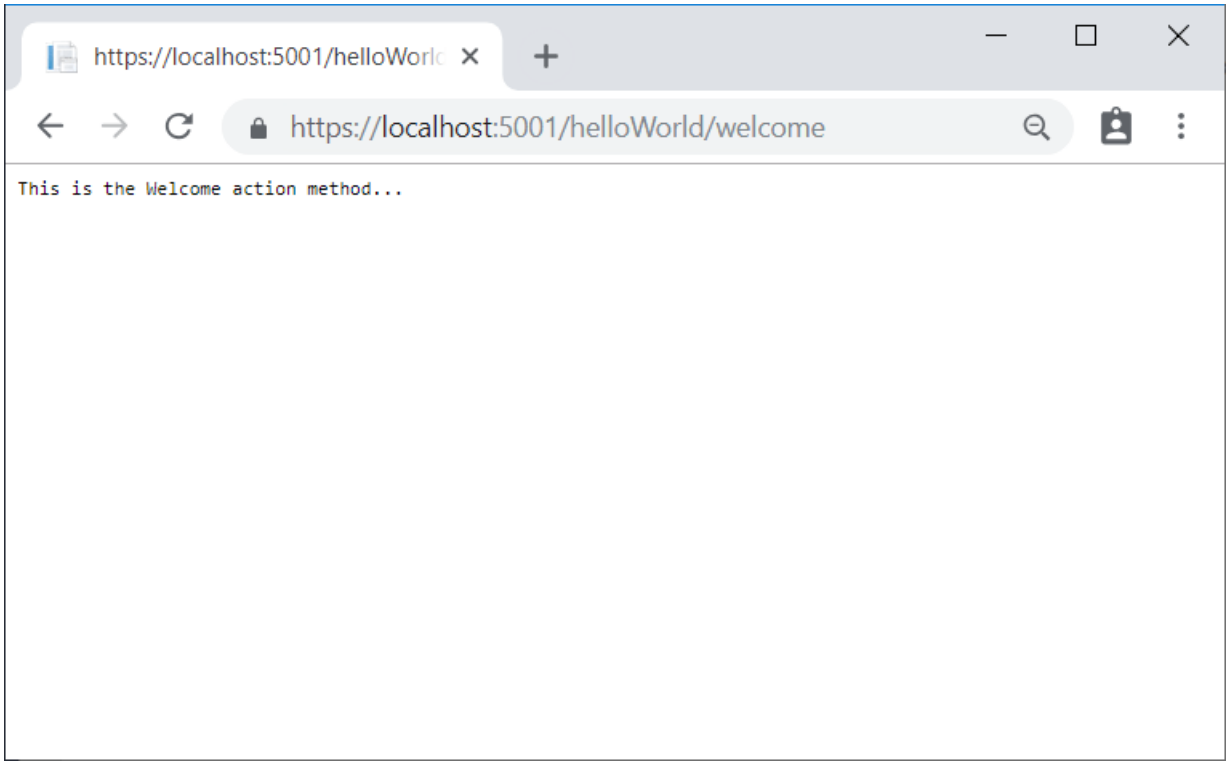
The routing format is set in the `Configure` method in *Startup.cs* file.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

When you browse to the app and don't supply any URL segments, it defaults to the "Home" controller and the "Index" method specified in the template line highlighted above.

The first URL segment determines the controller class to run. So `localhost:{PORT}/HelloWorld` maps to the **HelloWorld**Controller class. The second part of the URL segment determines the action method on the class. So `localhost:{PORT}/HelloWorld/Index` would cause the `Index` method of the `HelloWorldController` class to run. Notice that you only had to browse to `localhost:{PORT}/HelloWorld` and the `Index` method was called by default. That's because `Index` is the default method that will be called on a controller if a method name isn't explicitly specified. The third part of the URL segment (`id`) is for route data. Route data is explained later in the tutorial.

Browse to `https://localhost:{PORT}/HelloWorld/Welcome`. The `Welcome` method runs and returns the string `This is the Welcome action method...`. For this URL, the controller is `HelloWorld` and `Welcome` is the action method. You haven't used the `[Parameters]` part of the URL yet.



Modify the code to pass some parameter information from the URL to the controller. For example, `/HelloWorld/Welcome?name=Rick&numtimes=4`. Change the `Welcome` method to include two parameters as shown in the following code.

```
// GET: /HelloWorld/Welcome/
// Requires using System.Text.Encodings.Web;
public string Welcome(string name, int numTimes = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, NumTimes is: {numTimes}");
}
```

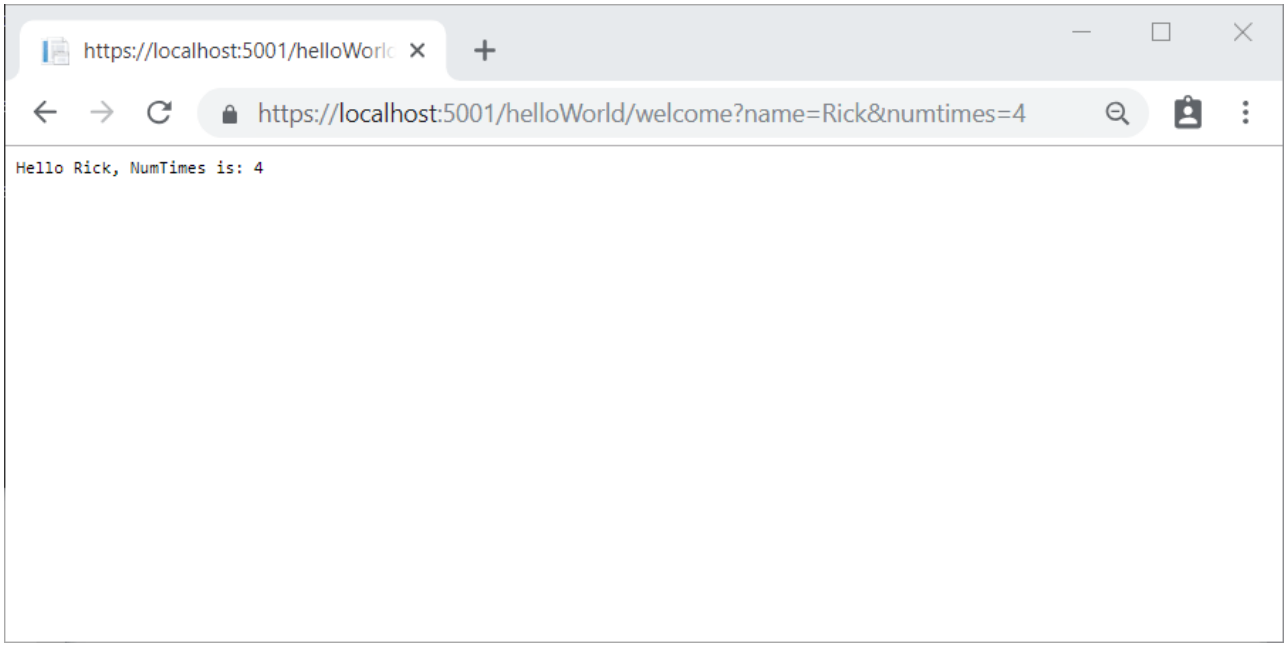
The preceding code:

- Uses the C# optional-parameter feature to indicate that the `numTimes` parameter defaults to 1 if no value is passed for that parameter.
- Uses `HtmlEncoder.Default.Encode` to protect the app from malicious input (namely JavaScript).
- Uses Interpolated Strings in `$"Hello {name}, NumTimes is: {numTimes}"`.

Run the app and browse to:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

(Replace `{PORT}` with your port number.) You can try different values for `name` and `numtimes` in the URL. The MVC model binding system automatically maps the named parameters from the query string in the address bar to parameters in your method. See Model Binding for more information.



In the image above, the URL segment (`Parameters`) isn't used, the `name` and `numTimes` parameters are passed in the query string. The `?` (question mark) in the above URL is a separator, and the query string follows. The `&` character separates field-value pairs.

Replace the `Welcome` method with the following code:

```
public string Welcome(string name, int ID = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, ID: {ID}");
}
```

Run the app and enter the following URL: `https://localhost:{PORT}/HelloWorld/Welcome/3?name=Rick`

This time the third URL segment matched the route parameter `id`. The `Welcome` method contains a parameter `id` that matched the URL template in the `MapControllerRoute` method. The trailing `?` (in `id?`) indicates the `id` parameter is optional.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

In these examples the controller has been doing the "VC" portion of MVC - that is, the **V**iew and the **C**ontroller work. The controller is returning HTML directly. Generally you don't want controllers returning HTML directly, since that becomes very cumbersome to code and maintain. Instead you typically use a separate Razor view template file to generate the HTML response. You do that in the next tutorial.

PREVIOUS NEXT

The Model-View-Controller (MVC) architectural pattern separates an app into three main components: **M**odel, **V**iew, and **C**ontroller. The MVC pattern helps you create apps that are more testable and easier to update than traditional monolithic apps. MVC-based apps contain:

- **M**odels: Classes that represent the data of the app. The model classes use validation logic to enforce business rules for that data. Typically, model objects retrieve and store model state in a database. In this tutorial, a `Movie` model retrieves movie data from a database, provides it to the view or updates it. Updated data is written to a database.
- **V**iews: Views are the components that display the app's user interface (UI). Generally, this UI displays the model data.
- **C**ontrollers: Classes that handle browser requests. They retrieve model data and call view templates that return a response. In an MVC app, the view only displays information; the controller handles and responds to user input and interaction. For example, the controller handles route data and query-string values, and passes these values to the model. The model might use these values to query the database. For example, `https://localhost:5001/Home/About` has route data of `Home` (the controller) and `About` (the action method to call on the home controller). `https://localhost:5001/Movies/Edit/5` is a request to edit the movie with ID=5 using the movie controller. Route data is explained later in the tutorial.

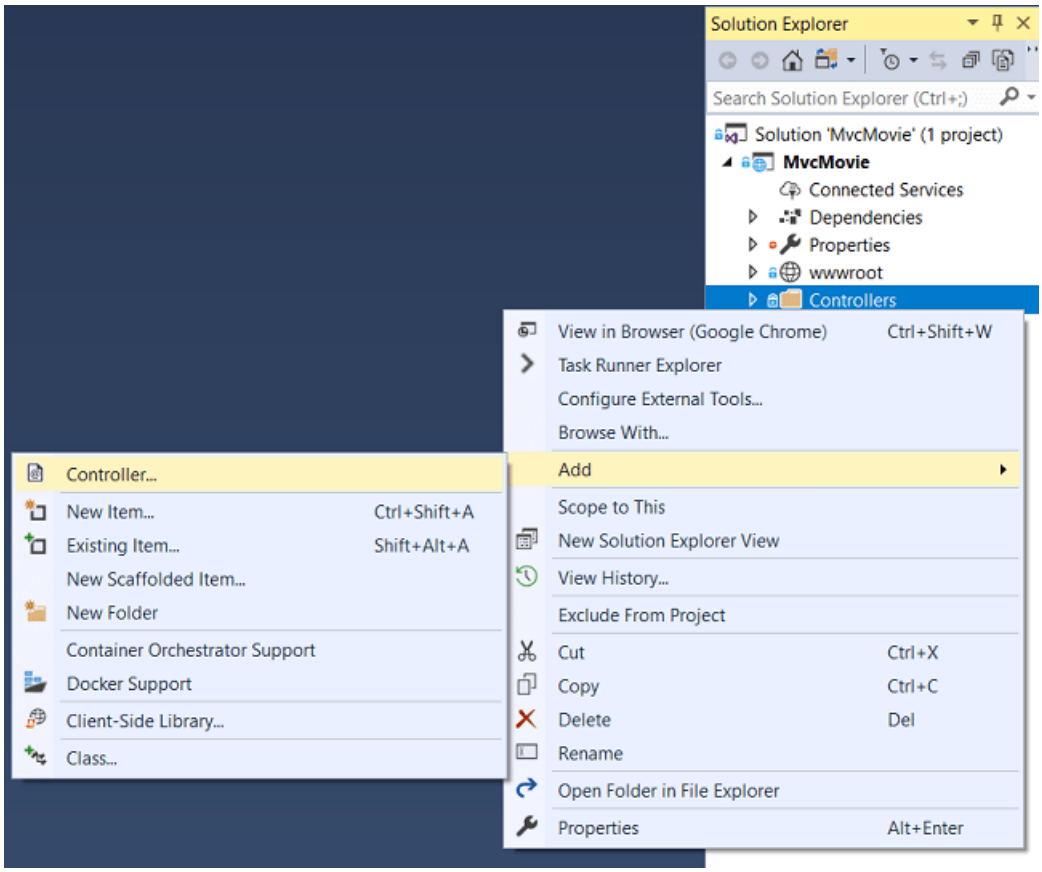
The MVC pattern helps you create apps that separate the different aspects of the app (input logic, business logic, and UI logic), while providing a loose coupling between these elements. The pattern specifies where each kind of logic should be located in the app. The UI logic belongs in the view. Input logic belongs in the controller. Business logic belongs in the model. This separation helps you manage complexity when you build an app, because it enables you to work on one aspect of the implementation at a time without impacting the code of another. For example, you can work on the view code without depending on the business logic code.

We cover these concepts in this tutorial series and show you how to use them to build a movie app. The MVC project contains folders for the *Controllers* and *Views*.

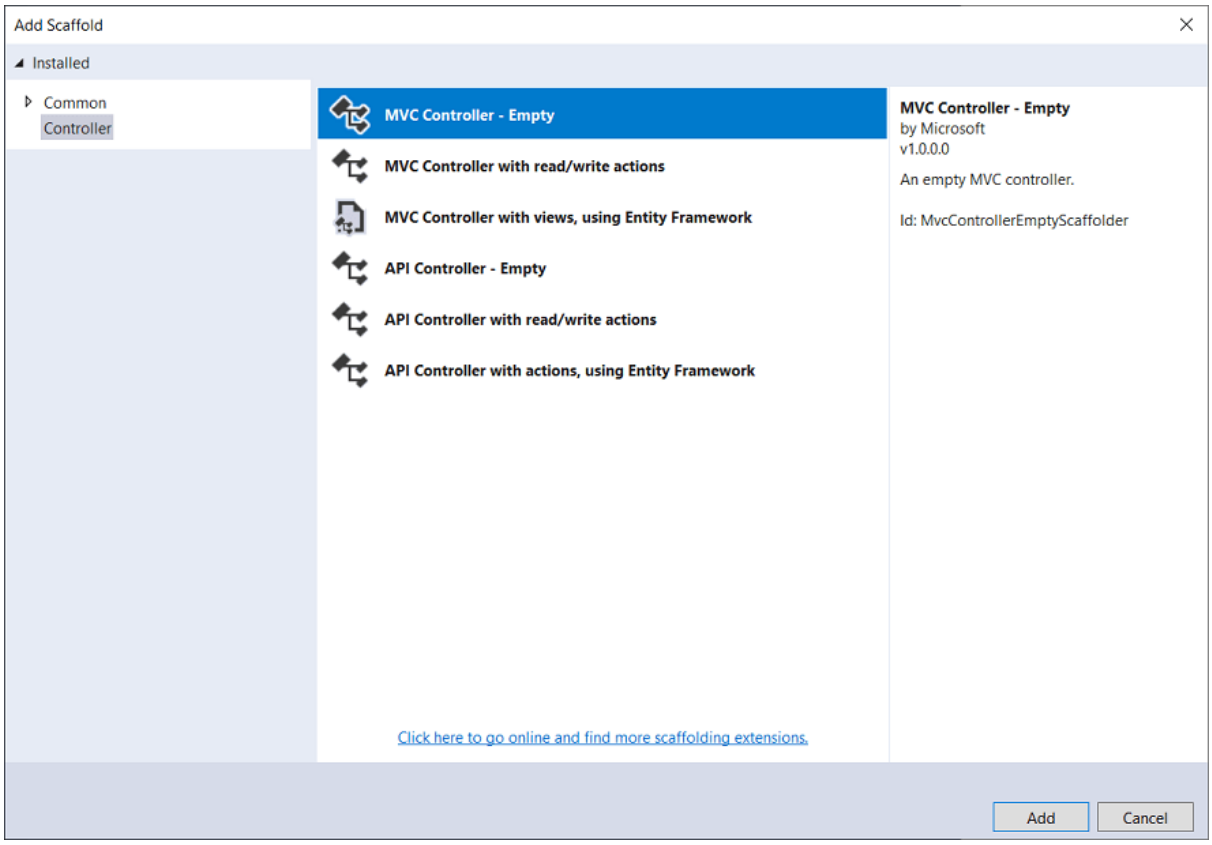
Add a controller

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click **Controllers** > **Add** > **Controller**



- In the **Add Scaffold** dialog box, select **MVC Controller - Empty**



- In the **Add Empty MVC Controller dialog**, enter **HelloWorldController** and select **ADD**.

Replace the contents of *Controllers/HelloWorldController.cs* with the following:

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        //
        // GET: /HelloWorld/

        public string Index()
        {
            return "This is my default action...";
        }

        //
        // GET: /HelloWorld/Welcome/

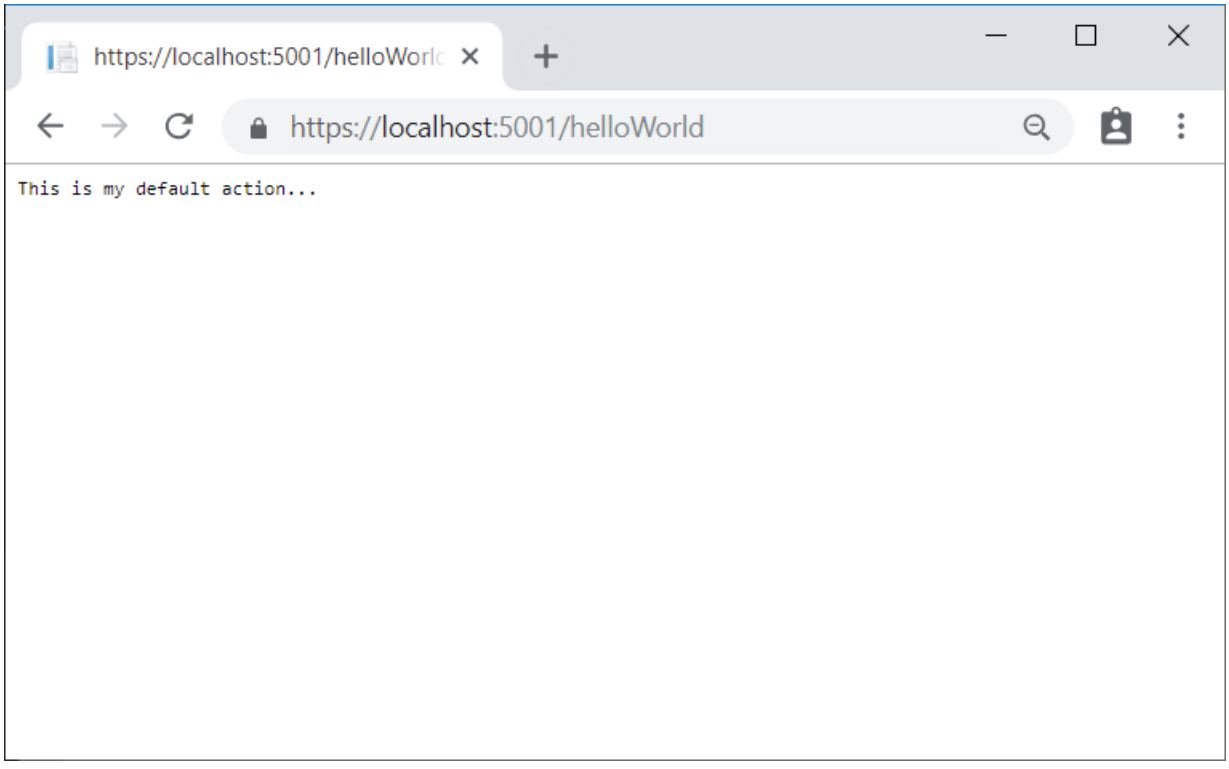
        public string Welcome()
        {
            return "This is the Welcome action method...";
        }
    }
}
```

Every `public` method in a controller is callable as an HTTP endpoint. In the sample above, both methods return a string. Note the comments preceding each method.

An HTTP endpoint is a targetable URL in the web application, such as `https://localhost:5001/HelloWorld`, and combines the protocol used: `HTTPS`, the network location of the web server (including the TCP port): `localhost:5001` and the target URI `HelloWorld`.

The first comment states this is an HTTP GET method that's invoked by appending `/HelloWorld/` to the base URL. The second comment specifies an HTTP GET method that's invoked by appending `/HelloWorld/Welcome/` to the URL. Later on in the tutorial the scaffolding engine is used to generate `HTTP POST` methods which update data.

Run the app in non-debug mode and append "HelloWorld" to the path in the address bar. The `Index` method returns a string.



MVC invokes controller classes (and the action methods within them) depending on the incoming URL. The default URL routing logic used by MVC uses a format like this to determine what code to invoke:

`/[Controller]/[ActionName]/[Parameters]`

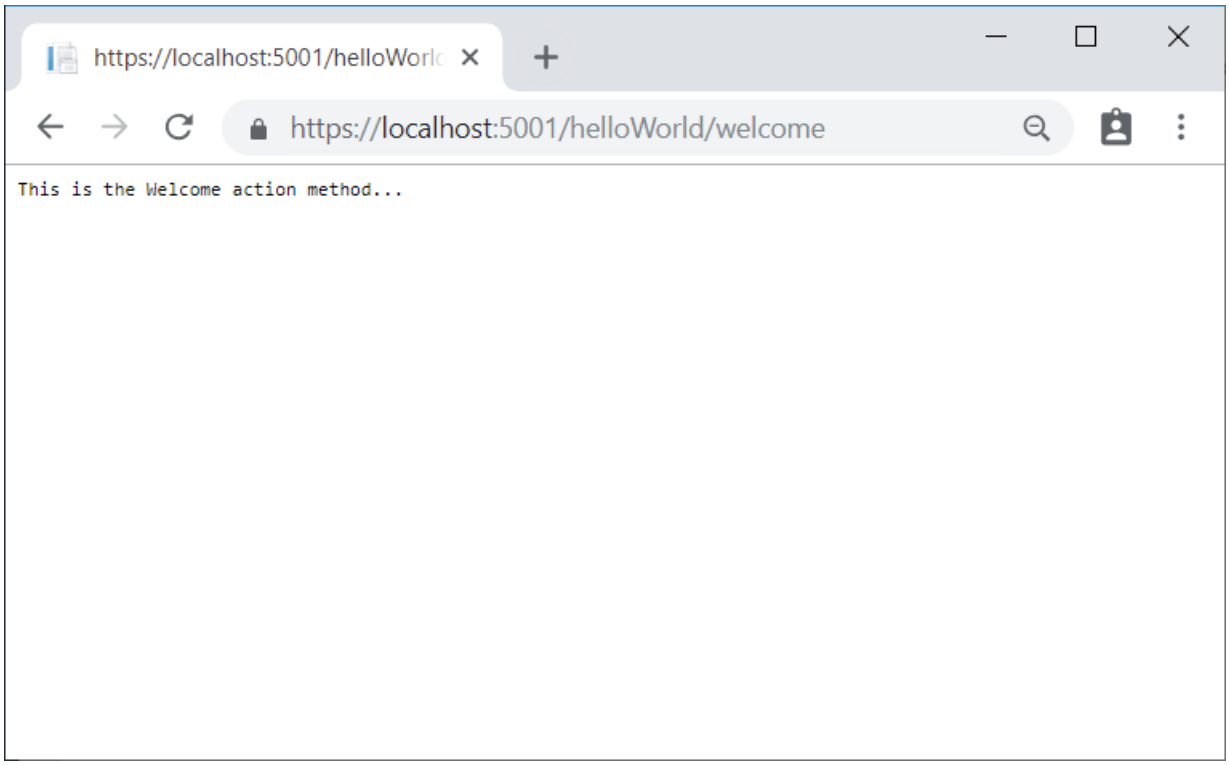
The routing format is set in the `Configure` method in *Startup.cs* file.

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

When you browse to the app and don't supply any URL segments, it defaults to the "Home" controller and the "Index" method specified in the template line highlighted above.

The first URL segment determines the controller class to run. So `localhost:{PORT}/HelloWorld` maps to the `HelloWorldController` class. The second part of the URL segment determines the action method on the class. So `localhost:{PORT}/HelloWorld/Index` would cause the `Index` method of the `HelloWorldController` class to run. Notice that you only had to browse to `localhost:{PORT}/HelloWorld` and the `Index` method was called by default. This is because `Index` is the default method that will be called on a controller if a method name isn't explicitly specified. The third part of the URL segment (`id`) is for route data. Route data is explained later in the tutorial.

Browse to `https://localhost:{PORT}/HelloWorld/Welcome`. The `Welcome` method runs and returns the string `This is the Welcome action method...`. For this URL, the controller is `HelloWorld` and `Welcome` is the action method. You haven't used the `[Parameters]` part of the URL yet.



Modify the code to pass some parameter information from the URL to the controller. For example, `/HelloWorld/Welcome?name=Rick&numtimes=4`. Change the `Welcome` method to include two parameters as shown in the following code.

```
// GET: /HelloWorld/Welcome/
// Requires using System.Text.Encodings.Web;
public string Welcome(string name, int numTimes = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, NumTimes is: {numTimes}");
}
```

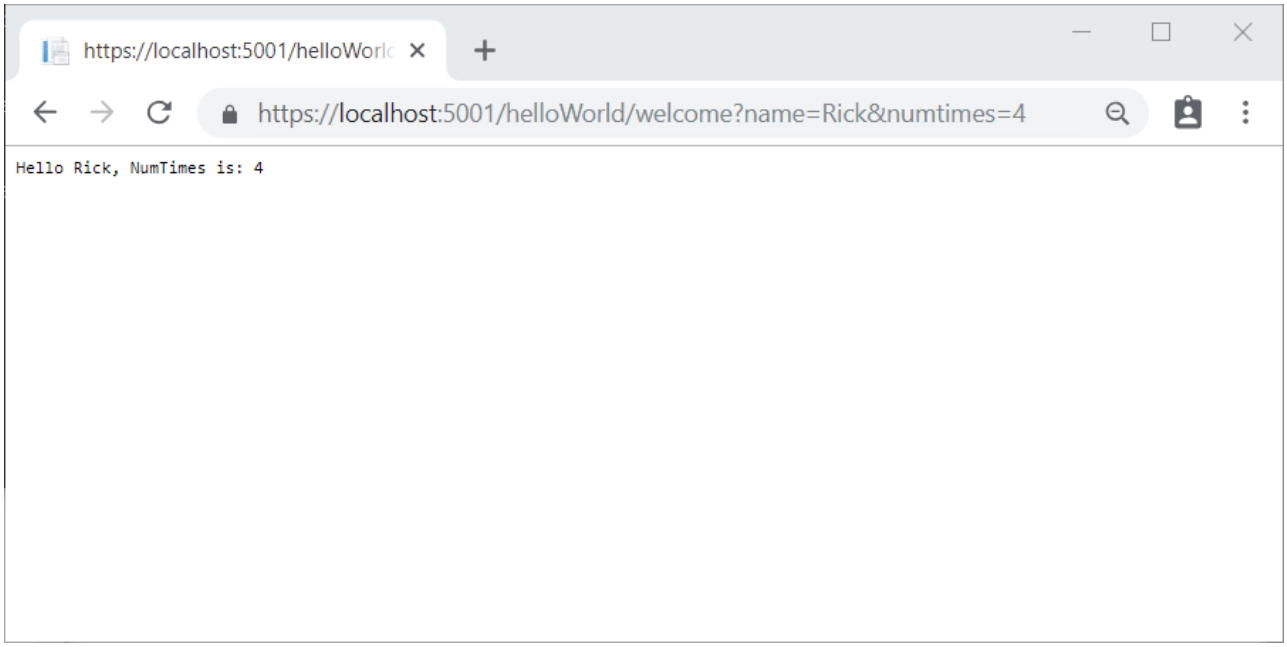
The preceding code:

- Uses the C# optional-parameter feature to indicate that the `numTimes` parameter defaults to 1 if no value is passed for that parameter.
- Uses `HtmlEncoder.Default.Encode` to protect the app from malicious input (namely JavaScript).
- Uses Interpolated Strings in `$"Hello {name}, NumTimes is: {numTimes}"`.

Run the app and browse to:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

(Replace `{PORT}` with your port number.) You can try different values for `name` and `numtimes` in the URL. The MVC model binding system automatically maps the named parameters from the query string in the address bar to parameters in your method. See Model Binding for more information.



In the image above, the URL segment (`Parameters`) isn't used, the `name` and `numTimes` parameters are passed in the query string. The `?` (question mark) in the above URL is a separator, and the query string follows. The `&` character separates field-value pairs.

Replace the `Welcome` method with the following code:

```
public string Welcome(string name, int ID = 1)
{
    return HtmlEncoder.Default.Encode($"Hello {name}, ID: {ID}");
}
```

Run the app and enter the following URL: `https://localhost:{PORT}/HelloWorld/Welcome/3?name=Rick`

This time the third URL segment matched the route parameter `id`. The `Welcome` method contains a parameter `id` that matched the URL template in the `MapRoute` method. The trailing `?` (in `id?`) indicates the `id` parameter is optional.

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

In these examples the controller has been doing the "VC" portion of MVC - that is, the view and controller work. The controller is returning HTML directly. Generally you don't want controllers returning HTML directly, since that becomes very cumbersome to code and maintain. Instead you typically use a separate Razor view template file to help generate the HTML response. You do that in the next tutorial.

Part 3, add a view to an ASP.NET Core MVC app

9/22/2020 • 16 minutes to read • Edit Online

By Rick Anderson

In this section you modify the `HelloWorldController` class to use Razor view files to cleanly encapsulate the process of generating HTML responses to a client.

You create a view template file using Razor. Razor-based view templates have a *.cshtml* file extension. They provide an elegant way to create HTML output with C#.

Currently the `Index` method returns a string with a message that's hard-coded in the controller class. In the `HelloWorldController` class, replace the `Index` method with the following code:

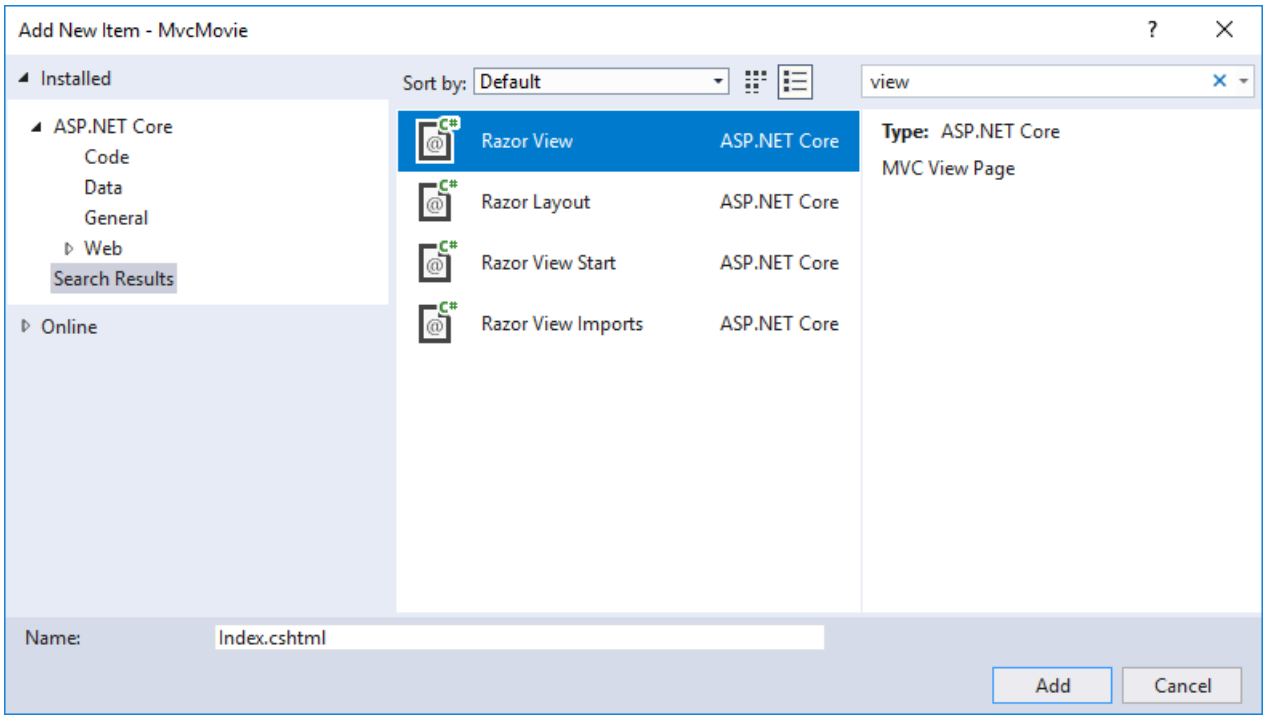
```
public IActionResult Index()
{
    return View();
}
```

The preceding code calls the controller's View method. It uses a view template to generate an HTML response. Controller methods (also known as *action methods*), such as the `Index` method above, generally return an IActionResult (or a class derived from ActionResult), not a type like `string`.

Add a view

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Right click on the *Views* folder, and then **Add > New Folder** and name the folder *HelloWorld*.
- Right click on the *Views/HelloWorld* folder, and then **Add > New Item**.
- In the **Add New Item - MvcMovie** dialog
  - In the search box in the upper-right, enter *view*
  - Select **Razor View**
  - Keep the **Name** box value, *Index.cshtml*.
  - Select **Add**



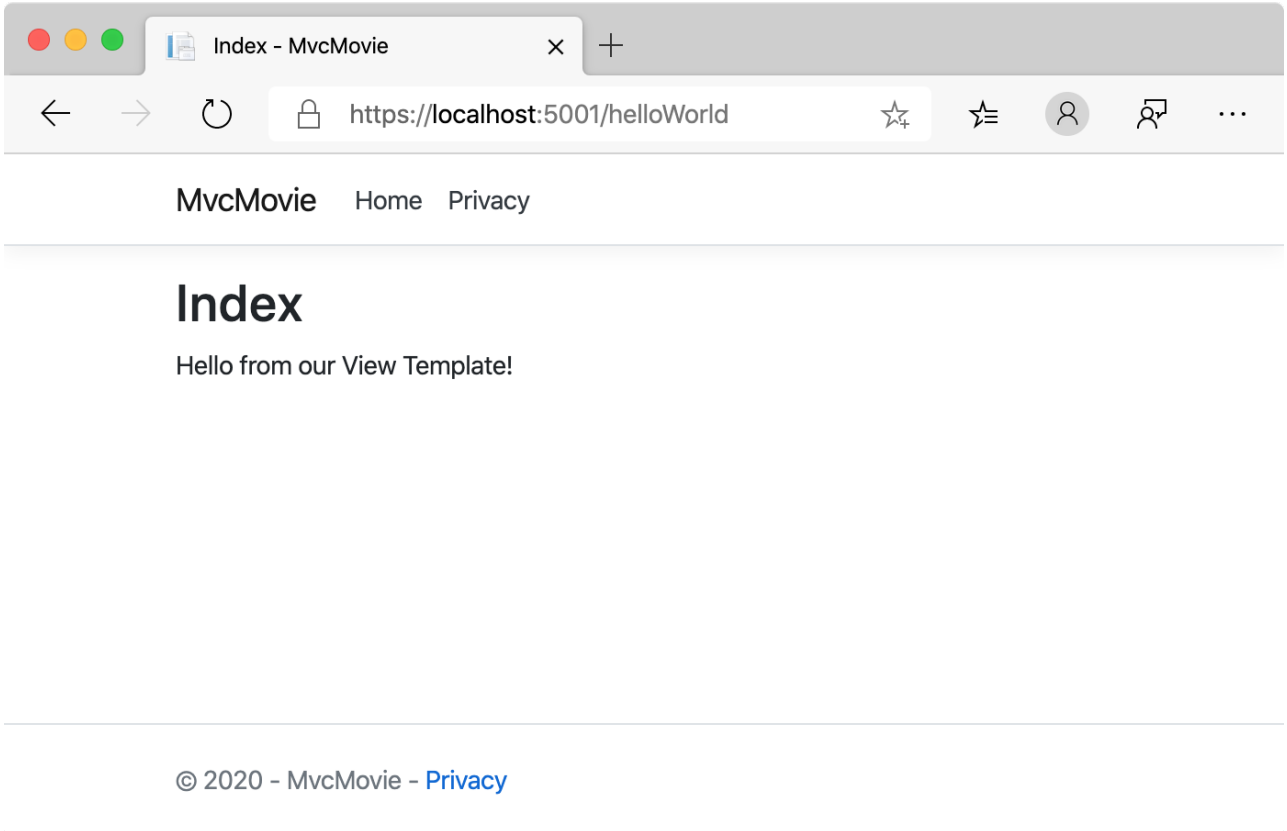
Replace the contents of the *Views/HelloWorld/Index.cshtml* Razor view file with the following:

```
@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

Navigate to `https://localhost:{PORT}/HelloWorld`. The `Index` method in the `HelloWorldController` didn't do much; it ran the statement `return View();`, which specified that the method should use a view template file to render a response to the browser. Because a view template file name wasn't specified, MVC defaulted to using the default view file. The default view file has the same name as the method (`Index`), so the view template in */Views/HelloWorld/Index.cshtml* is used. The image below shows the string "Hello from our View Template!" hard-coded in the view.



Change views and layout pages

Select the menu links (**MvcMovie**, **Home**, and **Privacy**). Each page shows the same menu layout. The menu layout is implemented in the *Views/Shared/_Layout.cshtml* file. Open the *Views/Shared/_Layout.cshtml* file.

Layout templates allow you to specify the HTML container layout of your site in one place and then apply it across multiple pages in your site. Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the view-specific pages you create show up, *wrapped* in the layout page. For example, if you select the **Privacy** link, the **Views/Home/Privacy.cshtml** view is rendered inside the `RenderBody` method.

Change the title, footer, and menu link in the layout file

Replace the content of the *Views/Shared/_Layout.cshtml* file with the following markup. The changes are highlighted:

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie App</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.min.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom box-shadow
mb-3">
            <div class="container">
                <a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-target=".navbar-
collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-controller="Home" asp-
action="Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-controller="Home" asp-
action="Privacy">Privacy</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2020 - Movie App - <a asp-area="" asp-controller="Home" asp-action="Privacy">Privacy</a>
        </div>
    </footer>
    <script src="~/lib/jquery/dist/jquery.min.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.min.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>
    @RenderSection("Scripts", required: false)
</body>
</html>
```

The preceding markup made the following changes:

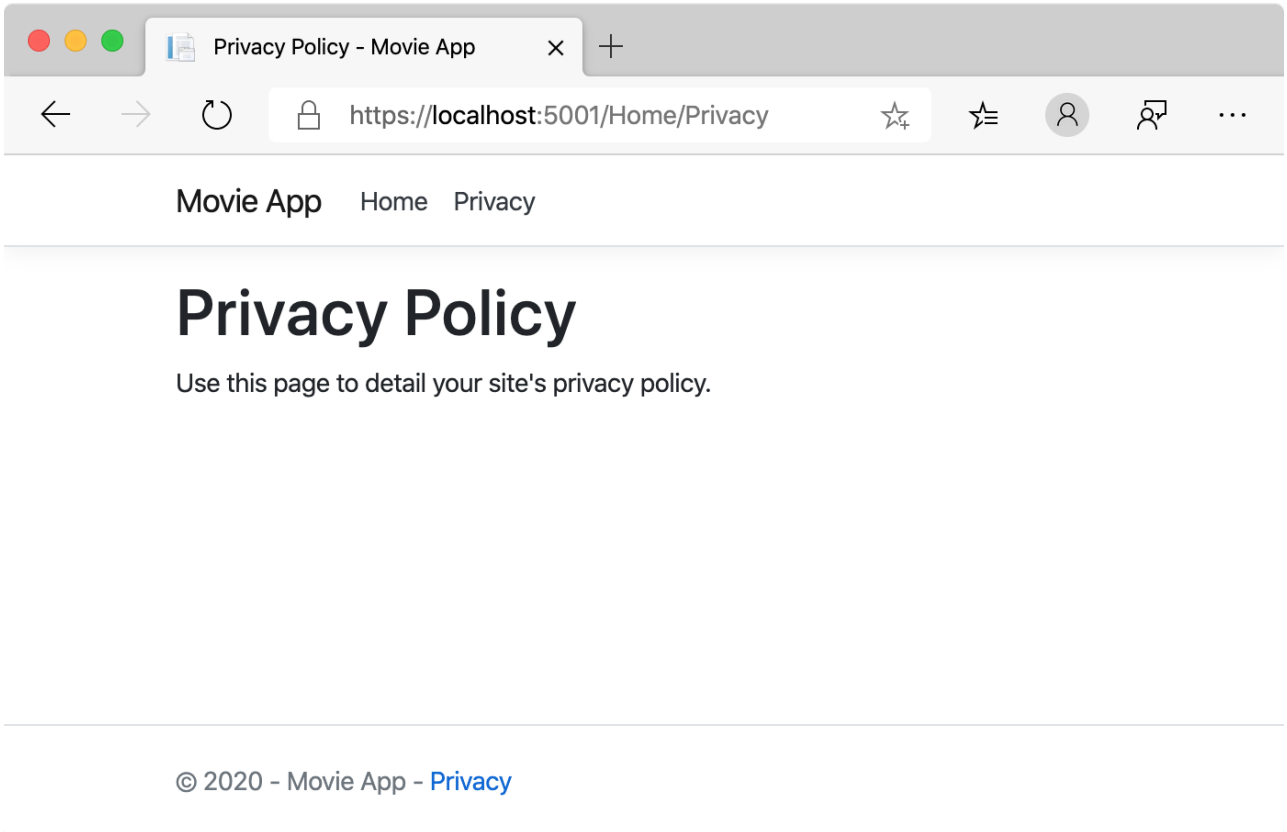
- 3 occurrences of `MvcMovie` to `Movie App`.
- The anchor element `<a class="navbar-brand" asp-area="" asp-controller="Home" asp-action="Index">MvcMovie</a>` to `<a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>`.

In the preceding markup, the `asp-area=""` anchor Tag Helper attribute and attribute value was omitted because this app is not using Areas.

Note: The `Movies` controller has not been implemented. At this point, the `Movie App` link is not functional.

Save your changes and select the **Privacy** link. Notice how the title on the browser tab displays **Privacy Policy** -

Movie App instead of **Privacy Policy - Mvc Movie**:



Select the **Home** link and notice that the title and anchor text also display **Movie App**. We were able to make the change once in the layout template and have all pages on the site reflect the new link text and new title.

Examine the *Views/_ViewStart.cshtml* file:

```
@{
    Layout = "_Layout";
}
```

The *Views/_ViewStart.cshtml* file brings in the *Views/Shared/_Layout.cshtml* file to each view. The `Layout` property can be used to set a different layout view, or set it to `null` so no layout file will be used.

Change the title and `<h2>` element of the *Views/HelloWorld/Index.cshtml* view file:

```
@{
    ViewData["Title"] = "Movie List";
}

<h2>My Movie List</h2>

<p>Hello from our View Template!</p>
```

The title and `<h2>` element are slightly different so you can see which bit of code changes the display.

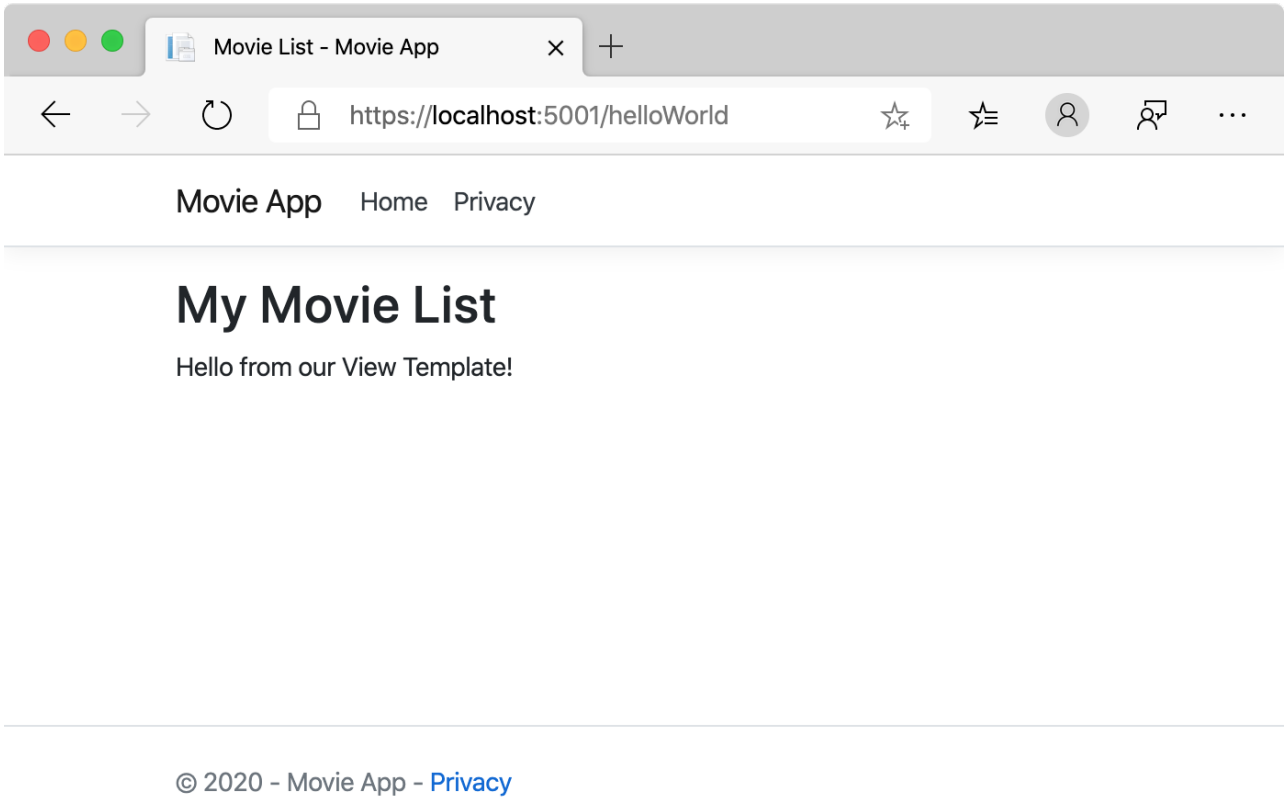
`ViewData["Title"] = "Movie List";` in the code above sets the `Title` property of the `ViewData` dictionary to "Movie List". The `Title` property is used in the `<title>` HTML element in the layout page:

```
<title>@ViewData["Title"] - Movie App</title>
```

Save the change and navigate to `https://localhost:{PORT}/HelloWorld`. Notice that the browser title, the primary heading, and the secondary headings have changed. (If you don't see changes in the browser, you might be viewing

cached content. Press Ctrl+F5 in your browser to force the response from the server to be loaded.) The browser title is created with `ViewData["Title"]` we set in the *Index.cshtml* view template and the additional "- Movie App" added in the layout file.

The content in the *Index.cshtml* view template is merged with the *Views/Shared/_Layout.cshtml* view template. A single HTML response is sent to the browser. Layout templates make it easy to make changes that apply across all of the pages in an app. To learn more, see Layout.



Our little bit of "data" (in this case the "Hello from our View Template!" message) is hard-coded, though. The MVC application has a "V" (view) and you've got a "C" (controller), but no "M" (model) yet.

Passing Data from the Controller to the View

Controller actions are invoked in response to an incoming URL request. A controller class is where the code is written that handles the incoming browser requests. The controller retrieves data from a data source and decides what type of response to send back to the browser. View templates can be used from a controller to generate and format an HTML response to the browser.

Controllers are responsible for providing the data required in order for a view template to render a response. A best practice: View templates should **not** perform business logic or interact with a database directly. Rather, a view template should work only with the data that's provided to it by the controller. Maintaining this "separation of concerns" helps keep the code clean, testable, and maintainable.

Currently, the `Welcome` method in the `HelloWorldController` class takes a `name` and a `ID` parameter and then outputs the values directly to the browser. Rather than have the controller render this response as a string, change the controller to use a view template instead. The view template generates a dynamic response, which means that appropriate bits of data must be passed from the controller to the view in order to generate the response. Do this by having the controller put the dynamic data (parameters) that the view template needs in a `ViewData` dictionary that the view template can then access.

In *HelloWorldController.cs*, change the `Welcome` method to add a `Message` and `NumTimes` value to the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object, which means any type can be used; the `ViewData` object

has no defined properties until you put something inside it. The MVC model binding system automatically maps the named parameters (`name` and `numTimes`) from the query string in the address bar to parameters in your method. The complete *HelloWorldController.cs* file looks like this:

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        public IActionResult Index()
        {
            return View();
        }

        public IActionResult Welcome(string name, int numTimes = 1)
        {
            ViewData["Message"] = "Hello " + name;
            ViewData["NumTimes"] = numTimes;

            return View();
        }
    }
}
```

The `ViewData` dictionary object contains data that will be passed to the view.

Create a Welcome view template named *Views/HelloWorld/Welcome.cshtml*.

You'll create a loop in the *Welcome.cshtml* view template that displays "Hello" `NumTimes` . Replace the contents of *Views/HelloWorld/Welcome.cshtml* with the following:

```
@{
    ViewData["Title"] = "Welcome";
}

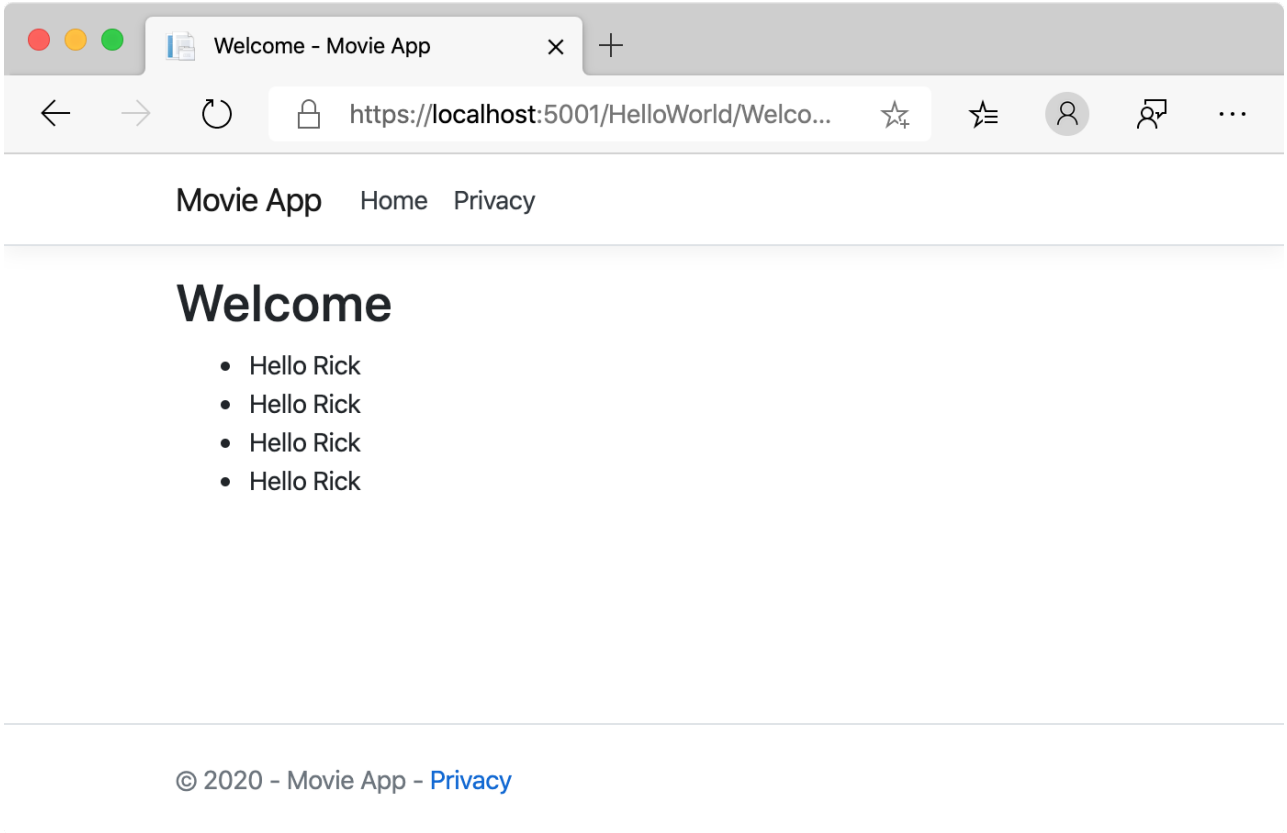
<h2>Welcome</h2>

<ul>
    @for (int i = 0; i < (int)ViewData["NumTimes"]; i++)
    {
        <li>@ViewData["Message"]</li>
    }
</ul>
```

Save your changes and browse to the following URL:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

Data is taken from the URL and passed to the controller using the MVC model binder . The controller packages the data into a `ViewData` dictionary and passes that object to the view. The view then renders the data as HTML to the browser.



In the sample above, the `ViewData` dictionary was used to pass data from the controller to a view. Later in the tutorial, a view model is used to pass data from a controller to a view. The view model approach to passing data is generally much preferred over the `ViewData` dictionary approach. See When to use ViewBag, ViewData, or TempData for more information.

In the next tutorial, a database of movies is created.

PREVIOUS NEXT

In this section you modify the `HelloWorldController` class to use Razor view files to cleanly encapsulate the process of generating HTML responses to a client.

You create a view template file using Razor. Razor-based view templates have a *.cshtml* file extension. They provide an elegant way to create HTML output with C#.

Currently the `Index` method returns a string with a message that's hard-coded in the controller class. In the `HelloWorldController` class, replace the `Index` method with the following code:

```
public IActionResult Index()
{
    return View();
}
```

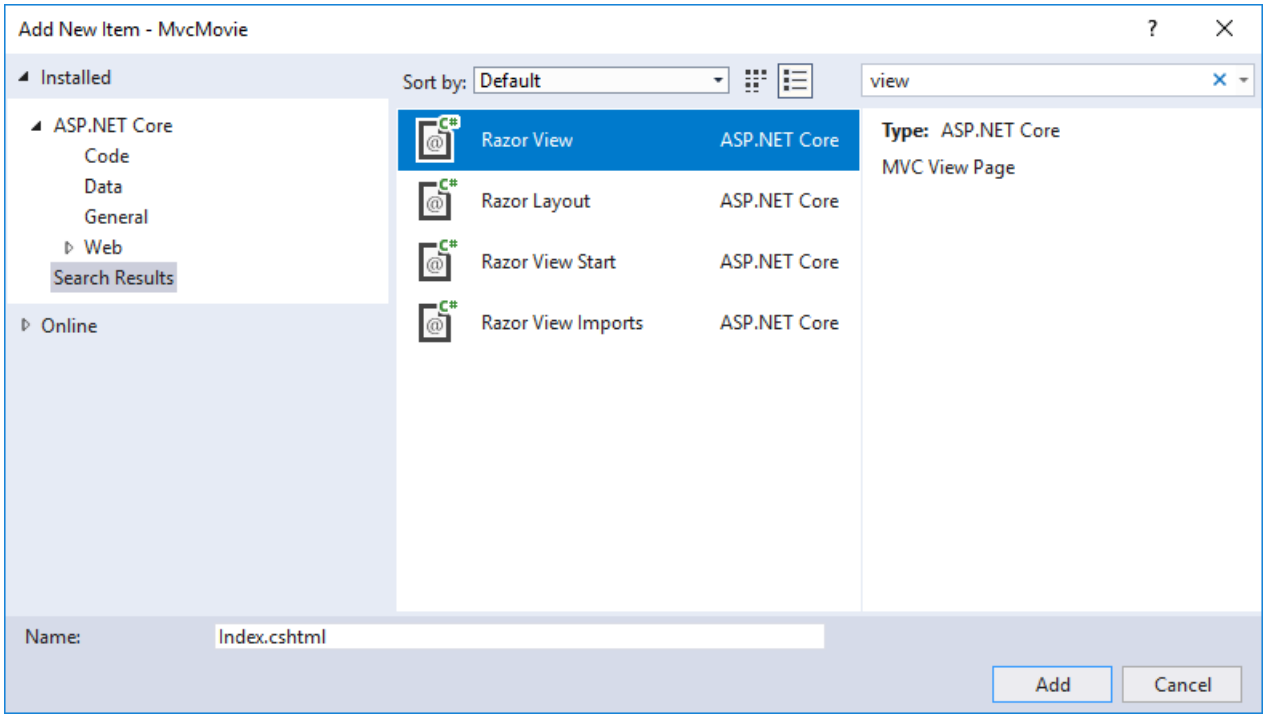
The preceding code calls the controller's View method. It uses a view template to generate an HTML response. Controller methods (also known as *action methods*), such as the `Index` method above, generally return an IActionResult (or a class derived from ActionResult), not a type like `string`.

Add a view

- Visual Studio

- Visual Studio Code
- Visual Studio for Mac

- Right click on the *Views* folder, and then **Add > New Folder** and name the folder *HelloWorld*.
- Right click on the *Views/HelloWorld* folder, and then **Add > New Item**.
- In the **Add New Item - MvcMovie** dialog
  - In the search box in the upper-right, enter *view*
  - Select **Razor View**
  - Keep the **Name** box value, *Index.cshtml*.
  - Select **Add**



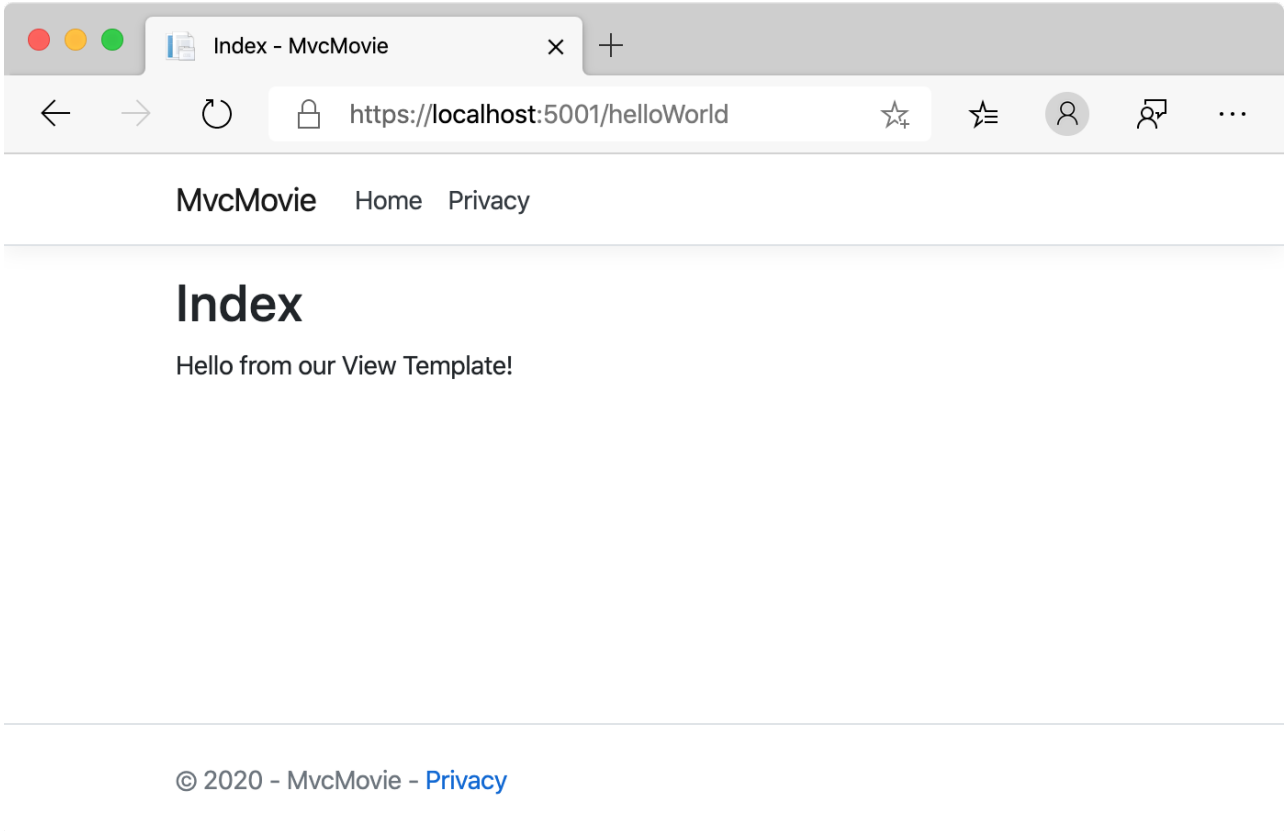
Replace the contents of the *Views/HelloWorld/Index.cshtml* Razor view file with the following:

```
@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

Navigate to `https://localhost:{PORT}/HelloWorld`. The `Index` method in the `HelloWorldController` didn't do much; it ran the statement `return View();`, which specified that the method should use a view template file to render a response to the browser. Because a view template file name wasn't specified, MVC defaulted to using the default view file. The default view file has the same name as the method (`Index`), so in the */Views/HelloWorld/Index.cshtml* is used. The image below shows the string "Hello from our View Template!" hard-coded in the view.



Change views and layout pages

Select the menu links (**MvcMovie**, **Home**, and **Privacy**). Each page shows the same menu layout. The menu layout is implemented in the *Views/Shared/_Layout.cshtml* file. Open the *Views/Shared/_Layout.cshtml* file.

Layout templates allow you to specify the HTML container layout of your site in one place and then apply it across multiple pages in your site. Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the view-specific pages you create show up, *wrapped* in the layout page. For example, if you select the **Privacy** link, the **Views/Home/Privacy.cshtml** view is rendered inside the `RenderBody` method.

Change the title, footer, and menu link in the layout file

- In the title and footer elements, change `MvcMovie` to `Movie App`.
- Change the anchor element
  `<a class="navbar-brand" asp-area="" asp-controller="Home" asp-action="Index">MvcMovie</a>` to
  `<a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>`.

The following markup shows the highlighted changes:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Movie App</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet" href="https://cdnjs.cloudflare.com/ajax/libs/twitter-
bootstrap/4.1.3/css/bootstrap.min.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-property="position" asp-fallback-test-
value="absolute"
```

```
value= absolute
              crossorigin="anonymous"
              integrity="sha256-eSi1q2PG6J7g7ib17yAaWMcrr5GrtohYChqibrV7PBE="/>
    </environment>
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom box-shadow
mb-3">
            <div class="container">
                <a class="navbar-brand" asp-controller="Movies" asp-action="Index">Movie App</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-target=".navbar-
collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-controller="Home" asp-
action="Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-controller="Home" asp-
action="Privacy">Privacy</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <partial name="_CookieConsentPartial" />
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2019 - Movie App - <a asp-area="" asp-controller="Home" asp-action="Privacy">Privacy</a>
        </div>
    </footer>

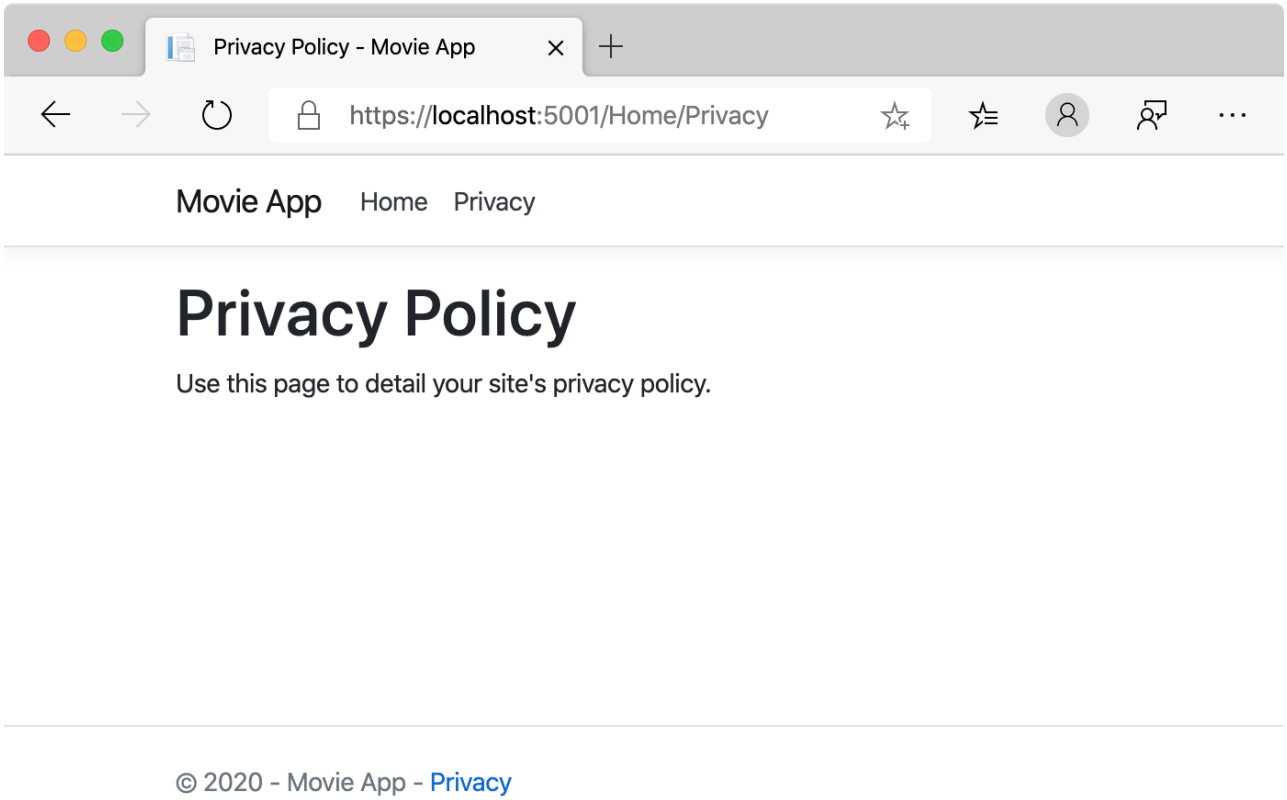
    <environment include="Development">
        <script src="~/lib/jquery/dist/jquery.js"></script>
        <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    </environment>
    <environment exclude="Development">
        <script src="https://cdnjs.cloudflare.com/ajax/libs/jquery/3.3.1/jquery.min.js"
                asp-fallback-src="~/lib/jquery/dist/jquery.min.js"
                asp-fallback-test="window.jQuery"
                crossorigin="anonymous"
                integrity="sha256-FgpCb/KJQlLNfOu91ta32o/NMZxltwRo8QtmkMRdAu8=">
        </script>
        <script src="https://cdnjs.cloudflare.com/ajax/libs/twitter-bootstrap/4.1.3/js/bootstrap.bundle.min.js"
                asp-fallback-src="~/lib/bootstrap/dist/js/bootstrap.bundle.min.js"
                asp-fallback-test="window.jQuery && window.jQuery.fn && window.jQuery.fn.modal"
                crossorigin="anonymous"
                integrity="sha256-E/V4cWE4qvAeO5MOhjtGtqDzPndRO1LBk8lJ/PR7CA4=">
        </script>
    </environment>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

In the preceding markup, the `asp-area` anchor Tag Helper attribute was omitted because this app is not using Areas.

Note: The `Movies` controller has not been implemented. At this point, the `Movie App` link is not functional.

Save your changes and select the **Privacy** link. Notice how the title on the browser tab displays **Privacy Policy - Movie App** instead of **Privacy Policy - Mvc Movie**:



Select the **Home** link and notice that the title and anchor text also display **Movie App**. We were able to make the change once in the layout template and have all pages on the site reflect the new link text and new title.

Examine the *Views/_ViewStart.cshtml* file:

```
@{
    Layout = "_Layout";
}
```

The *Views/_ViewStart.cshtml* file brings in the *Views/Shared/_Layout.cshtml* file to each view. The `Layout` property can be used to set a different layout view, or set it to `null` so no layout file will be used.

Change the title and `<h2>` element of the *Views/HelloWorld/Index.cshtml* view file:

```
@{
    ViewData["Title"] = "Movie List";
}

<h2>My Movie List</h2>

<p>Hello from our View Template!</p>
```

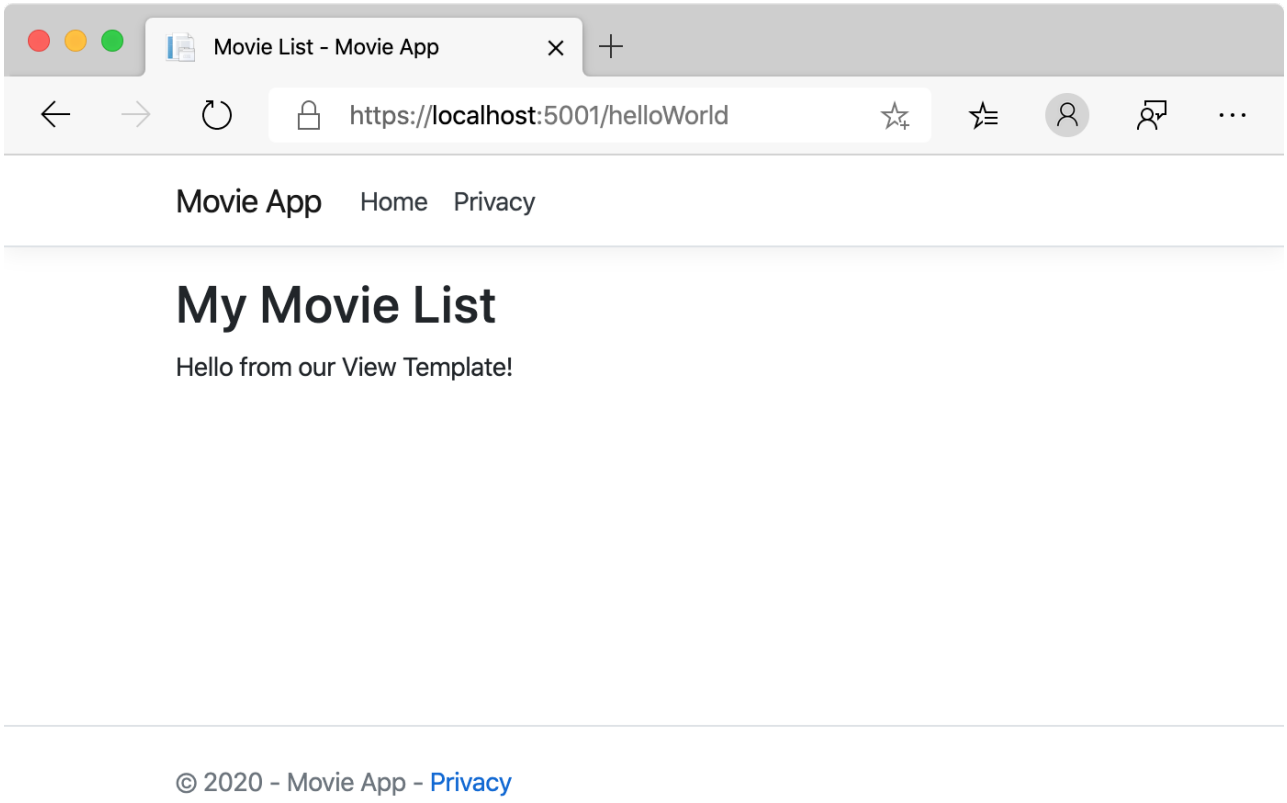
The title and `<h2>` element are slightly different so you can see which bit of code changes the display.

`ViewData["Title"] = "Movie List";` in the code above sets the `Title` property of the `ViewData` dictionary to "Movie List". The `Title` property is used in the `<title>` HTML element in the layout page:

```
<title>@ViewData["Title"] - Movie App</title>
```

Save the change and navigate to `https://localhost:{PORT}/HelloWorld`. Notice that the browser title, the primary heading, and the secondary headings have changed. (If you don't see changes in the browser, you might be viewing cached content. Press Ctrl+F5 in your browser to force the response from the server to be loaded.) The browser title is created with `ViewData["Title"]` we set in the *Index.cshtml* view template and the additional "- Movie App" added in the layout file.

Also notice how the content in the *Index.cshtml* view template was merged with the *Views/Shared/_Layout.cshtml* view template and a single HTML response was sent to the browser. Layout templates make it really easy to make changes that apply across all of the pages in your application. To learn more see Layout.



Our little bit of "data" (in this case the "Hello from our View Template!" message) is hard-coded, though. The MVC application has a "V" (view) and you've got a "C" (controller), but no "M" (model) yet.

Passing Data from the Controller to the View

Controller actions are invoked in response to an incoming URL request. A controller class is where the code is written that handles the incoming browser requests. The controller retrieves data from a data source and decides what type of response to send back to the browser. View templates can be used from a controller to generate and format an HTML response to the browser.

Controllers are responsible for providing the data required in order for a view template to render a response. A best practice: View templates should **not** perform business logic or interact with a database directly. Rather, a view template should work only with the data that's provided to it by the controller. Maintaining this "separation of concerns" helps keep the code clean, testable, and maintainable.

Currently, the `Welcome` method in the `HelloWorldController` class takes a `name` and a `ID` parameter and then outputs the values directly to the browser. Rather than have the controller render this response as a string, change the controller to use a view template instead. The view template generates a dynamic response, which means that appropriate bits of data must be passed from the controller to the view in order to generate the response. Do this

by having the controller put the dynamic data (parameters) that the view template needs in a `ViewData` dictionary that the view template can then access.

In *HelloWorldController.cs*, change the `Welcome` method to add a `Message` and `NumTimes` value to the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object, which means any type can be used; the `ViewData` object has no defined properties until you put something inside it. The MVC model binding system automatically maps the named parameters (`name` and `numTimes`) from the query string in the address bar to parameters in your method. The complete *HelloWorldController.cs* file looks like this:

```
using Microsoft.AspNetCore.Mvc;
using System.Text.Encodings.Web;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        public IActionResult Index()
        {
            return View();
        }

        public IActionResult Welcome(string name, int numTimes = 1)
        {
            ViewData["Message"] = "Hello " + name;
            ViewData["NumTimes"] = numTimes;

            return View();
        }
    }
}
```

The `ViewData` dictionary object contains data that will be passed to the view.

Create a Welcome view template named *Views/HelloWorld/Welcome.cshtml*.

You'll create a loop in the *Welcome.cshtml* view template that displays "Hello" `NumTimes`. Replace the contents of *Views/HelloWorld/Welcome.cshtml* with the following:

```
@{
    ViewData["Title"] = "Welcome";
}

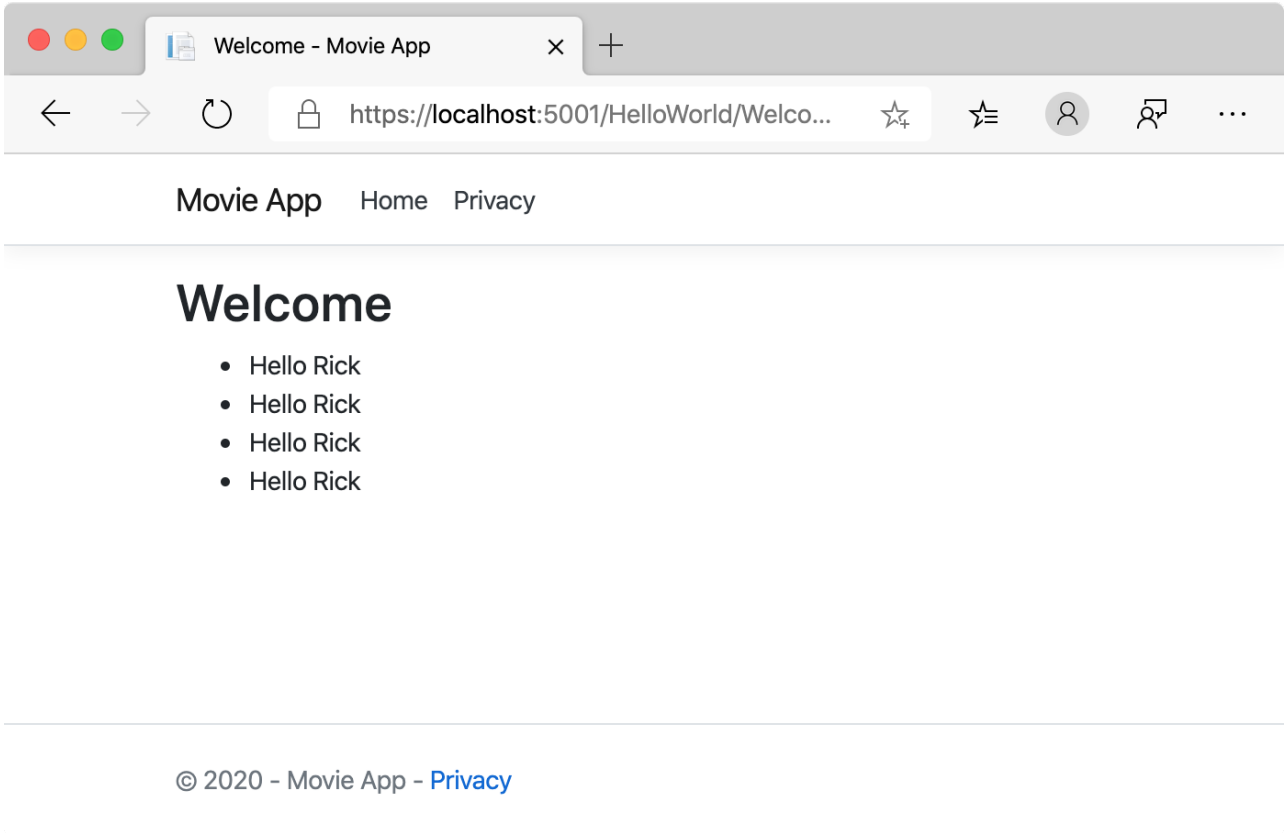
<h2>Welcome</h2>

<ul>
    @for (int i = 0; i < (int)ViewData["NumTimes"]; i++)
    {
        <li>@ViewData["Message"]</li>
    }
</ul>
```

Save your changes and browse to the following URL:

`https://localhost:{PORT}/HelloWorld/Welcome?name=Rick&numtimes=4`

Data is taken from the URL and passed to the controller using the MVC model binder . The controller packages the data into a `ViewData` dictionary and passes that object to the view. The view then renders the data as HTML to the browser.



In the sample above, the `ViewData` dictionary was used to pass data from the controller to a view. Later in the tutorial, a view model is used to pass data from a controller to a view. The view model approach to passing data is generally much preferred over the `ViewData` dictionary approach. See When to use ViewBag, ViewData, or TempData for more information.

In the next tutorial, a database of movies is created.

Part 4, add a model to an ASP.NET Core MVC app

9/22/2020 • 28 minutes to read • Edit Online

By Rick Anderson and Tom Dykstra

In this section, you add classes for managing movies in a database. These classes will be the "**M**odel" part of the **M**VC app.

You use these classes with Entity Framework Core (EF Core) to work with a database. EF Core is an object-relational mapping (ORM) framework that simplifies the data access code that you have to write.

The model classes you create are known as POCO classes (from **P**lain **O**ld **C**LR **O**bjects) because they don't have any dependency on EF Core. They just define the properties of the data that will be stored in the database.

In this tutorial, you write the model classes first, and EF Core creates the database.

Add a data model class

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Right-click the *Models* folder > **Add** > **Class**. Name the file *Movie.cs*.

Update the *Movie.cs* file with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int Id { get; set; }
        public string Title { get; set; }

        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }
}
```

The `Movie` class contains an `Id` field, which is required by the database for the primary key.

The DataType attribute on `ReleaseDate` specifies the type of the data (`Date`). With this attribute:

- The user is not required to enter time information in the date field.
- Only the date is displayed, not time information.

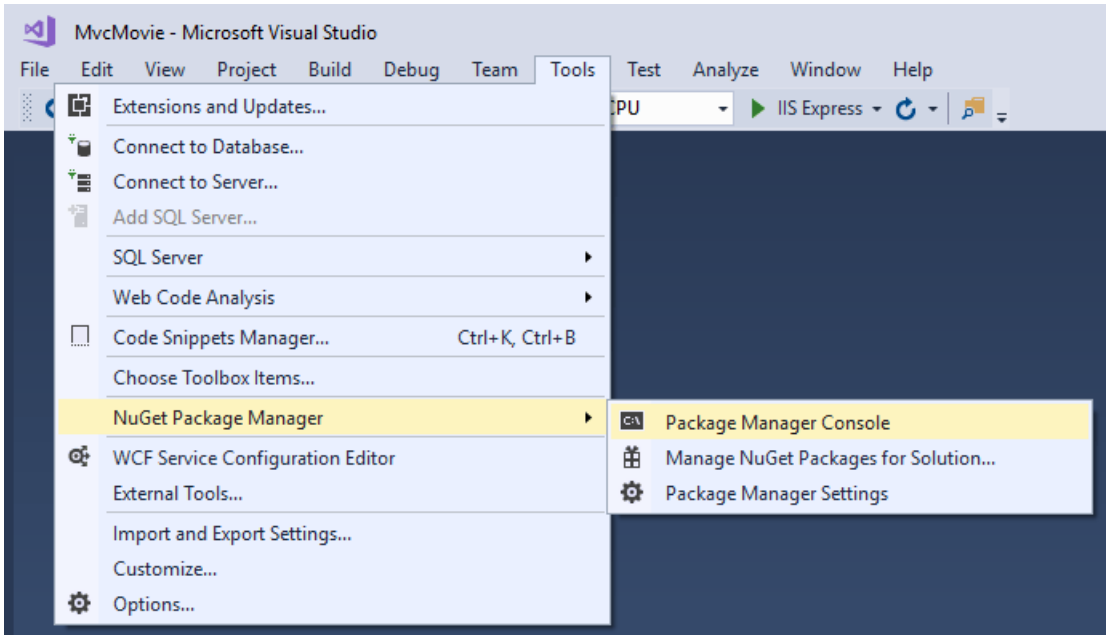
DataAnnotations are covered in a later tutorial.

Add NuGet packages

- Visual Studio

- Visual Studio Code
- Visual Studio for Mac

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console** (PMC).



In the PMC, run the following command:

```
Install-Package Microsoft.EntityFrameworkCore.SqlServer
```

The preceding command adds the EF Core SQL Server provider. The provider package installs the EF Core package as a dependency. Additional packages are installed automatically in the scaffolding step later in the tutorial.

Create a database context class

A database context class is needed to coordinate EF Core functionality (Create, Read, Update, Delete) for the `Movie` model. The database context is derived from Microsoft.EntityFrameworkCore.DbContext and specifies the entities to include in the data model.

Create a *Data* folder.

Add a *Data/MvcMovieContext.cs* file with the following code:

```
using Microsoft.EntityFrameworkCore;
using MvcMovie.Models;

namespace MvcMovie.Data
{
    public class MvcMovieContext : DbContext
    {
        public MvcMovieContext (DbContextOptions<MvcMovieContext> options)
            : base(options)
        {
        }

        public DbSet<Movie> Movie { get; set; }
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

Register the database context

ASP.NET Core is built with dependency injection (DI). Services (such as the EF Core DB context) must be registered with DI during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a DB context instance is shown later in the tutorial. In this section, you register the database context with the DI container.

Add the following `using` statements at the top of *Startup.cs*:

```
using MvcMovie.Data;
using Microsoft.EntityFrameworkCore;
```

Add the following highlighted code in `Startup.ConfigureServices`:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();

    services.AddDbContext<MvcMovieContext>(options =>
            options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Add a database connection string

Add a connection string to the *appsettings.json* file:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "MvcMovieContext": "Server=(localdb)\\mssqllocaldb;Database=MvcMovieContext-
1;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

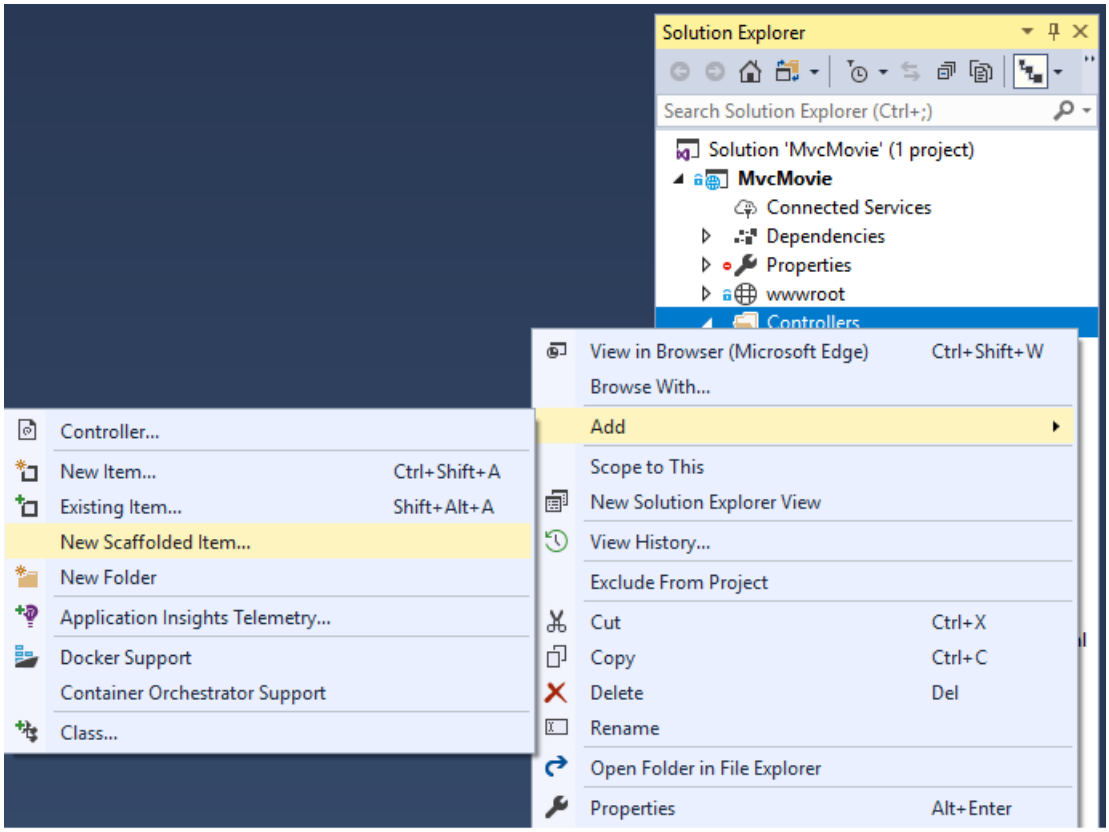
Build the project as a check for compiler errors.

Scaffold movie pages

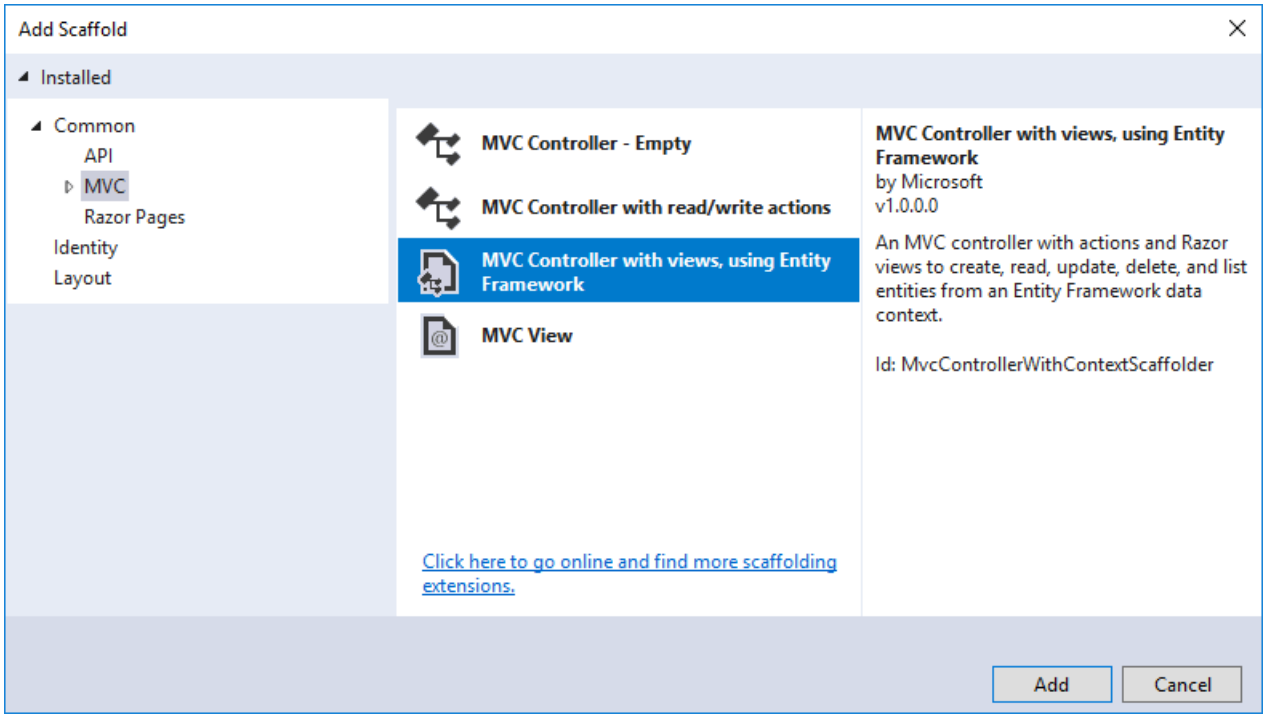
Use the scaffolding tool to produce Create, Read, Update, and Delete (CRUD) pages for the movie model.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

In **Solution Explorer**, right-click the *Controllers* folder > **Add** > **New Scaffolded Item**.

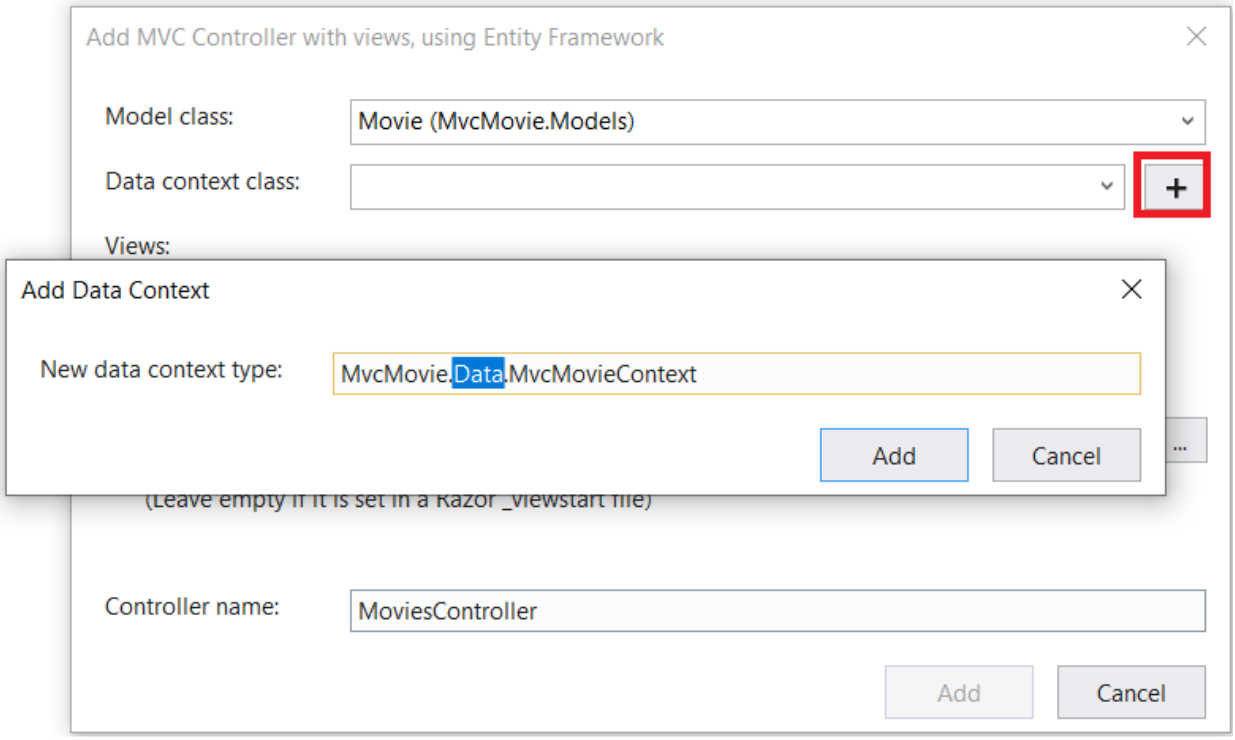


In the **Add Scaffold** dialog, select **MVC Controller with views, using Entity Framework** > **Add**.



Complete the **Add Controller** dialog:

- **Model class:** *Movie (MvcMovie.Models)*
- **Data context class:** *MvcMovieContext (MvcMovie.Data)*



- **Views:** Keep the default of each option checked
- **Controller name:** Keep the default *MoviesController*
- Select **Add**

Visual Studio creates:

- A movies controller (*Controllers/MoviesController.cs*)
- Razor view files for Create, Delete, Details, Edit, and Index pages (*Views/Movies/*.cshtml*)

The automatic creation of these files is known as *scaffolding*.

You can't use the scaffolded pages yet because the database doesn't exist. If you run the app and click on the **Movie App** link, you get a *Cannot open database* or *no such table: Movie* error message.

Initial migration

Use the EF Core Migrations feature to create the database. Migrations is a set of tools that let you create and update a database to match your data model.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console** (PMC).

In the PMC, enter the following commands:

```
Add-Migration InitialCreate
Update-Database
```

- `Add-Migration InitialCreate`: Generates a *Migrations/{timestamp}_InitialCreate.cs* migration file. The `InitialCreate` argument is the migration name. Any name can be used, but by convention, a name is selected that describes the migration. Because this is the first migration, the generated class contains code to create the database schema. The database schema is based on the model specified in the `MvcMovieContext` class.

- `Update-Database`: Updates the database to the latest migration, which the previous command created. This command runs the `Up` method in the *Migrations/{time-stamp}_InitialCreate.cs* file, which creates the database.

  The database update command generates the following warning:

  > No type was specified for the decimal column 'Price' on entity type 'Movie'. This will cause values to be silently truncated if they do not fit in the default precision and scale. Explicitly specify the SQL server column type that can accommodate all the values using 'HasColumnType()'.

  You can ignore that warning, it will be fixed in a later tutorial.

For more information on the PMC tools for EF Core, see EF Core tools reference - PMC in Visual Studio.

The InitialCreate class

Examine the *Migrations/{timestamp}_InitialCreate.cs* migration file:

```
public partial class Initial : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.CreateTable(
            name: "Movie",
            columns: table => new
            {
                Id = table.Column<int>(nullable: false)
                    .Annotation("SqlServer:ValueGenerationStrategy",
                                SqlServerValueGenerationStrategy.IdentityColumn),
                Title = table.Column<string>(nullable: true),
                ReleaseDate = table.Column<DateTime>(nullable: false),
                Genre = table.Column<string>(nullable: true),
                Price = table.Column<decimal>(nullable: false)
            },
            constraints: table =>
            {
                table.PrimaryKey("PK_Movie", x => x.Id);
            });
    }

    protected override void Down(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.DropTable(
            name: "Movie");
    }
}
```

The `Up` method creates the Movie table and configures `Id` as the primary key. The `Down` method reverts the schema changes made by the `Up` migration.

Test the app

- Run the app and click the **Movie App** link.

  If you get an exception similar to one of the following:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
SqlException: Cannot open database "MvcMovieContext-1" requested by the login. The login failed.
```

You probably missed the migrations step.

- Test the **Create** page. Enter and submit data.

> **NOTE**
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

- Test the **Edit**, **Details**, and **Delete** pages.

Dependency injection in the controller

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Open the *Controllers/MoviesController.cs* file and examine the constructor:

```
public class MoviesController : Controller
{
    private readonly MvcMovieContext _context;

    public MoviesController(MvcMovieContext context)
    {
        _context = context;
    }
```

The constructor uses Dependency Injection to inject the database context (`MvcMovieContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

Strongly typed models and the @model keyword

Earlier in this tutorial, you saw how a controller can pass data or objects to a view using the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object that provides a convenient late-bound way to pass information to a view.

MVC also provides the ability to pass strongly typed model objects to a view. This strongly typed approach enables compile time code checking. The scaffolding mechanism used this approach (that is, passing a strongly typed model) with the `MoviesController` class and views.

Examine the generated `Details` method in the *Controllers/MoviesController.cs* file:

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}
```

The `id` parameter is generally passed as route data. For example `https://localhost:5001/movies/details/1` sets:

- The controller to the `movies` controller (the first URL segment).
- The action to `details` (the second URL segment).
- The id to 1 (the last URL segment).

You can also pass in the `id` with a query string as follows:

`https://localhost:5001/movies/details?id=1`

The `id` parameter is defined as a nullable type (`int?`) in case an ID value isn't provided.

A lambda expression is passed in to `FirstOrDefaultAsync` to select movie entities that match the route data or query string value.

```
var movie = await _context.Movie
    .FirstOrDefaultAsync(m => m.Id == id);
```

If a movie is found, an instance of the `Movie` model is passed to the `Details` view:

```
return View(movie);
```

Examine the contents of the *Views/Movies/Details.cshtml* file:

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Movie</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.ReleaseDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.ReleaseDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Genre)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Genre)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Price)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Price)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.Id">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

The `@model` statement at the top of the view file specifies the type of object that the view expects. When the movie controller was created, the following `@model` statement was included:

```
@model MvcMovie.Models.Movie
```

This `@model` directive allows access to the movie that the controller passed to the view. The `Model` object is strongly typed. For example, in the *Details.cshtml* view, the code passes each movie field to the `DisplayNameFor` and `DisplayFor` HTML Helpers with the strongly typed `Model` object. The `Create` and `Edit` methods and views also pass a `Movie` model object.

Examine the *Index.cshtml* view and the `Index` method in the Movies controller. Notice how the code creates a `List` object when it calls the `View` method. The code passes this `Movies` list from the `Index` action method to the view:

```
// GET: Movies
public async Task<IActionResult> Index()
{
    return View(await _context.Movie.ToListAsync());
}
```

When the movies controller was created, scaffolding included the following `@model` statement at the top of the *Index.cshtml* file:

```
@model IEnumerable<MvcMovie.Models.Movie>
```

The `@model` directive allows you to access the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Index.cshtml* view, the code loops through the movies with a `foreach` statement over the strongly typed `Model` object:

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.Id">Details</a> |
                <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Because the `Model` object is strongly typed (as an `IEnumerable<Movie>` object), each item in the loop is typed as `Movie`. Among other benefits, this means that you get compile time checking of the code.

Additional resources

- Tag Helpers
- Globalization and localization

PREVIOUS ADDING A VIEW

NEXT WORKING WITH SQL

Add a data model class

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Right-click the *Models* folder > **Add** > **Class**. Name the class **Movie**.

Add the following properties to the `Movie` class:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int Id { get; set; }
        public string Title { get; set; }

        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }
}
```

The `Movie` class contains:

- The `Id` field which is required by the database for the primary key.
- `[DataType(DataType.Date)]`: The DataType attribute specifies the type of the data (`Date`). With this attribute:
  - The user is not required to enter time information in the date field.
  - Only the date is displayed, not time information.

DataAnnotations are covered in a later tutorial.

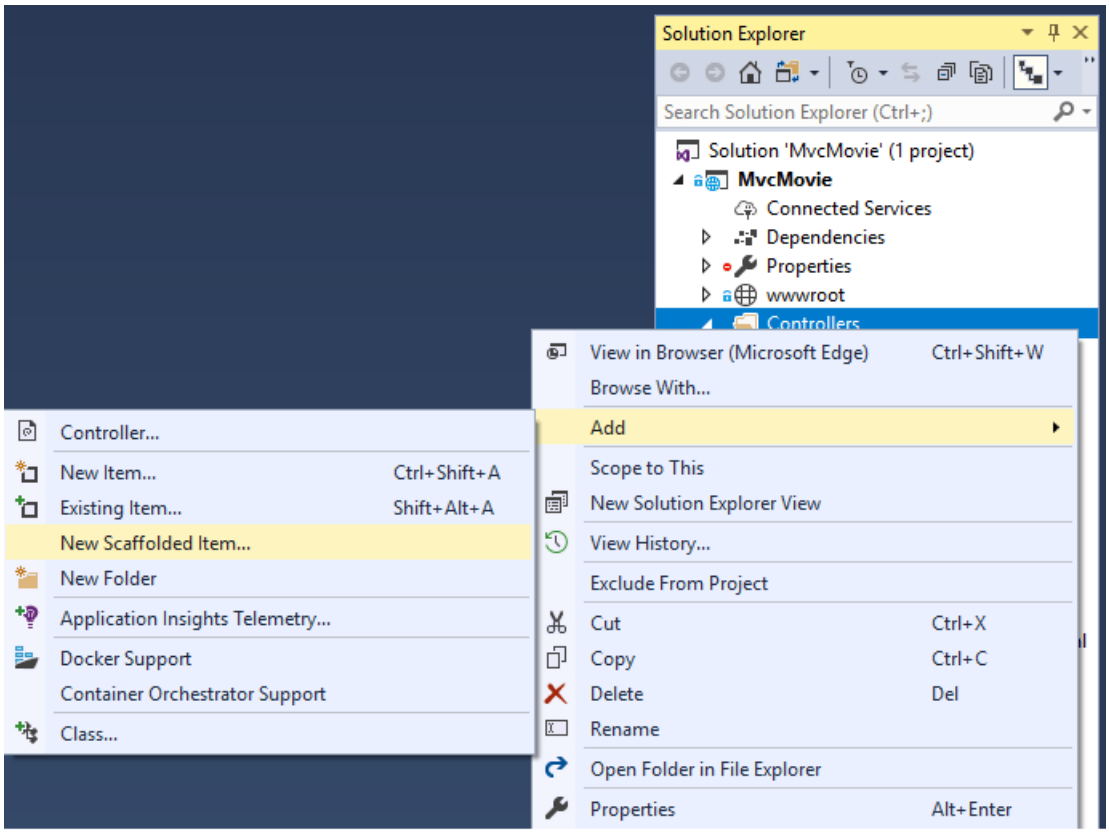
Scaffold the movie model

In this section, the movie model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the movie model.

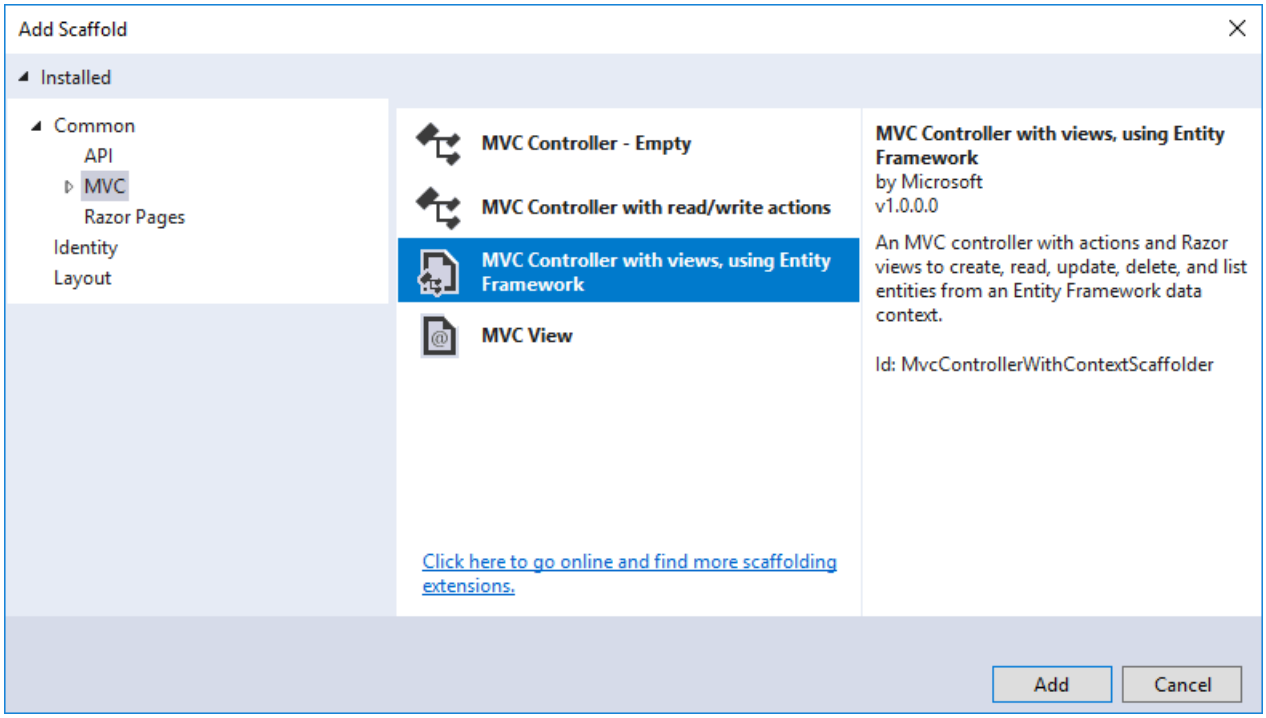
- Visual Studio
- Visual Studio Code

- Visual Studio for Mac

In **Solution Explorer**, right-click the *Controllers* folder > **Add** > **New Scaffolded Item**.

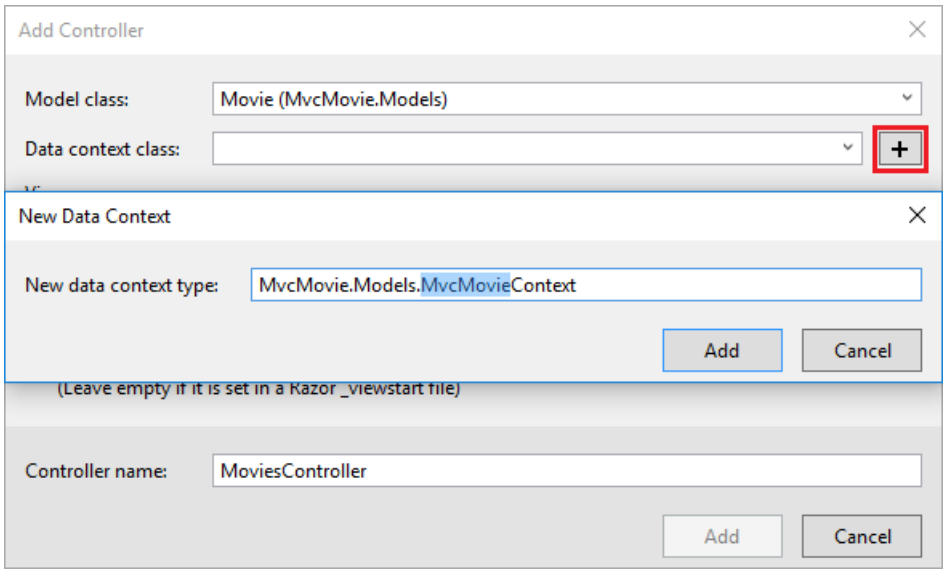


In the **Add Scaffold** dialog, select **MVC Controller with views, using Entity Framework** > **Add**.

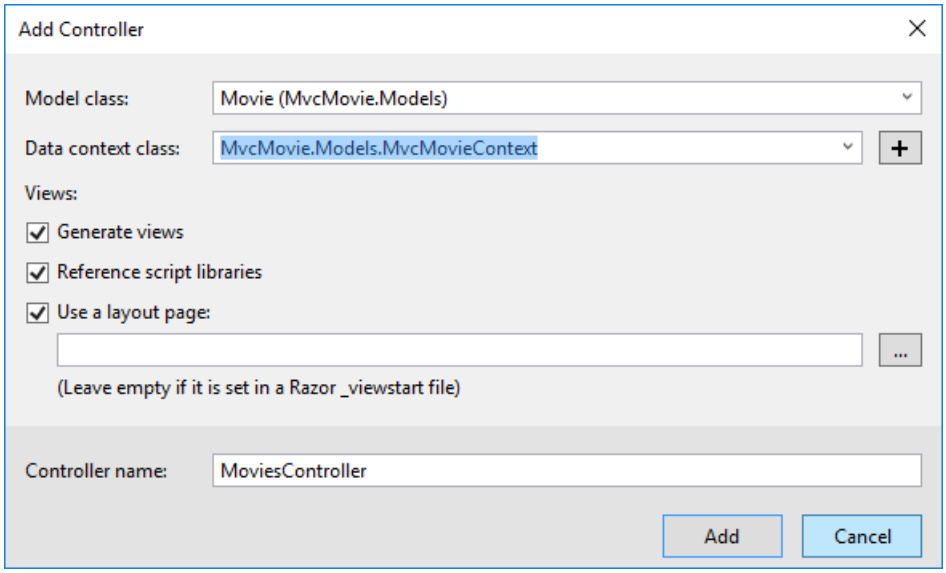


Complete the **Add Controller** dialog:

- **Model class:** *Movie (MvcMovie.Models)*
- **Data context class:** Select the **+** icon and add the default **MvcMovie.Models.MvcMovieContext**



- **Views**: Keep the default of each option checked
- **Controller name**: Keep the default *MoviesController*
- Select **Add**



Visual Studio creates:

- An Entity Framework Core database context class (*Data/MvcMovieContext.cs*)
- A movies controller (*Controllers/MoviesController.cs*)
- Razor view files for Create, Delete, Details, Edit, and Index pages (*Views/Movies/*.cshtml*)

The automatic creation of the database context and CRUD (create, read, update, and delete) action methods and views is known as *scaffolding*.

If you run the app and click on the **Mvc Movie** link, you get an error similar to the following:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
An unhandled exception occurred while processing the request.

SqlException: Cannot open database "MvcMovieContext-<GUID removed>" requested by the login. The login failed.
Login failed for user 'Rick'.

System.Data.SqlClient.SqlInternalConnectionTds..ctor(DbConnectionPoolIdentity identity, SqlConnectionString
```

You need to create the database, and you use the EF Core Migrations feature to do that. Migrations lets you create a database that matches your data model and update the database schema when your data model changes.

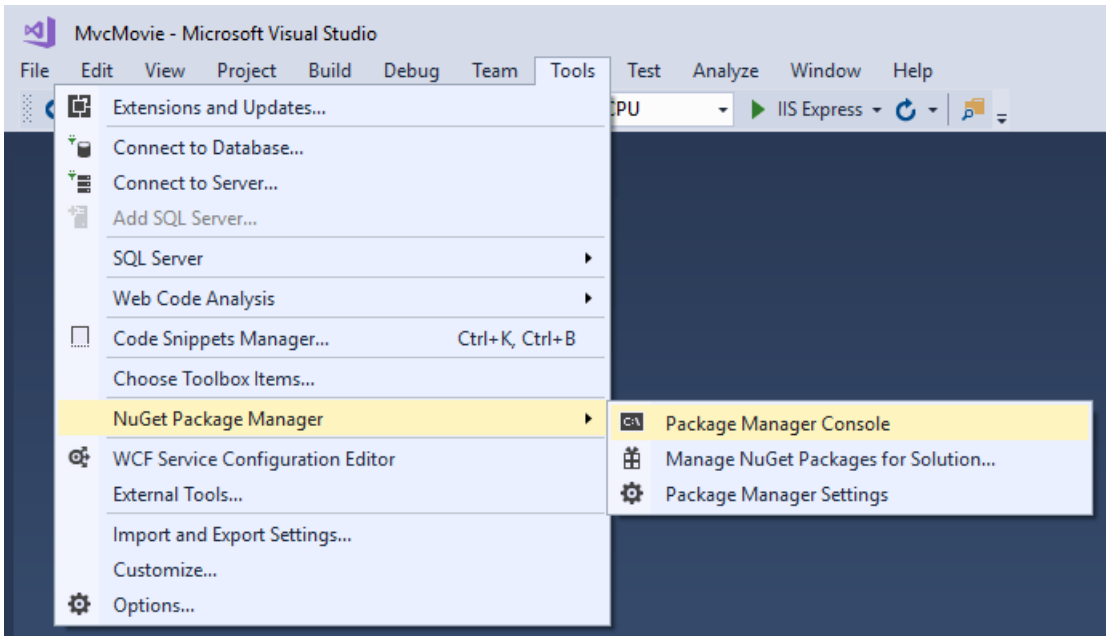
Initial migration

In this section, the following tasks are completed:

- Add an initial migration.
- Update the database with the initial migration.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

1. From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console** (PMC).



2. In the PMC, enter the following commands:

```
Add-Migration Initial
Update-Database
```

   The `Add-Migration` command generates code to create the initial database schema.

   The database schema is based on the model specified in the `MvcMovieContext` class. The `Initial` argument is the migration name. Any name can be used, but by convention, a name that describes the migration is used. For more information, see Tutorial: Using the migrations feature - ASP.NET MVC with EF Core.

   The `Update-Database` command runs the `Up` method in the *Migrations/{time-stamp}_InitialCreate.cs* file, which creates the database.

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection (DI). Services (such as the EF Core DB context) are registered with DI during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a DB context instance is shown later in the tutorial.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

The scaffolding tool automatically created a DB context and registered it with the DI container.

Examine the following `Startup.ConfigureServices` method. The highlighted line was added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for non-essential cookies
        // is needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddDbContext<MvcMovieContext>(options =>
         options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The `MvcMovieContext` coordinates EF Core functionality (Create, Read, Update, Delete, etc.) for the `Movie` model. The data context (`MvcMovieContext`) is derived from Microsoft.EntityFrameworkCore.DbContext. The data context specifies which entities are included in the data model:

```
// Unused usings removed.
using Microsoft.EntityFrameworkCore;
using MvcMovie.Models;  // Enables public DbSet<Movie> Movie

namespace MvcMovie.Data
{
    public class MvcMovieContext : DbContext
    {
        public MvcMovieContext (DbContextOptions<MvcMovieContext> options)
            : base(options)
        {
        }

        public DbSet<Movie> Movie { get; set; }
    }
}
```

The preceding code creates a DbSet<Movie> property for the entity set. In Entity Framework terminology, an entity set typically corresponds to a database table. An entity corresponds to a row in the table.

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Test the app

- Run the app and append `/Movies` to the URL in the browser (`http://localhost:port/movies`).

If you get a database exception similar to the following:

```
SqlException: Cannot open database "MvcMovieContext-GUID" requested by the login. The login failed.
Login failed for user 'User-name'.
```

You missed the migrations step.

- Test the **Create** link. Enter and submit data.

> **NOTE**
> You may not be able to enter decimal commas in the `Price` field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point and for non US-English date formats, the app must be globalized. For globalization instructions, see this GitHub issue.

- Test the **Edit**, **Details**, and **Delete** links.

Examine the `Startup` class:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for non-essential cookies
        // is needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddDbContext<MvcMovieContext>(options =>
         options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The preceding highlighted code shows the movie database context being added to the Dependency Injection container:

- `services.AddDbContext<MvcMovieContext>(options =>` specifies the database to use and the connection string.
- `=>` is a lambda operator

Open the *Controllers/MoviesController.cs* file and examine the constructor:

```
public class MoviesController : Controller
{
    private readonly MvcMovieContext _context;

    public MoviesController(MvcMovieContext context)
    {
        _context = context;
    }
```

The constructor uses Dependency Injection to inject the database context (`MvcMovieContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

Strongly typed models and the @model keyword

Earlier in this tutorial, you saw how a controller can pass data or objects to a view using the `ViewData` dictionary. The `ViewData` dictionary is a dynamic object that provides a convenient late-bound way to pass information to a view.

MVC also provides the ability to pass strongly typed model objects to a view. This strongly typed approach enables better compile time checking of your code. The scaffolding mechanism used this approach (that is, passing a strongly typed model) with the `MoviesController` class and views when it created the methods and views.

Examine the generated `Details` method in the *Controllers/MoviesController.cs* file:

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}
```

The `id` parameter is generally passed as route data. For example `https://localhost:5001/movies/details/1` sets:

- The controller to the `movies` controller (the first URL segment).
- The action to `details` (the second URL segment).
- The id to 1 (the last URL segment).

You can also pass in the `id` with a query string as follows:

`https://localhost:5001/movies/details?id=1`

The `id` parameter is defined as a nullable type (`int?`) in case an ID value isn't provided.

A lambda expression is passed in to `FirstOrDefaultAsync` to select movie entities that match the route data or query string value.

```
var movie = await _context.Movie
    .FirstOrDefaultAsync(m => m.Id == id);
```

If a movie is found, an instance of the `Movie` model is passed to the `Details` view:

```
return View(movie);
```

Examine the contents of the *Views/Movies/Details.cshtml* file:

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Movie</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.ReleaseDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.ReleaseDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Genre)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Genre)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Price)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Price)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.Id">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

By including a `@model` statement at the top of the view file, you can specify the type of object that the view expects. When you created the movie controller, the following `@model` statement was automatically included at the top of the *Details.cshtml* file:

```
@model MvcMovie.Models.Movie
```

This `@model` directive allows you to access the movie that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Details.cshtml* view, the code passes each movie field to the `DisplayNameFor` and `DisplayFor` HTML Helpers with the strongly typed `Model` object. The `Create` and `Edit` methods and views also pass a `Movie` model object.

Examine the *Index.cshtml* view and the `Index` method in the Movies controller. Notice how the code creates a `List` object when it calls the `View` method. The code passes this `Movies` list from the `Index` action method to the view:

```
// GET: Movies
public async Task<IActionResult> Index()
{
    return View(await _context.Movie.ToListAsync());
}
```

When you created the movies controller, scaffolding automatically included the following `@model` statement at the top of the *Index.cshtml* file:

```
@model IEnumerable<MvcMovie.Models.Movie>
```

The `@model` directive allows you to access the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Index.cshtml* view, the code loops through the movies with a `foreach` statement over the strongly typed `Model` object:

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.ReleaseDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Genre)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Price)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.Id">Details</a> |
                <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Because the `Model` object is strongly typed (as an `IEnumerable<Movie>` object), each item in the loop is typed as `Movie`. Among other benefits, this means that you get compile time checking of the code:

PREVIOUS ADDING A VIEW

NEXT WORKING WITH A DATABASE

Part 5, work with a database in an ASP.NET Core MVC app

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

The `MvcMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to database records. The database context is registered with the Dependency Injection container in the `ConfigureServices` method in the *Startup.cs* file:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllersWithViews();

    services.AddDbContext<MvcMovieContext>(options =>
            options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The ASP.NET Core Configuration system reads the `ConnectionString`. For local development, it gets the connection string from the *appsettings.json* file:

```
"ConnectionStrings": {
  "MvcMovieContext": "Server=(localdb)\\mssqllocaldb;Database=MvcMovieContext-
2;Trusted_Connection=True;MultipleActiveResultSets=true"
}
```

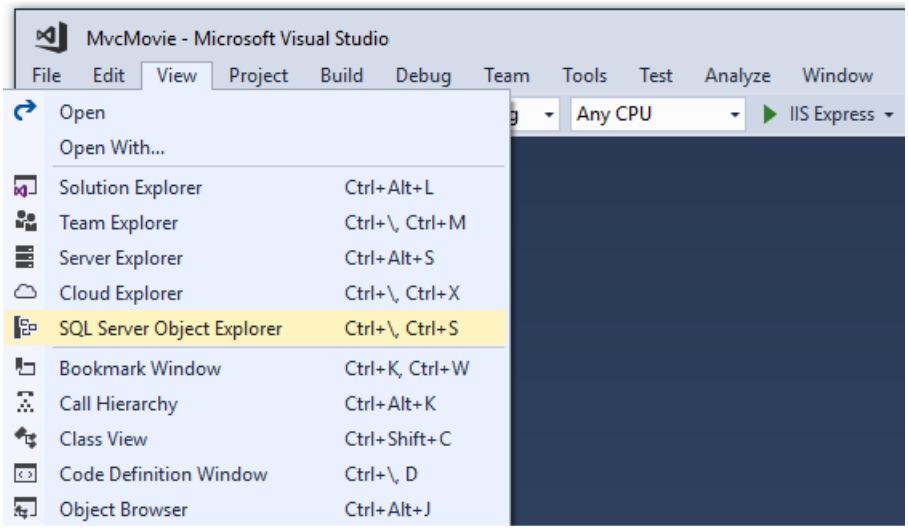
When the app is deployed to a test or production server, an environment variable can be used to set the connection string to a production SQL Server. See Configuration for more information.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

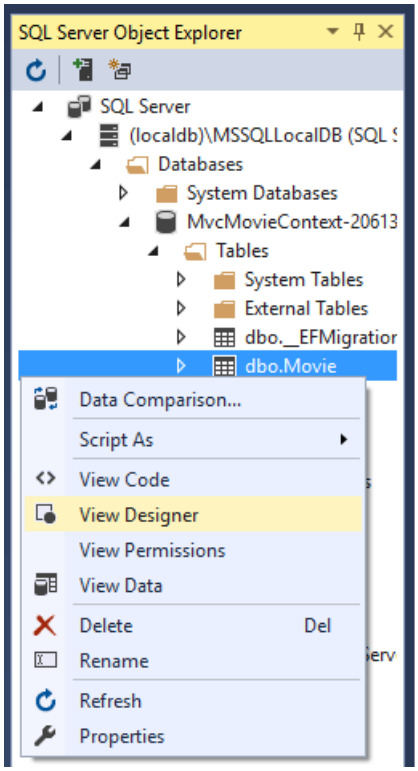
SQL Server Express LocalDB

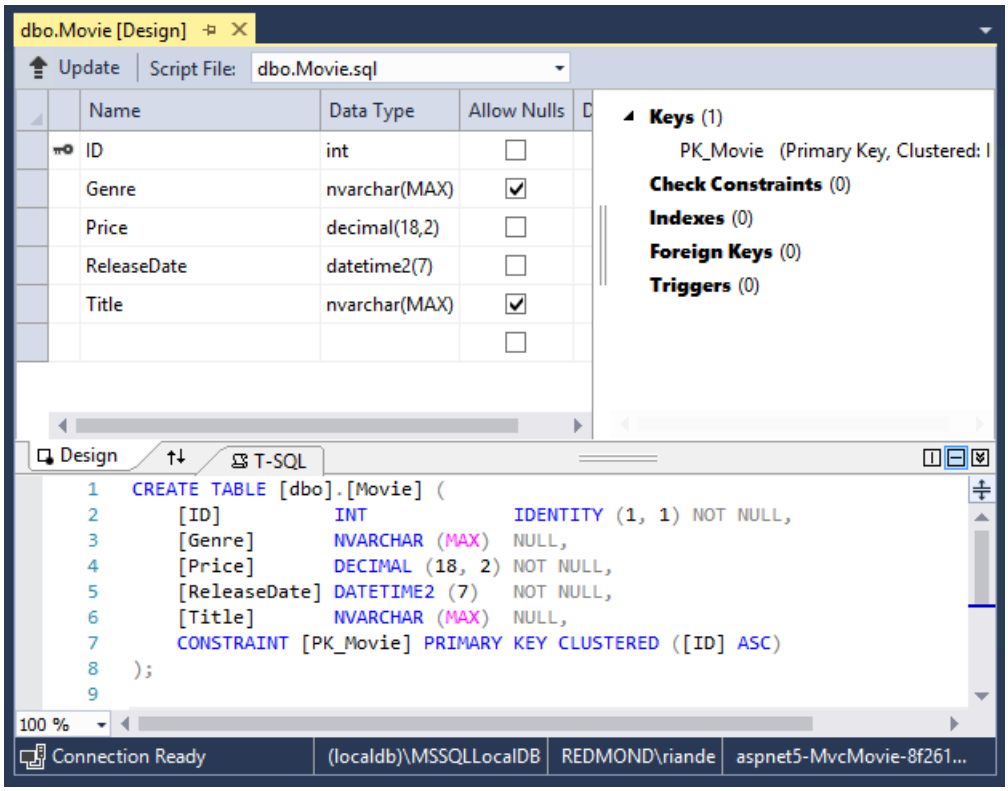
LocalDB is a lightweight version of the SQL Server Express Database Engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates *.mdf* files in the *C:/Users/{user}* directory.

- From the **View** menu, open **SQL Server Object Explorer** (SSOX).



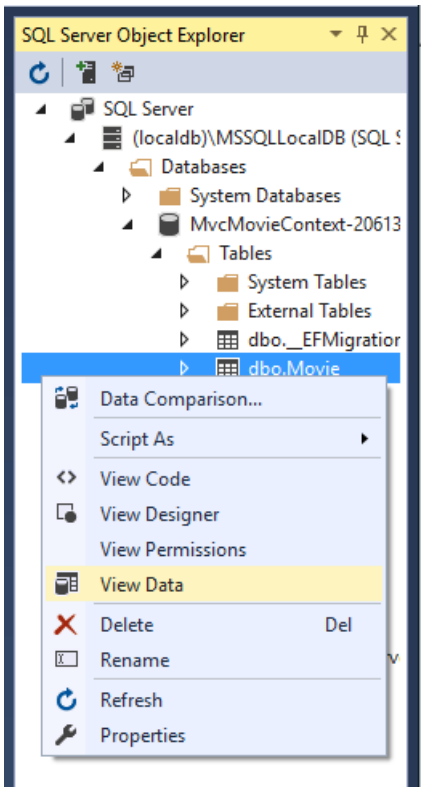
- Right click on the `Movie` table > **View Designer**

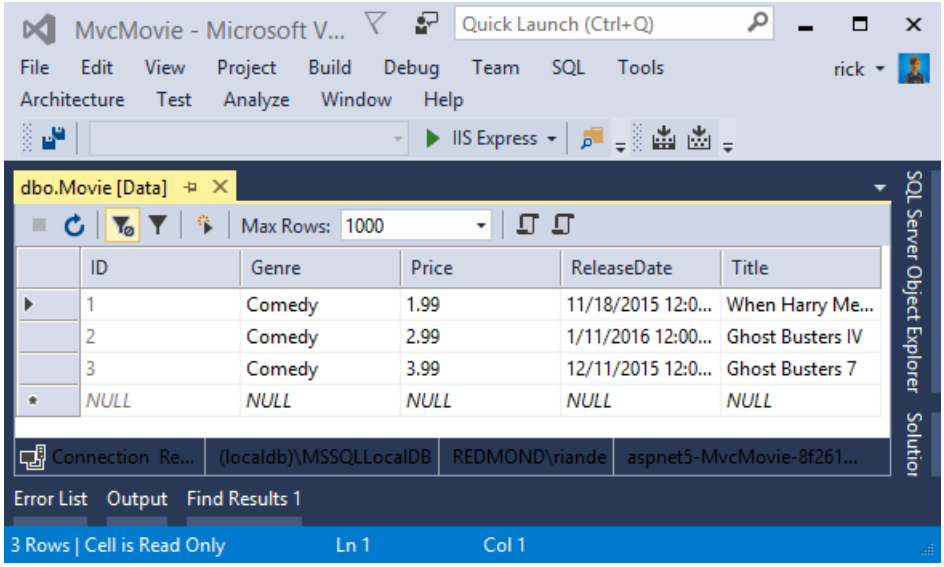




Note the key icon next to `ID`. By default, EF will make a property named `ID` the primary key.

- Right click on the `Movie` table > **View Data**





Seed the database

Create a new class named `SeedData` in the *Models* folder. Replace the generated code with the following:

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using MvcMovie.Data;
using System;
using System.Linq;

namespace MvcMovie.Models
{
    public static class SeedData
    {
        public static void Initialize(IServiceProvider serviceProvider)
        {
            using (var context = new MvcMovieContext(
                serviceProvider.GetRequiredService<
                    DbContextOptions<MvcMovieContext>>()))
            {
                // Look for any movies.
                if (context.Movie.Any())
                {
                    return;   // DB has been seeded
                }

                context.Movie.AddRange(
                    new Movie
                    {
                        Title = "When Harry Met Sally",
                        ReleaseDate = DateTime.Parse("1989-2-12"),
                        Genre = "Romantic Comedy",
                        Price = 7.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters ",
                        ReleaseDate = DateTime.Parse("1984-3-13"),
                        Genre = "Comedy",
                        Price = 8.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters 2",
                        ReleaseDate = DateTime.Parse("1986-2-23"),
                        Genre = "Comedy",
                        Price = 9.99M
                    },

                    new Movie
                    {
                        Title = "Rio Bravo",
                        ReleaseDate = DateTime.Parse("1959-4-15"),
                        Genre = "Western",
                        Price = 3.99M
                    }
                );
                context.SaveChanges();
            }
        }
    }
}
```

If there are any movies in the DB, the seed initializer returns and no movies are added.

```
if (context.Movie.Any())
{
    return;   // DB has been seeded.
}
```

Add the seed initializer

Replace the contents of *Program.cs* with the following code:

```
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using MvcMovie.Data;
using MvcMovie.Models;
using System;

namespace MvcMovie
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    SeedData.Initialize(services);
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred seeding the DB.");
                }
            }

            host.Run();

        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

Test the app

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Delete all the records in the DB. You can do this with the delete links in the browser or from SSOX.
- Force the app to initialize (call the methods in the `Startup` class) so the seed method runs. To force initialization, IIS Express must be stopped and restarted. You can do this with any of the following approaches:

- Right click the IIS Express system tray icon in the notification area and tap **Exit** or **Stop Site**

  - If you were running VS in non-debug mode, press F5 to run in debug mode
  - If you were running VS in debug mode, stop the debugger and press F5

The app shows the seeded data.

The `MvcMovieContext` object handles the task of connecting to the database and mapping `Movie` objects to

database records. The database context is registered with the Dependency Injection container in the `ConfigureServices` method in the *Startup.cs* file:

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for non-essential cookies
        // is needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddDbContext<MvcMovieContext>(options =>
         options.UseSqlServer(Configuration.GetConnectionString("MvcMovieContext")));
}
```

The ASP.NET Core Configuration system reads the `ConnectionString`. For local development, it gets the connection string from the *appsettings.json* file:

```
"ConnectionStrings": {
  "MvcMovieContext": "Server=(localdb)\\mssqllocaldb;Database=MvcMovieContext-
2;Trusted_Connection=True;MultipleActiveResultSets=true"
}
```

When you deploy the app to a test or production server, you can use an environment variable or another approach to set the connection string to a real SQL Server. See Configuration for more information.

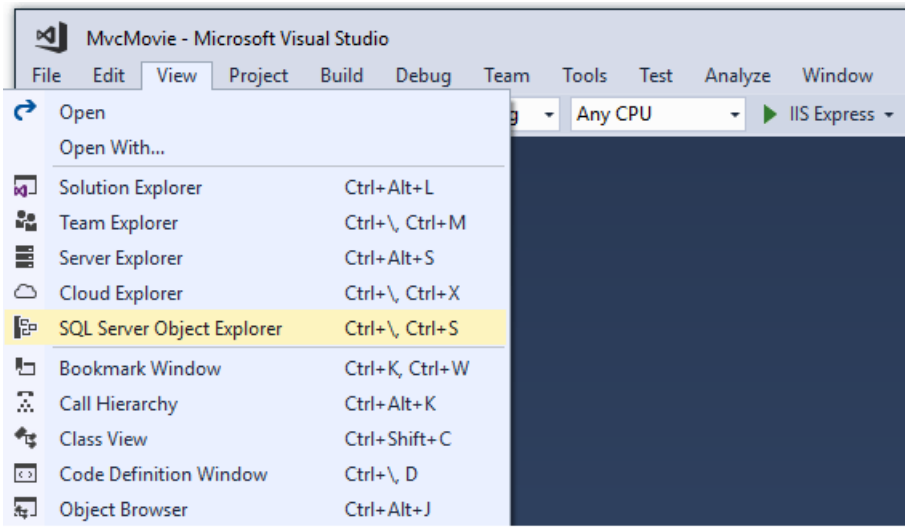
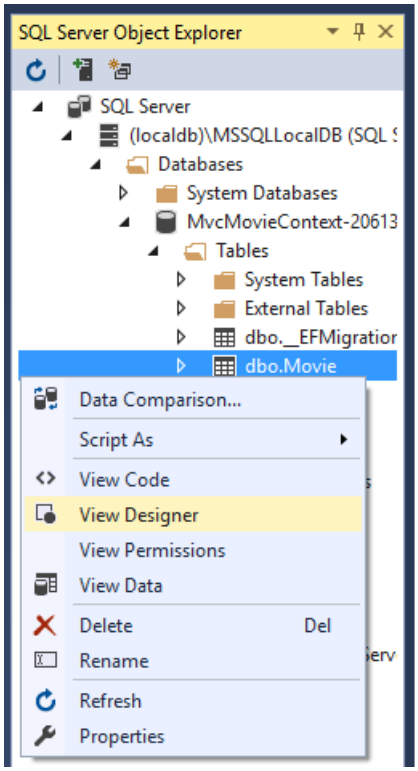
SQL Server Express LocalDB

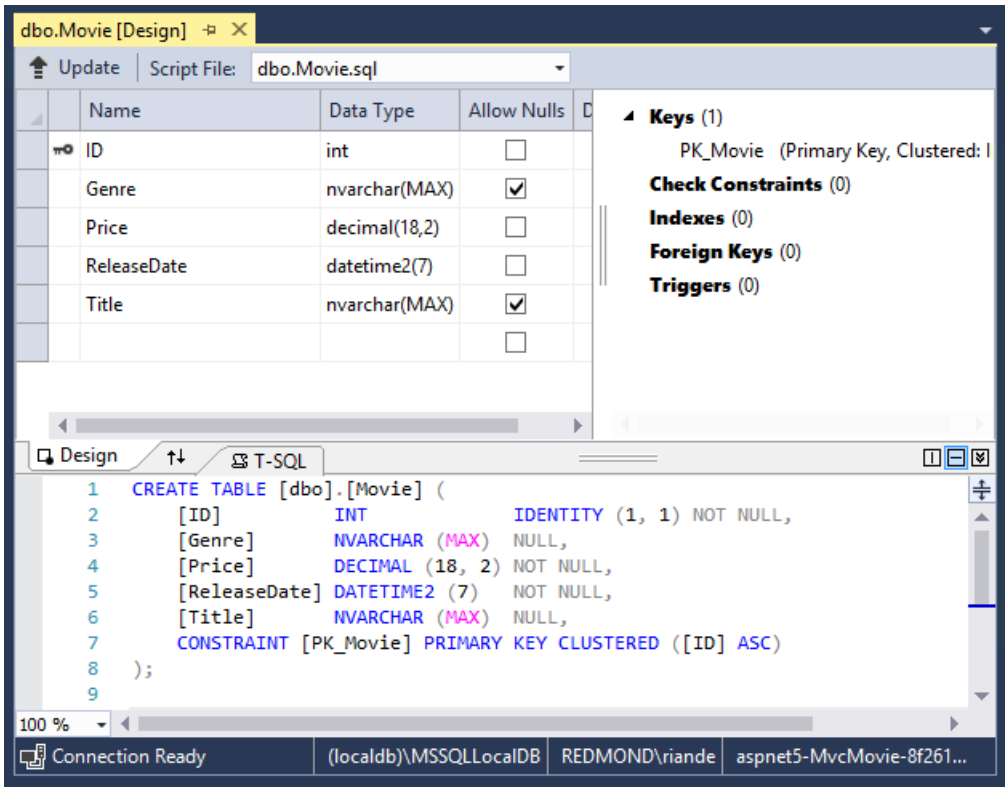
LocalDB is a lightweight version of the SQL Server Express Database Engine that's targeted for program development. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB database creates *.mdf* files in the *C:/Users/{user}* directory.

- From the **View** menu, open **SQL Server Object Explorer** (SSOX).



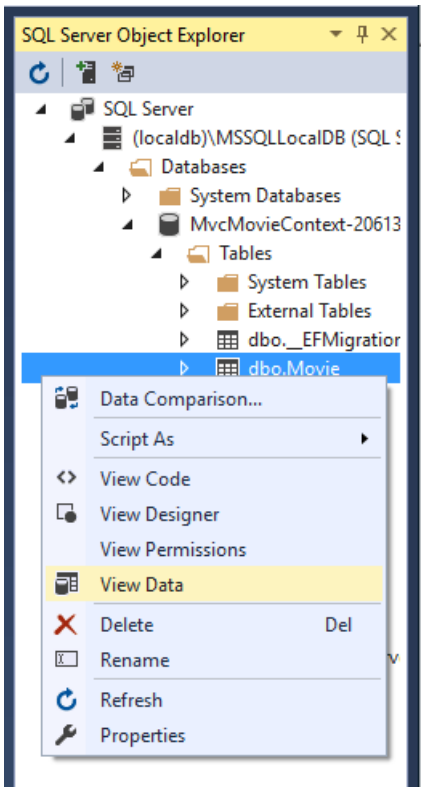
- Right click on the `Movie` table > **View Designer**

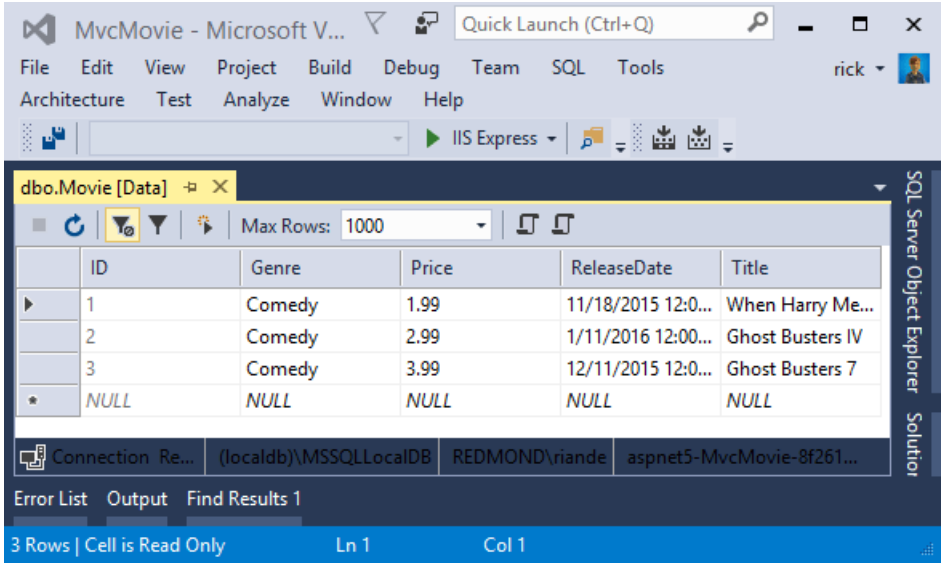




Note the key icon next to `ID`. By default, EF will make a property named `ID` the primary key.

- Right click on the `Movie` table > **View Data**





Seed the database

Create a new class named `SeedData` in the *Models* folder. Replace the generated code with the following:

```
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using System;
using System.Linq;

namespace MvcMovie.Models
{
    public static class SeedData
    {
        public static void Initialize(IServiceProvider serviceProvider)
        {
            using (var context = new MvcMovieContext(
                serviceProvider.GetRequiredService<
                    DbContextOptions<MvcMovieContext>>()))
            {
                // Look for any movies.
                if (context.Movie.Any())
                {
                    return;   // DB has been seeded
                }

                context.Movie.AddRange(
                    new Movie
                    {
                        Title = "When Harry Met Sally",
                        ReleaseDate = DateTime.Parse("1989-2-12"),
                        Genre = "Romantic Comedy",
                        Price = 7.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters ",
                        ReleaseDate = DateTime.Parse("1984-3-13"),
                        Genre = "Comedy",
                        Price = 8.99M
                    },

                    new Movie
                    {
                        Title = "Ghostbusters 2",
                        ReleaseDate = DateTime.Parse("1986-2-23"),
                        Genre = "Comedy",
                        Price = 9.99M
                    },

                    new Movie
                    {
                        Title = "Rio Bravo",
                        ReleaseDate = DateTime.Parse("1959-4-15"),
                        Genre = "Western",
                        Price = 3.99M
                    }
                );
                context.SaveChanges();
            }
        }
    }
}
```

If there are any movies in the DB, the seed initializer returns and no movies are added.

```
if (context.Movie.Any())
{
    return;   // DB has been seeded.
}
```

Add the seed initializer

Replace the contents of *Program.cs* with the following code:

```
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Logging;
using System;
using Microsoft.EntityFrameworkCore;
using MvcMovie.Models;
using MvcMovie;

namespace MvcMovie
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateWebHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context = services.GetRequiredService<MvcMovieContext>();
                    context.Database.Migrate();
                    SeedData.Initialize(services);
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred seeding the DB.");
                }
            }

            host.Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();
    }
}
```

Test the app

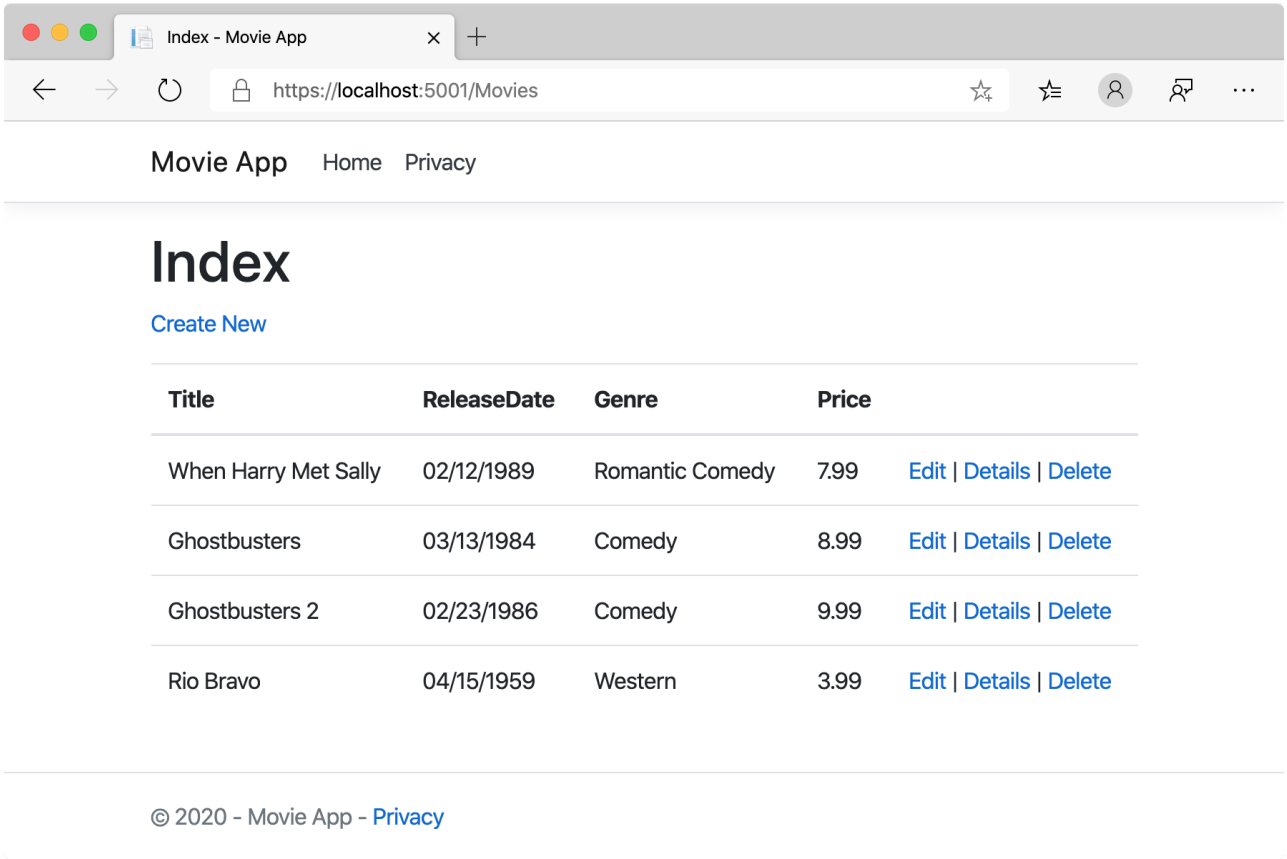
- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Delete all the records in the DB. You can do this with the delete links in the browser or from SSOX.
- Force the app to initialize (call the methods in the `Startup` class) so the seed method runs. To force initialization, IIS Express must be stopped and restarted. You can do this with any of the following approaches:

- Right click the IIS Express system tray icon in the notification area and tap **Exit** or **Stop Site**

  - If you were running VS in non-debug mode, press F5 to run in debug mode
  - If you were running VS in debug mode, stop the debugger and press F5

The app shows the seeded data.

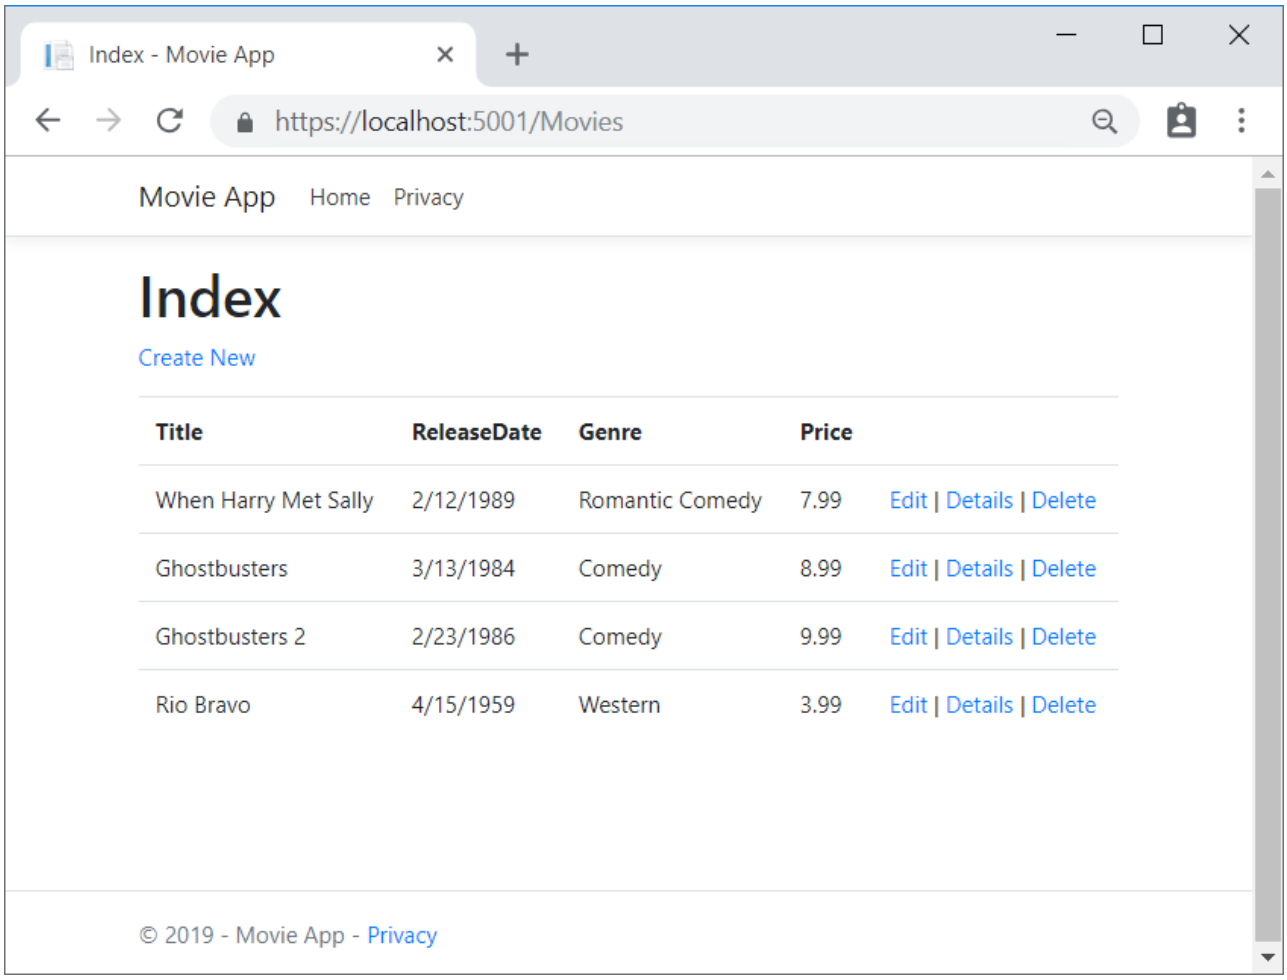


Part 6, controller methods and views in ASP.NET Core

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

We have a good start to the movie app, but the presentation isn't ideal, for example, **ReleaseDate** should be two words.



Open the *Models/Movie.cs* file and add the highlighted lines shown below:

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int Id { get; set; }
        public string Title { get; set; }

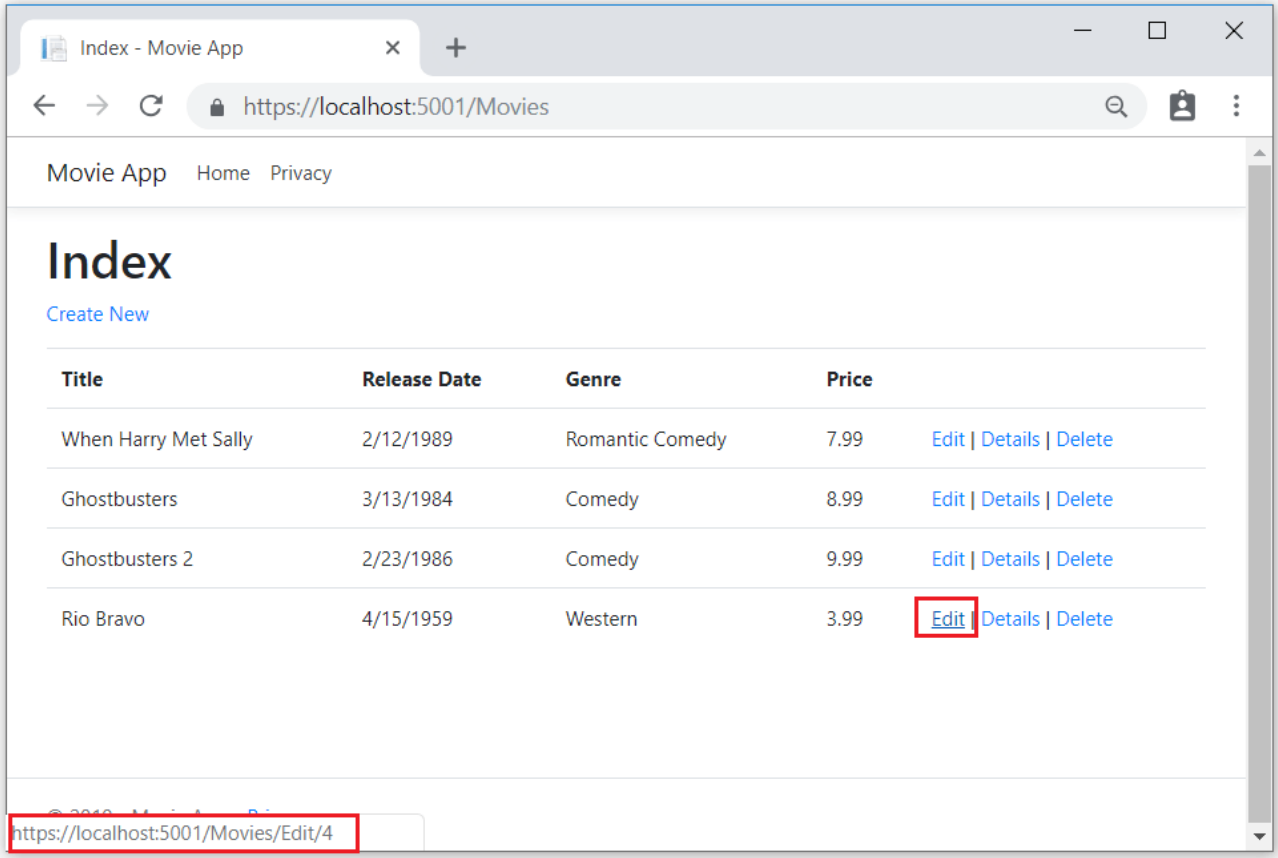
        [Display(Name = "Release Date")]
        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }

        [Column(TypeName = "decimal(18, 2)")]
        public decimal Price { get; set; }
    }
}
```

We cover DataAnnotations in the next tutorial. The Display attribute specifies what to display for the name of a field (in this case "Release Date" instead of "ReleaseDate"). The DataType attribute specifies the type of the data (Date), so the time information stored in the field isn't displayed.

The `[Column(TypeName = "decimal(18, 2)")]` data annotation is required so Entity Framework Core can correctly map `Price` to currency in the database. For more information, see Data Types.

Browse to the `Movies` controller and hold the mouse pointer over an **Edit** link to see the target URL.



The **Edit**, **Details**, and **Delete** links are generated by the Core MVC Anchor Tag Helper in the *Views/Movies/Index.cshtml* file.

```
        <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
        <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
        <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
    </td>
</tr>
```

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. In the code above, the `AnchorTagHelper` dynamically generates the HTML `href` attribute value from the controller action method and route id. You use **View Source** from your favorite browser or use the developer tools to examine the generated markup. A portion of the generated HTML is shown below:

```
 <td>
    <a href="/Movies/Edit/4"> Edit </a> |
    <a href="/Movies/Details/4"> Details </a> |
    <a href="/Movies/Delete/4"> Delete </a>
</td>
```

Recall the format for routing set in the *Startup.cs* file:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

ASP.NET Core translates `https://localhost:5001/Movies/Edit/4` into a request to the `Edit` action method of the `Movies` controller with the parameter `Id` of 4. (Controller methods are also known as action methods.)

Tag Helpers are one of the most popular new features in ASP.NET Core. For more information, see Additional resources.

Open the `Movies` controller and examine the two `Edit` action methods. The following code shows the `HTTP GET Edit` method, which fetches the movie and populates the edit form generated by the *Edit.cshtml* Razor file.

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FindAsync(id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

The following code shows the `HTTP POST Edit` method, which processes the posted movie values:

```
// POST: Movies/Edit/5
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.SingleOrDefaultAsync(m => m.ID == id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

The following code shows the `HTTP POST Edit` method, which processes the posted movie values:

```
// POST: Movies/Edit/5
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The `[Bind]` attribute is one way to protect against over-posting. You should only include properties in the `[Bind]` attribute that you want to change. For more information, see Protect your controller from over-posting. ViewModels provide an alternative approach to prevent over-posting.

Notice the second `Edit` action method is preceded by the `[HttpPost]` attribute.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

```
// POST: Movies/Edit/5
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The `HttpPost` attribute specifies that this `Edit` method can be invoked *only* for `POST` requests. You could apply the `[HttpGet]` attribute to the first edit method, but that's not necessary because `[HttpGet]` is the default.

The `ValidateAntiForgeryToken` attribute is used to prevent forgery of a request and is paired up with an anti-forgery token generated in the edit view file (*Views/Movies/Edit.cshtml*). The edit view file generates the anti-forgery token with the Form Tag Helper.

```
<form asp-action="Edit">
```

The Form Tag Helper generates a hidden anti-forgery token that must match the `[ValidateAntiForgeryToken]` generated anti-forgery token in the `Edit` method of the Movies controller. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

The `HttpGet Edit` method takes the movie `ID` parameter, looks up the movie using the Entity Framework `FindAsync` method, and returns the selected movie to the Edit view. If a movie cannot be found, `NotFound` (HTTP 404) is returned.

```
// GET: Movies/Edit/5
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie.FindAsync(id);
    if (movie == null)
    {
        return NotFound();
    }
    return View(movie);
}
```

When the scaffolding system created the Edit view, it examined the `Movie` class and created code to render `<label>` and `<input>` elements for each property of the class. The following example shows the Edit view that was generated by the Visual Studio scaffolding system:

```
@model MvcMovie.Models.Movie

@{
    ViewData["Title"] = "Edit";
}

<h1>Edit</h1>

<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Edit">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Id" />
            <div class="form-group">
                <label asp-for="Title" class="control-label"></label>
                <input asp-for="Title" class="form-control" />
                <span asp-validation-for="Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="ReleaseDate" class="control-label"></label>
                <input asp-for="ReleaseDate" class="form-control" />
                <span asp-validation-for="ReleaseDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Genre" class="control-label"></label>
                <input asp-for="Genre" class="form-control" />
                <span asp-validation-for="Genre" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Price" class="control-label"></label>
                <input asp-for="Price" class="form-control" />
                <span asp-validation-for="Price" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Notice how the view template has a `@model MvcMovie.Models.Movie` statement at the top of the file. `@model MvcMovie.Models.Movie` specifies that the view expects the model for the view template to be of type `Movie`.

The scaffolded code uses several Tag Helper methods to streamline the HTML markup. The Label Tag Helper displays the name of the field ("Title", "ReleaseDate", "Genre", or "Price"). The Input Tag Helper renders an HTML `<input>` element. The Validation Tag Helper displays any validation messages associated with that property.

Run the application and navigate to the `/Movies` URL. Click an **Edit** link. In the browser, view the source for the page. The generated HTML for the `<form>` element is shown below.

```
<form action="/Movies/Edit/7" method="post">
    <div class="form-horizontal">
        <h4>Movie</h4>
        <hr />
        <div class="text-danger" />
        <input type="hidden" data-val="true" data-val-required="The ID field is required." id="ID" name="ID"
value="7" />
        <div class="form-group">
            <label class="control-label col-md-2" for="Genre" />
            <div class="col-md-10">
                <input class="form-control" type="text" id="Genre" name="Genre" value="Western" />
                <span class="text-danger field-validation-valid" data-valmsg-for="Genre" data-valmsg-
replace="true"></span>
            </div>
        </div>
        <div class="form-group">
            <label class="control-label col-md-2" for="Price" />
            <div class="col-md-10">
                <input class="form-control" type="text" data-val="true" data-val-number="The field Price must
be a number." data-val-required="The Price field is required." id="Price" name="Price" value="3.99" />
                <span class="text-danger field-validation-valid" data-valmsg-for="Price" data-valmsg-
replace="true"></span>
            </div>
        </div>
        <!-- Markup removed for brevity -->
        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </div>
    </div>
    <input name="__RequestVerificationToken" type="hidden"
value="CfDJ8Inyxgp63fRFqUePGvuI5jGZsloJu1L7X9le1gy7NCIlSduCRx9jDQClrV9pOTTmqUyXnJBXhmrjcUVDJyDUMm7-
MF_9rK8aAZdRdlOri7FmKVkRe_2v5LIHGKFcTjPrWPYnc9AdSbomkiOSaTEg7RU" />
</form>
```

The `<input>` elements are in an `HTML <form>` element whose `action` attribute is set to post to the `/Movies/Edit/id` URL. The form data will be posted to the server when the `Save` button is clicked. The last line before the closing `</form>` element shows the hidden XSRF token generated by the Form Tag Helper.

Processing the POST Request

The following listing shows the `[HttpPost]` version of the `Edit` action method.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction(nameof(Index));
    }
    return View(movie);
}
```

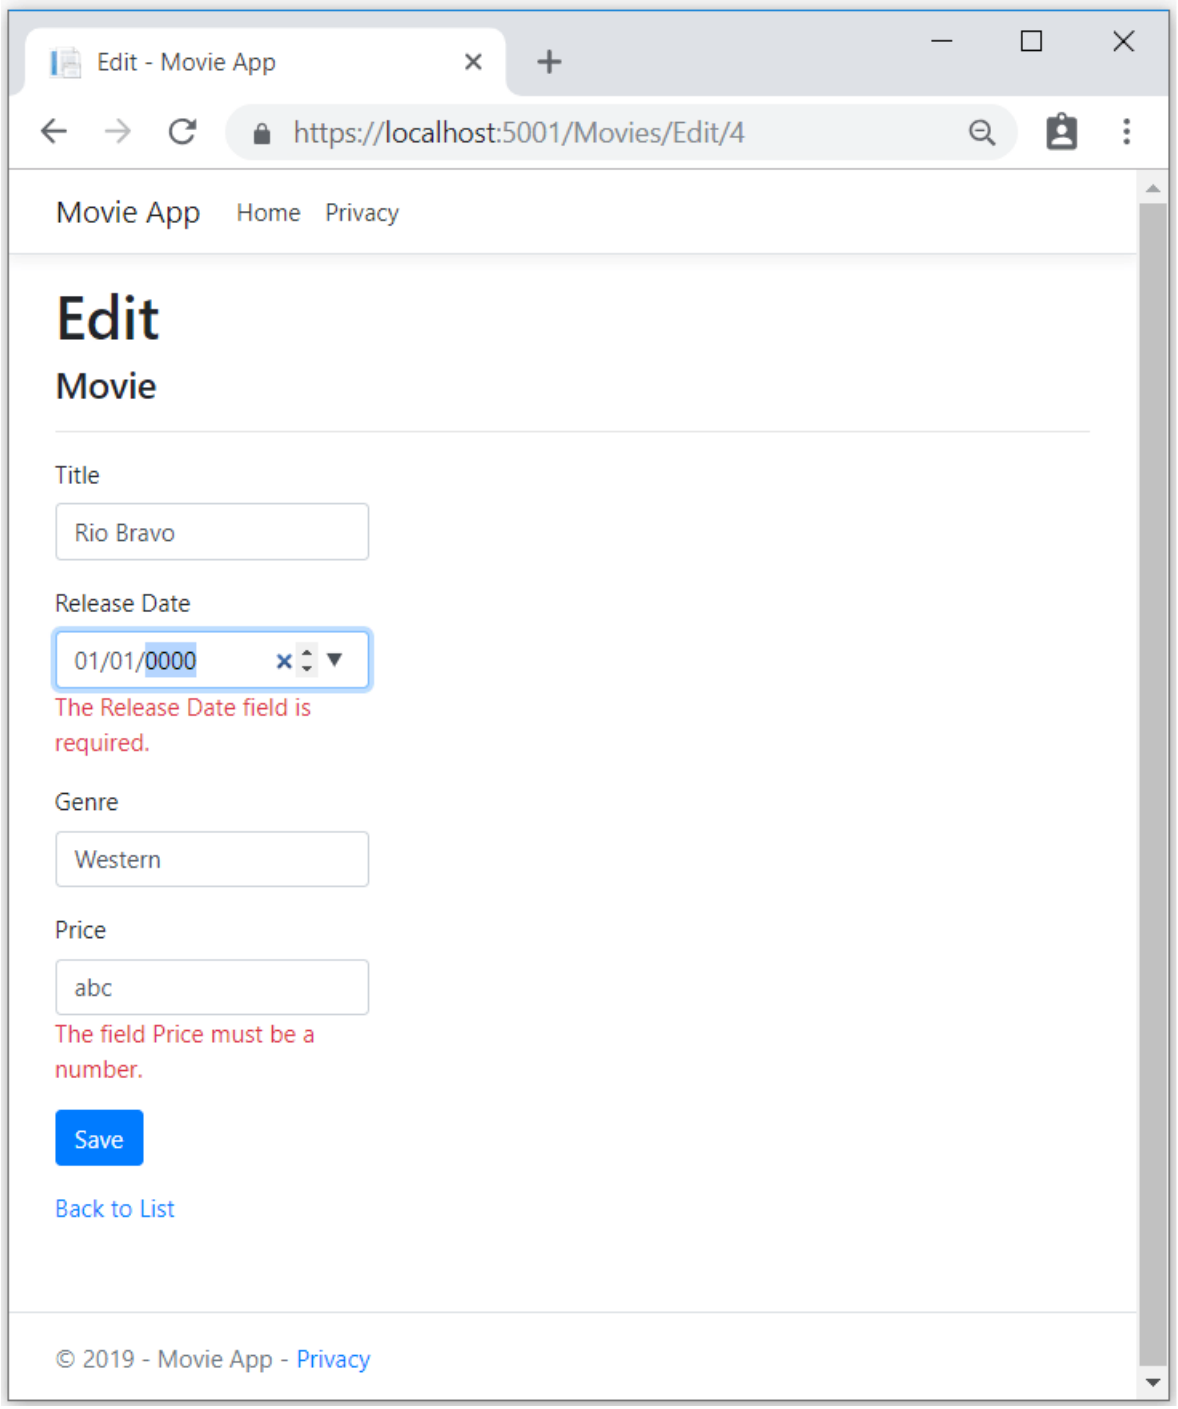
```
// POST: Movies/Edit/5
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see http://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int id, [Bind("ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (id != movie.ID)
    {
        return NotFound();
    }

    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(movie);
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException)
        {
            if (!MovieExists(movie.ID))
            {
                return NotFound();
            }
            else
            {
                throw;
            }
        }
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The `[ValidateAntiForgeryToken]` attribute validates the hidden XSRF token generated by the anti-forgery token generator in the Form Tag Helper

The model binding system takes the posted form values and creates a `Movie` object that's passed as the `movie` parameter. The `ModelState.IsValid` method verifies that the data submitted in the form can be used to modify (edit or update) a `Movie` object. If the data is valid, it's saved. The updated (edited) movie data is saved to the database by calling the `SaveChangesAsync` method of database context. After saving the data, the code redirects the user to the `Index` action method of the `MoviesController` class, which displays the movie collection, including the changes just made.

Before the form is posted to the server, client-side validation checks any validation rules on the fields. If there are any validation errors, an error message is displayed and the form isn't posted. If JavaScript is disabled, you won't have client-side validation but the server will detect the posted values that are not valid, and the form values will be redisplayed with error messages. Later in the tutorial we examine Model Validation in more detail. The Validation Tag Helper in the *Views/Movies/Edit.cshtml* view template takes care of displaying appropriate error messages.



All the `HttpGet` methods in the movie controller follow a similar pattern. They get a movie object (or list of objects, in the case of `Index`), and pass the object (model) to the view. The `Create` method passes an empty movie object to the `Create` view. All the methods that create, edit, delete, or otherwise modify data do so in the `[HttpPost]` overload of the method. Modifying data in an `HTTP GET` method is a security risk. Modifying data in an `HTTP GET` method also violates HTTP best practices and the architectural REST pattern, which specifies that GET requests shouldn't change the state of your application. In other words, performing a GET operation should be a safe operation that has no side effects and doesn't modify your persisted data.

Part 7, add search to an ASP.NET Core MVC app

9/22/2020 • 7 minutes to read • Edit Online

By Rick Anderson

In this section, you add search capability to the `Index` action method that lets you search movies by *genre* or *name*.

Update the `Index` method found inside *Controllers/MoviesController.cs* with the following code:

```
public async Task<IActionResult> Index(string searchString)
{
    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(await movies.ToListAsync());
}
```

The first line of the `Index` action method creates a LINQ query to select the movies:

```
var movies = from m in _context.Movie
             select m;
```

The query is *only* defined at this point, it has **not** been run against the database.

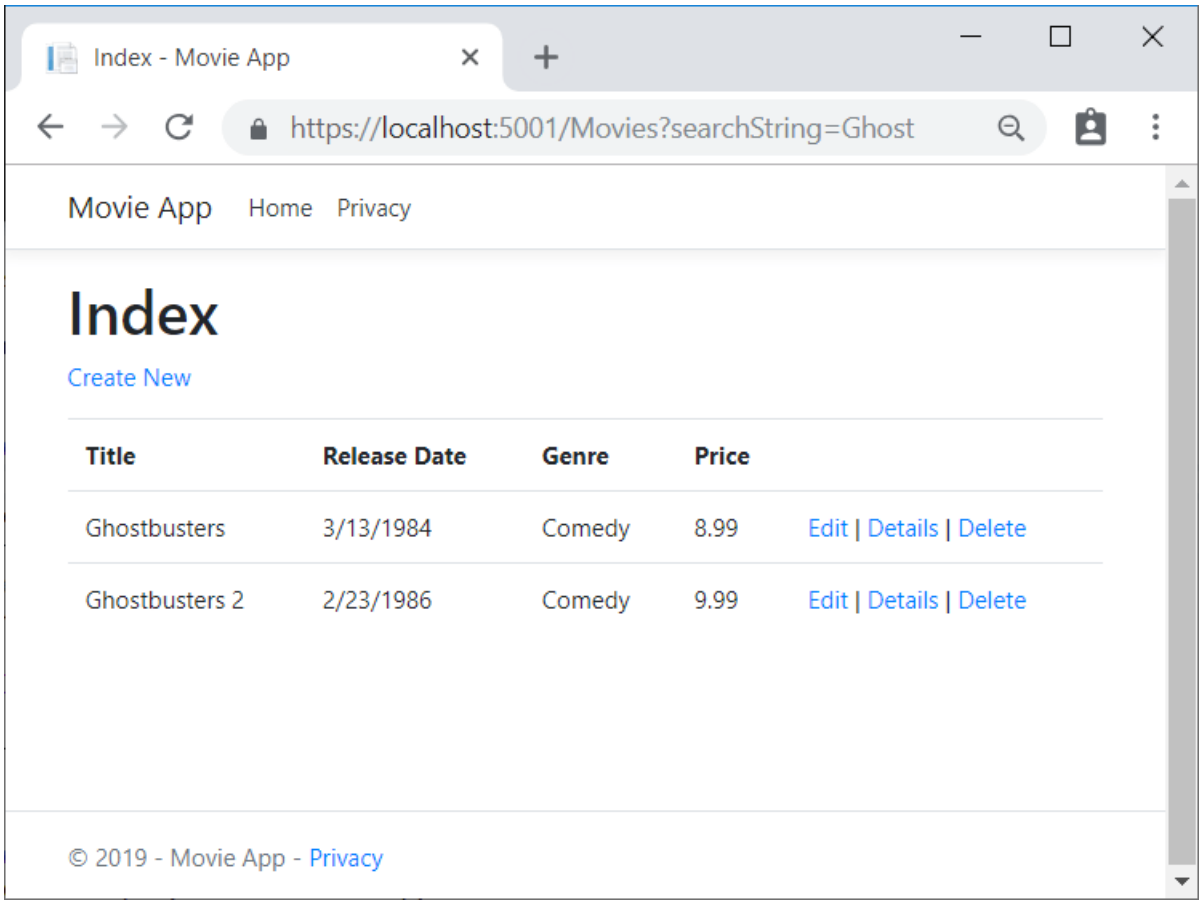
If the `searchString` parameter contains a string, the movies query is modified to filter on the value of the search string:

```
if (!String.IsNullOrEmpty(searchString))
{
    movies = movies.Where(s => s.Title.Contains(searchString));
}
```

The `s => s.Title.Contains()` code above is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method or `Contains` (used in the code above). LINQ queries are not executed when they're defined or when they're modified by calling a method such as `Where`, `Contains`, or `OrderBy`. Rather, query execution is deferred. That means that the evaluation of an expression is delayed until its realized value is actually iterated over or the `ToListAsync` method is called. For more information about deferred query execution, see Query Execution.

Note: The Contains method is run on the database, not in the c# code shown above. The case sensitivity on the query depends on the database and the collation. On SQL Server, Contains maps to SQL LIKE, which is case insensitive. In SQLite, with the default collation, it's case sensitive.

Navigate to `/Movies/Index`. Append a query string such as `?searchString=Ghost` to the URL. The filtered movies are displayed.



If you change the signature of the `Index` method to have a parameter named `id`, the `id` parameter will match the optional `{id}` placeholder for the default routes set in *Startup.cs*.

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

Change the parameter to `id` and all occurrences of `searchString` change to `id`.

The previous `Index` method:

```
public async Task<IActionResult> Index(string searchString)
{
    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(await movies.ToListAsync());
}
```

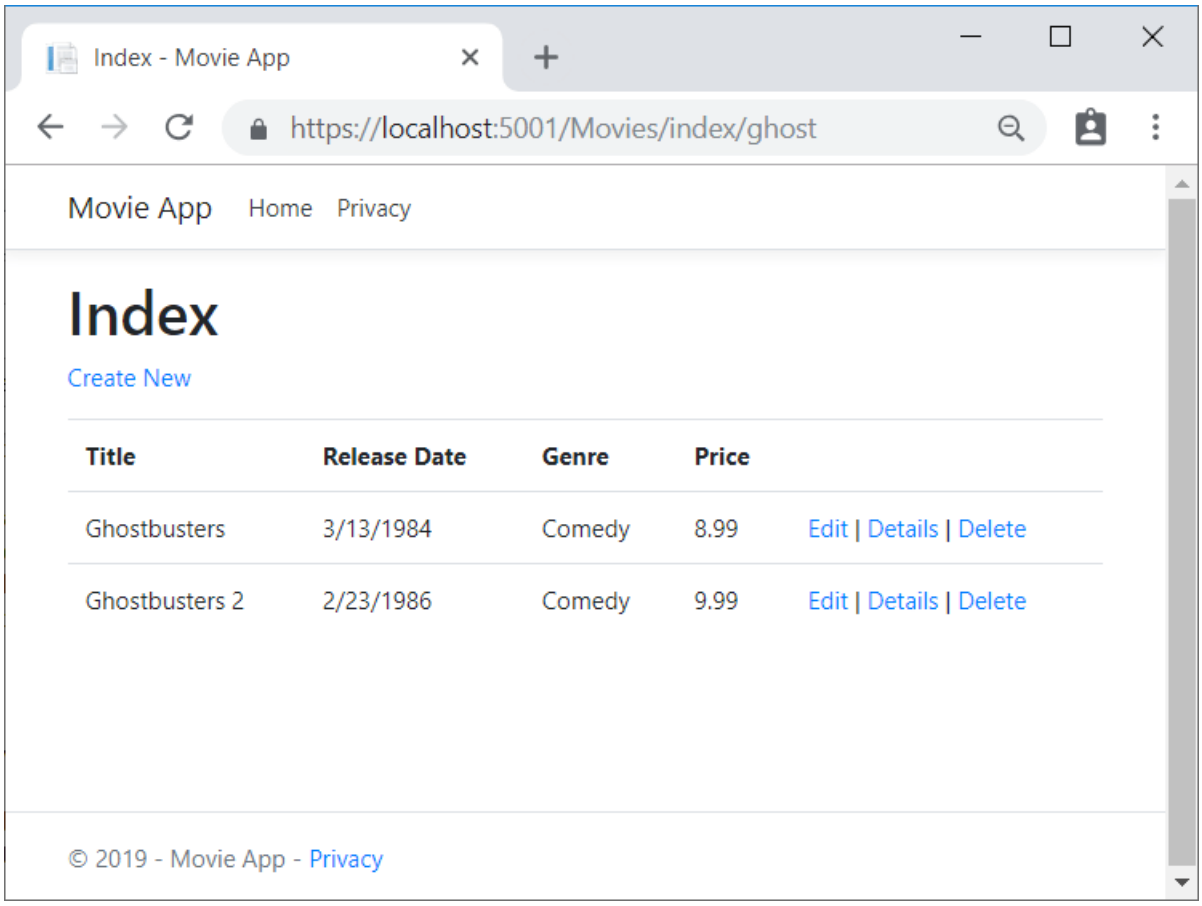
The updated `Index` method with `id` parameter:

```
public async Task<IActionResult> Index(string id)
{
    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(id))
    {
        movies = movies.Where(s => s.Title.Contains(id));
    }

    return View(await movies.ToListAsync());
}
```

You can now pass the search title as route data (a URL segment) instead of as a query string value.



However, you can't expect users to modify the URL every time they want to search for a movie. So now you'll add UI elements to help them filter movies. If you changed the signature of the `Index` method to test how to pass the route-bound `ID` parameter, change it back so that it takes a parameter named `searchString`:

```
public async Task<IActionResult> Index(string searchString)
{
    var movies = from m in _context.Movie
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(await movies.ToListAsync());
}
```

Open the *Views/Movies/Index.cshtml* file, and add the `<form>` markup highlighted below:

```
    ViewData["Title"] = "Index";
}

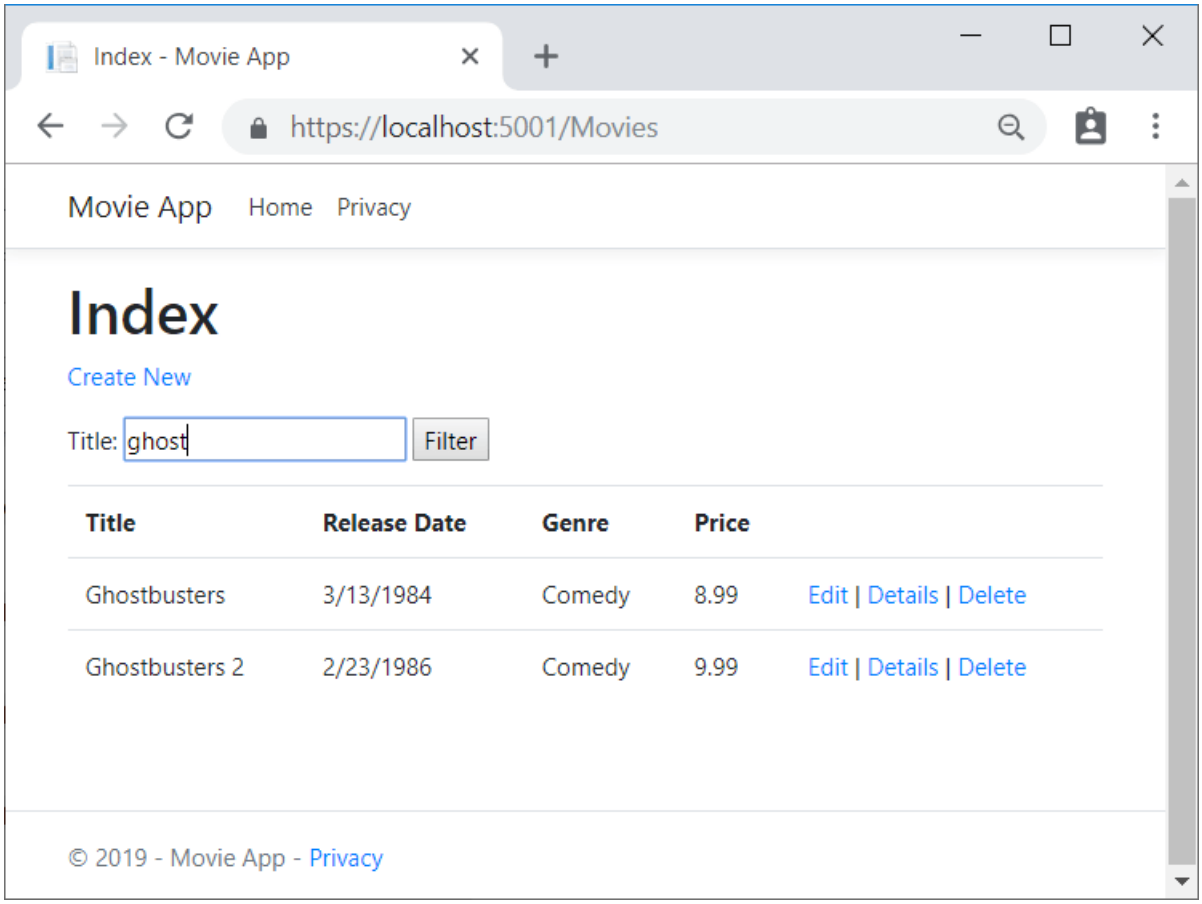
<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-controller="Movies" asp-action="Index">
    <p>
        Title: <input type="text" name="SearchString">
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    <thead>
```

The HTML `<form>` tag uses the Form Tag Helper, so when you submit the form, the filter string is posted to the `Index` action of the movies controller. Save your changes and then test the filter.



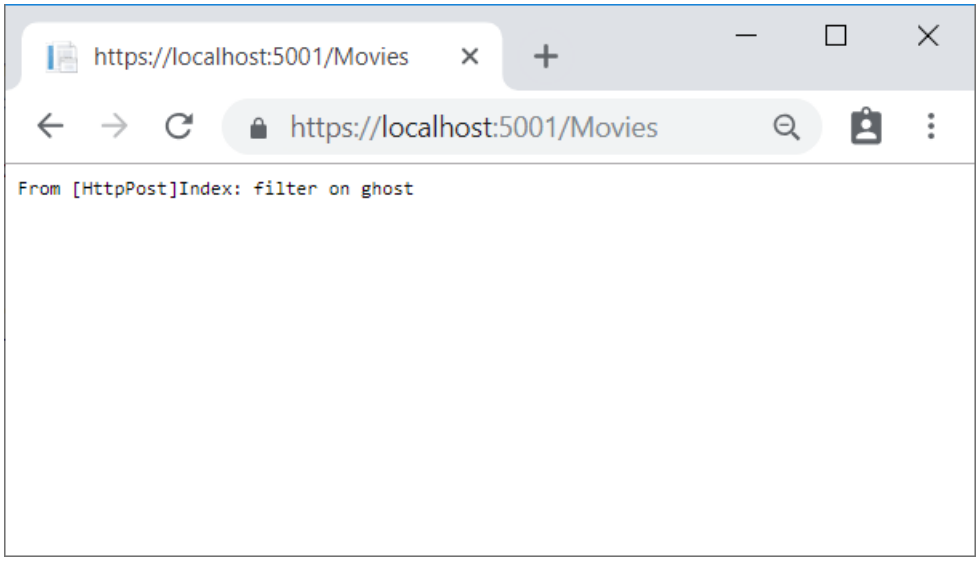
There's no `[HttpPost]` overload of the `Index` method as you might expect. You don't need it, because the method isn't changing the state of the app, just filtering data.

You could add the following `[HttpPost] Index` method.

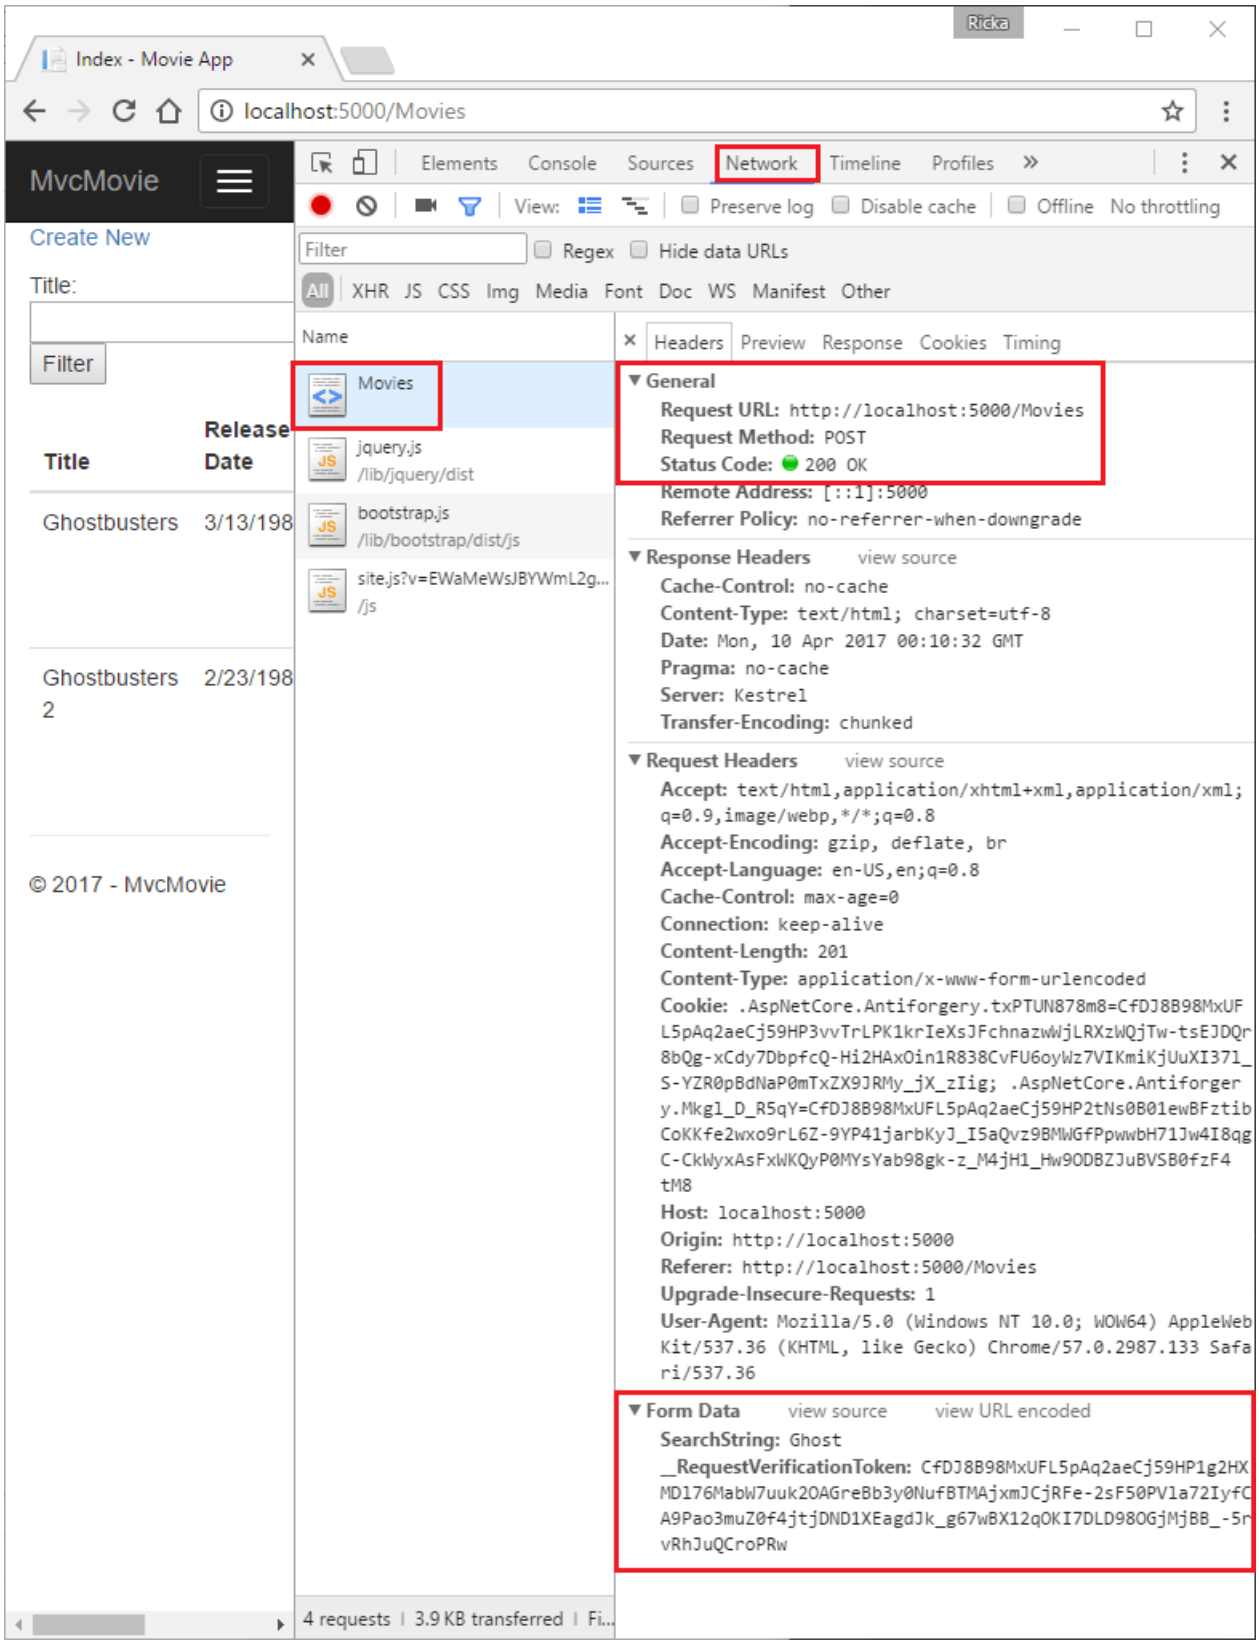
```
[HttpPost]
public string Index(string searchString, bool notUsed)
{
    return "From [HttpPost]Index: filter on " + searchString;
}
```

The `notUsed` parameter is used to create an overload for the `Index` method. We'll talk about that later in the tutorial.

If you add this method, the action invoker would match the `[HttpPost] Index` method, and the `[HttpPost] Index` method would run as shown in the image below.



However, even if you add this `[HttpPost]` version of the `Index` method, there's a limitation in how this has all been implemented. Imagine that you want to bookmark a particular search or you want to send a link to friends that they can click in order to see the same filtered list of movies. Notice that the URL for the HTTP POST request is the same as the URL for the GET request (localhost:{PORT}/Movies/Index) -- there's no search information in the URL. The search string information is sent to the server as a form field value. You can verify that with the browser Developer tools or the excellent Fiddler tool. The image below shows the Chrome browser Developer tools:



You can see the search parameter and XSRF token in the request body. Note, as mentioned in the previous tutorial, the Form Tag Helper generates an XSRF anti-forgery token. We're not modifying data, so we don't need to validate the token in the controller method.

Because the search parameter is in the request body and not the URL, you can't capture that search information to bookmark or share with others. Fix this by specifying the request should be `HTTP GET` found in the *Views/Movies/Index.cshtml* file.

```
@model IEnumerable<MvcMovie.Models.Movie>

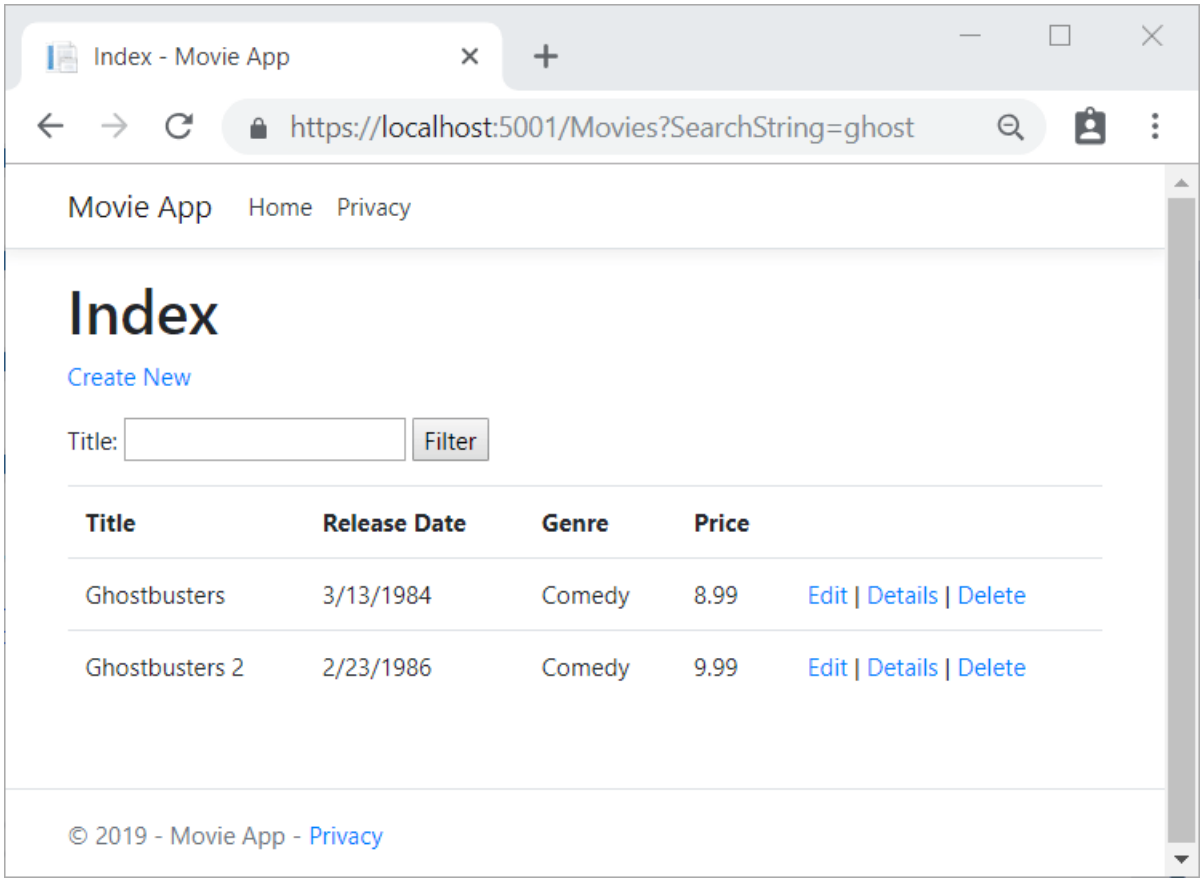
@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<form asp-controller="Movies" asp-action="Index" method="get">
    <p>
        Title: <input type="text" name="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Title)
```

Now when you submit a search, the URL contains the search query string. Searching will also go to the `HttpGet Index` action method, even if you have a `HttpPost Index` method.



The following markup shows the change to the `form` tag:

```
<form asp-controller="Movies" asp-action="Index" method="get">
```

Add Search by genre

Add the following `MovieGenreViewModel` class to the *Models* folder:

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace MvcMovie.Models
{
    public class MovieGenreViewModel
    {
        public List<Movie> Movies { get; set; }
        public SelectList Genres { get; set; }
        public string MovieGenre { get; set; }
        public string SearchString { get; set; }
    }
}
```

The movie-genre view model will contain:

- A list of movies.
- A `SelectList` containing the list of genres. This allows the user to select a genre from the list.
- `MovieGenre`, which contains the selected genre.
- `SearchString`, which contains the text users enter in the search text box.

Replace the `Index` method in `MoviesController.cs` with the following code:

```
// GET: Movies
public async Task<IActionResult> Index(string movieGenre, string searchString)
{
    // Use LINQ to get list of genres.
    IQueryable<string> genreQuery = from m in _context.Movie
                                    orderby m.Genre
                                    select m.Genre;

    var movies = from m in _context.Movie
                 select m;

    if (!string.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    if (!string.IsNullOrEmpty(movieGenre))
    {
        movies = movies.Where(x => x.Genre == movieGenre);
    }

    var movieGenreVM = new MovieGenreViewModel
    {
        Genres = new SelectList(await genreQuery.Distinct().ToListAsync()),
        Movies = await movies.ToListAsync()
    };

    return View(movieGenreVM);
}
```

The following code is a `LINQ` query that retrieves all the genres from the database.

```
// Use LINQ to get list of genres.
IQueryable<string> genreQuery = from m in _context.Movie
                                orderby m.Genre
                                select m.Genre;
```

The `SelectList` of genres is created by projecting the distinct genres (we don't want our select list to have duplicate genres).

When the user searches for the item, the search value is retained in the search box.

Add search by genre to the Index view

Update `Index.cshtml` found in *Views/Movies/* as follows:

```
@model MvcMovie.Models.MovieGenreViewModel

@{
    ViewData["Title"] = "Index";
}

<h1>Index</h1>

<p>
    <a asp-action="Create">Create New</a>
</p>
<form asp-controller="Movies" asp-action="Index" method="get">
    <p>

        <select asp-for="MovieGenre" asp-items="Model.Genres">
            <option value="">All</option>
        </select>

        Title: <input type="text" asp-for="SearchString" />
        <input type="submit" value="Filter" />
    </p>
</form>

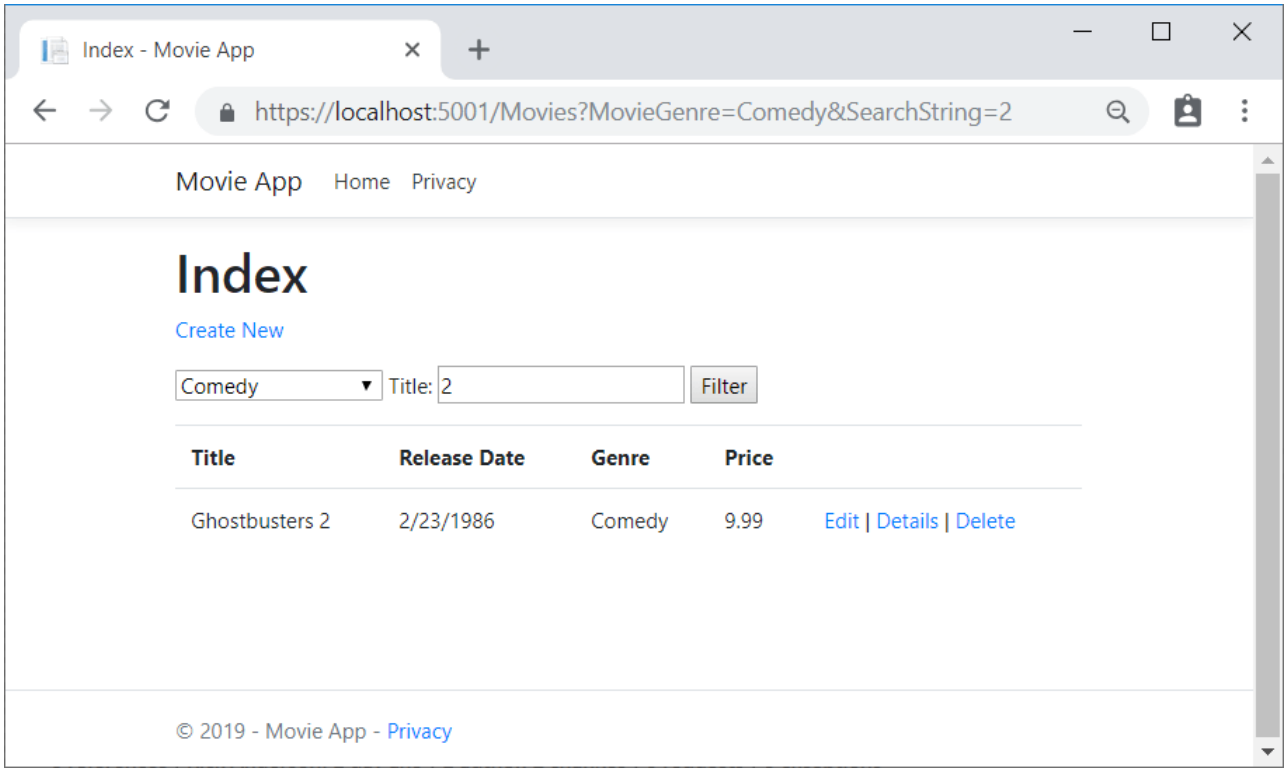
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Movies[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies[0].ReleaseDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies[0].Genre)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Movies[0].Price)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Movies)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.ReleaseDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Genre)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Price)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.Id">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.Id">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Examine the lambda expression used in the following HTML Helper:

```
@Html.DisplayNameFor(model => model.Movies[0].Title)
```

In the preceding code, the `DisplayNameFor` HTML Helper inspects the `Title` property referenced in the lambda expression to determine the display name. Since the lambda expression is inspected rather than evaluated, you don't receive an access violation when `model`, `model.Movies`, or `model.Movies[0]` are `null` or empty. When the lambda expression is evaluated (for example, `@Html.DisplayFor(modelItem => item.Title)`), the model's property values are evaluated.

Test the app by searching by genre, by movie title, and by both:



Part 8, add a new field to an ASP.NET Core MVC app

9/22/2020 • 4 minutes to read • Edit Online

By Rick Anderson

In this section Entity Framework Code First Migrations is used to:

- Add a new field to the model.
- Migrate the new field to the database.

When EF Code First is used to automatically create a database, Code First:

- Adds a table to the database to track the schema of the database.
- Verifies the database is in sync with the model classes it was generated from. If they aren't in sync, EF throws an exception. This makes it easier to find inconsistent database/code issues.

Add a Rating Property to the Movie Model

Add a `Rating` property to *Models/Movie.cs*:

```
public class Movie
{
    public int Id { get; set; }
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }

    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }
    public string Rating { get; set; }
}
```

Build the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Ctrl+Shift+B

Because you've added a new field to the `Movie` class, you need to update the binding white list so this new property will be included. In *MoviesController.cs*, update the `[Bind]` attribute for both the `Create` and `Edit` action methods to include the `Rating` property:

```
[Bind("Id,Title,ReleaseDate,Genre,Price,Rating")]
```

Update the view templates in order to display, create, and edit the new `Rating` property in the browser view.

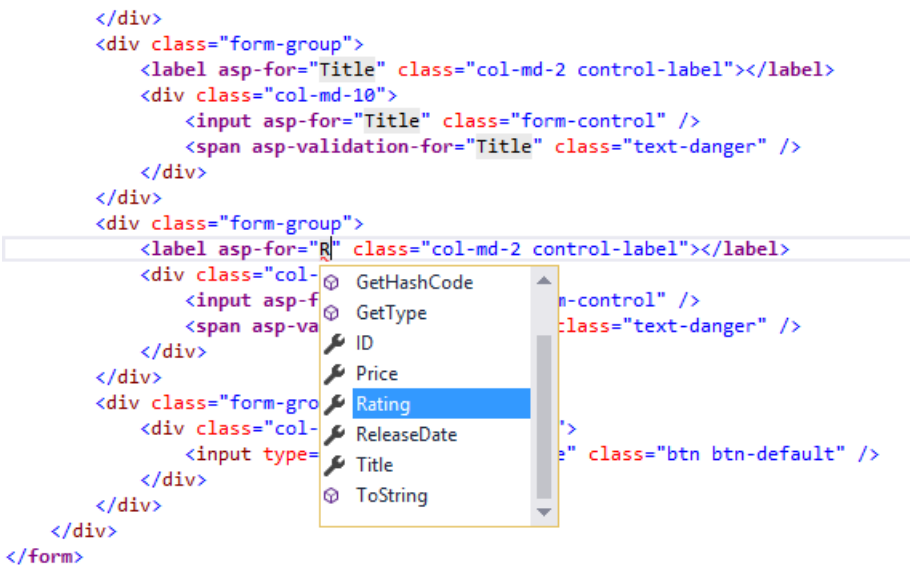
Edit the */Views/Movies/Index.cshtml* file and add a `Rating` field:

```
<thead>
    <tr>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].Title)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].ReleaseDate)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].Genre)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].Price)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Movies[0].Rating)
        </th>
        <th></th>
    </tr>
</thead>
<tbody>
    @foreach (var item in Model.Movies)
    {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Rating)
        </td>
        <td>
            <a asp-action="Edit" asp-route-id="@item.Id">Edit</a> |
```

Update the */Views/Movies/Create.cshtml* with a `Rating` field.

- Visual Studio / Visual Studio for Mac
- Visual Studio Code

You can copy/paste the previous "form group" and let intelliSense help you update the fields. IntelliSense works with Tag Helpers.



Update the remaining templates.

Update the `SeedData` class so that it provides a value for the new column. A sample change is shown below, but you'll want to make this change for each `new Movie`.

```
new Movie
{
    Title = "When Harry Met Sally",
    ReleaseDate = DateTime.Parse("1989-1-11"),
    Genre = "Romantic Comedy",
    Rating = "R",
    Price = 7.99M
},
```

The app won't work until the DB is updated to include the new field. If it's run now, the following `SqlException` is thrown:

```
SqlException: Invalid column name 'Rating'.
```

This error occurs because the updated Movie model class is different than the schema of the Movie table of the existing database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database based on the new model class schema. This approach is very convenient early in the development cycle when you're doing active development on a test database; it allows you to quickly evolve the model and database schema together. The downside, though, is that you lose existing data in the database — so you don't want to use this approach on a production database! Using an initializer to automatically seed a database with test data is often a productive way to develop an application. This is a good approach for early development and when using SQLite.

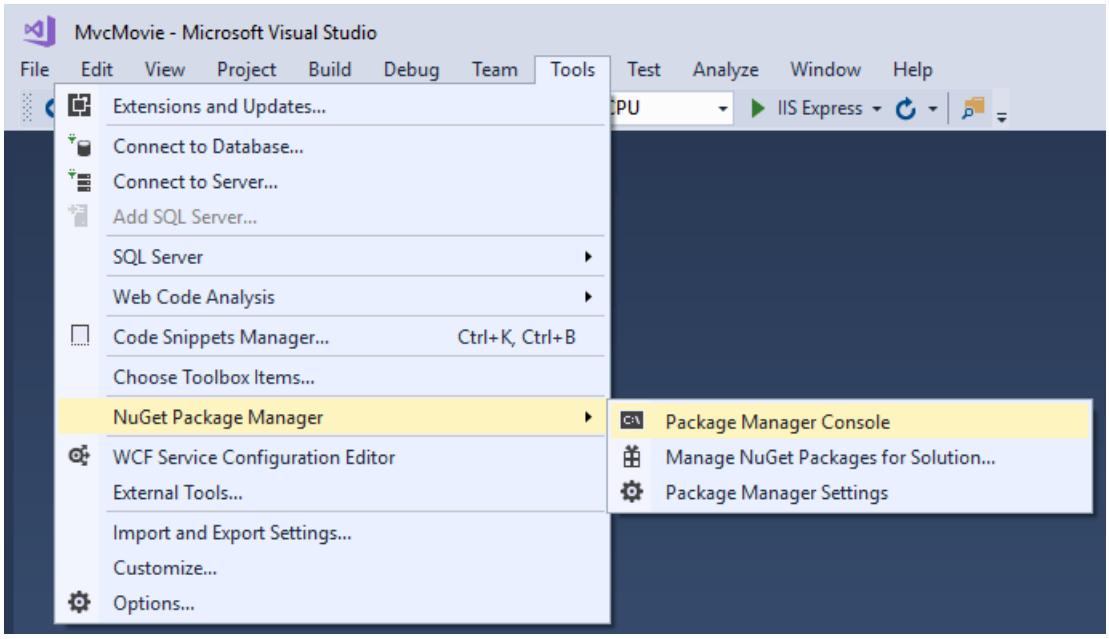
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.

3. Use Code First Migrations to update the database schema.

For this tutorial, Code First Migrations is used.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.



In the PMC, enter the following commands:

```
Add-Migration Rating
Update-Database
```

The `Add-Migration` command tells the migration framework to examine the current `Movie` model with the current `Movie` DB schema and create the necessary code to migrate the DB to the new model.

The name "Rating" is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration file.

If all the records in the DB are deleted, the initialize method will seed the DB and include the `Rating` field.

Run the app and verify you can create, edit, and display movies with a `Rating` field.

Part 9, add validation to an ASP.NET Core MVC app

9/22/2020 • 9 minutes to read • Edit Online

By Rick Anderson

In this section:

- Validation logic is added to the `Movie` model.
- You ensure that the validation rules are enforced any time a user creates or edits a movie.

Keeping things DRY

One of the design tenets of MVC is DRY ("Don't Repeat Yourself"). ASP.NET Core MVC encourages you to specify functionality or behavior only once, and then have it be reflected everywhere in an app. This reduces the amount of code you need to write and makes the code you do write less error prone, easier to test, and easier to maintain.

The validation support provided by MVC and Entity Framework Core Code First is a good example of the DRY principle in action. You can declaratively specify validation rules in one place (in the model class) and the rules are enforced everywhere in the app.

Add validation rules to the movie model

The DataAnnotations namespace provides a set of built-in validation attributes that are applied declaratively to a class or property. DataAnnotations also contains formatting attributes like `DataType` that help with formatting and don't provide any validation.

Update the `Movie` class to take advantage of the built-in `Required`, `StringLength`, `RegularExpression`, and `Range` validation attributes.

```
public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    [Required]
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
    [Required]
    [StringLength(30)]
    public string Genre { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$")]
    [StringLength(5)]
    [Required]
    public string Rating { get; set; }
}
```

The validation attributes specify behavior that you want to enforce on the model properties they're applied to:

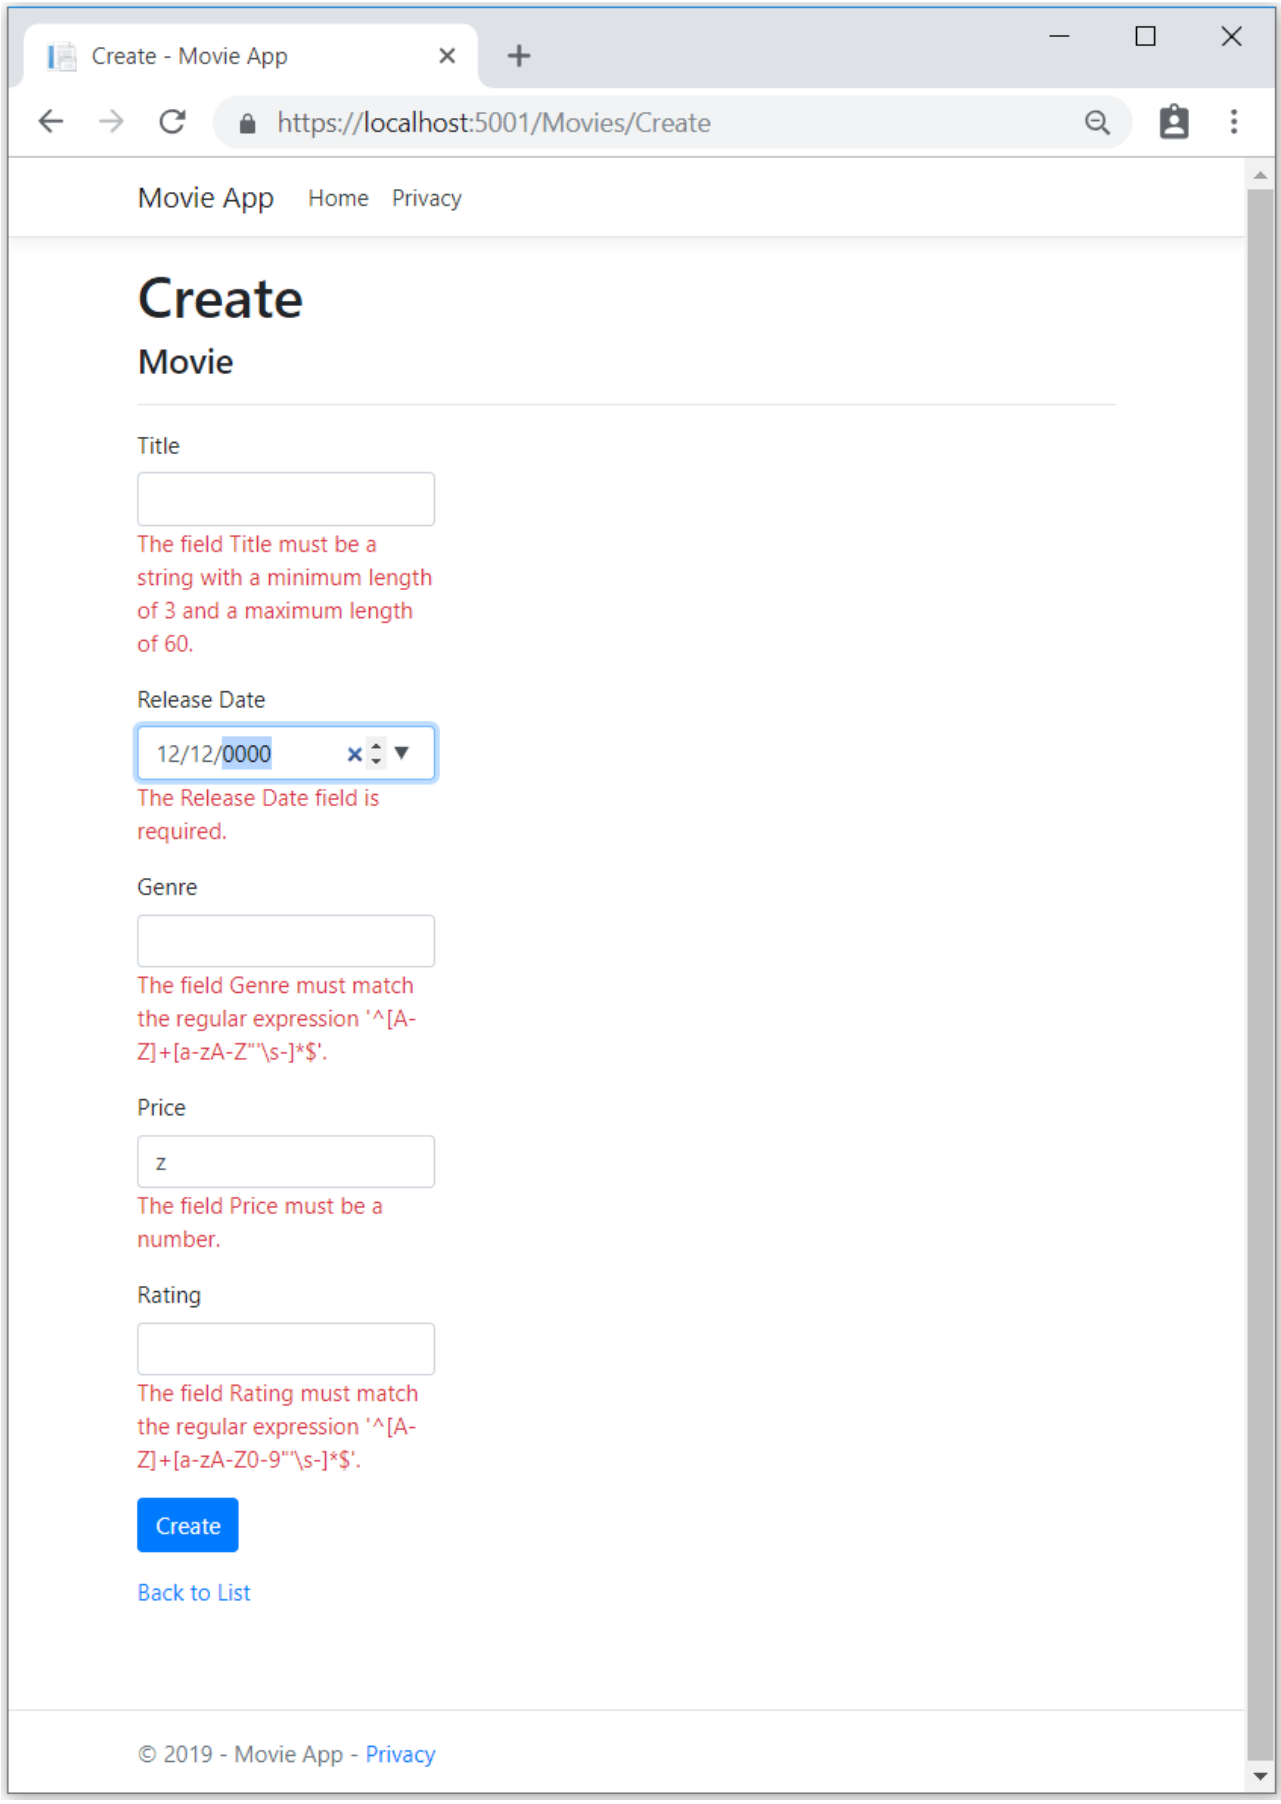
- The `Required` and `MinimumLength` attributes indicate that a property must have a value; but nothing prevents a user from entering white space to satisfy this validation.
- The `RegularExpression` attribute is used to limit what characters can be input. In the preceding code, "Genre":
  - Must only use letters.
  - The first letter is required to be uppercase. White space, numbers, and special characters are not allowed.
- The `RegularExpression` "Rating":
  - Requires that the first character be an uppercase letter.
  - Allows special characters and numbers in subsequent spaces. "PG-13" is valid for a rating, but fails for a "Genre".
- The `Range` attribute constrains a value to within a specified range.
- The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length.
- Value types (such as `decimal`, `int`, `float`, `DateTime`) are inherently required and don't need the `[Required]` attribute.

Having validation rules automatically enforced by ASP.NET Core helps make your app more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Validation Error UI

Run the app and navigate to the Movies controller.

Tap the **Create New** link to add a new movie. Fill out the form with some invalid values. As soon as jQuery client side validation detects the error, it displays an error message.



NOTE

You may not be able to enter decimal commas in decimal fields. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must take steps to globalize your app. See this GitHub issue 4076 for instructions on adding decimal comma.

Notice how the form has automatically rendered an appropriate validation error message in each field containing an invalid value. The errors are enforced both client-side (using JavaScript and jQuery) and server-side (in case a user has JavaScript disabled).

A significant benefit is that you didn't need to change a single line of code in the `MoviesController` class or in the *Create.cshtml* view in order to enable this validation UI. The controller and views you created earlier in this tutorial automatically picked up the validation rules that you specified by using validation attributes on the properties of the `Movie` model class. Test validation using the `Edit` action method, and the same validation is applied.

The form data isn't sent to the server until there are no client side validation errors. You can verify this by putting a break point in the `HTTP Post` method, by using the Fiddler tool , or the F12 Developer tools.

How validation works

You might wonder how the validation UI was generated without any updates to the code in the controller or views. The following code shows the two `Create` methods.

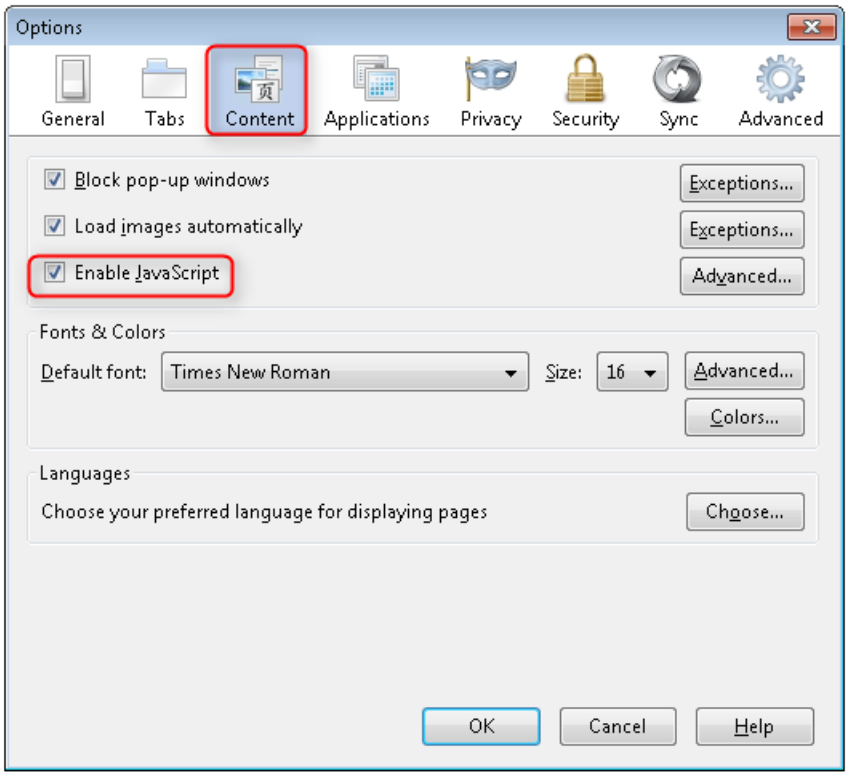
```
// GET: Movies/Create
public IActionResult Create()
{
    return View();
}

// POST: Movies/Create
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("ID,Title,ReleaseDate,Genre,Price, Rating")] Movie movie)
{
    if (ModelState.IsValid)
    {
        _context.Add(movie);
        await _context.SaveChangesAsync();
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

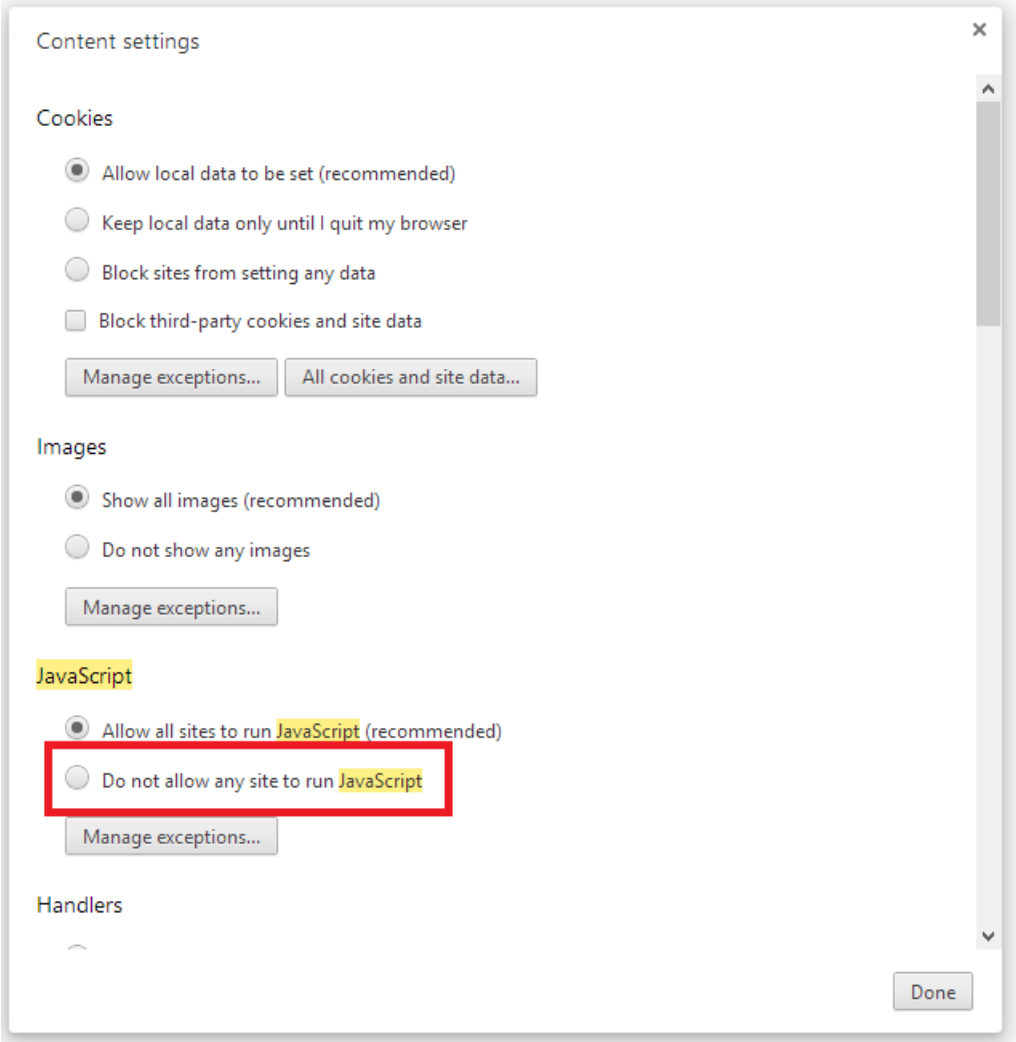
The first (HTTP GET) `Create` action method displays the initial Create form. The second (`[HttpPost]`) version handles the form post. The second `Create` method (The `[HttpPost]` version) calls `ModelState.IsValid` to check whether the movie has any validation errors. Calling this method evaluates any validation attributes that have been applied to the object. If the object has validation errors, the `Create` method re-displays the form. If there are no errors, the method saves the new movie in the database. In our movie example, the form isn't posted to the server when there are validation errors detected on the client side; the second `Create` method is never called when there are client side validation errors. If you disable JavaScript in your browser, client validation is disabled and you can test the HTTP POST `Create` method `ModelState.IsValid` detecting any validation errors.

You can set a break point in the `[HttpPost] Create` method and verify the method is never called, client side validation won't submit the form data when validation errors are detected. If you disable JavaScript in your browser, then submit the form with errors, the break point will be hit. You still get full validation without JavaScript.

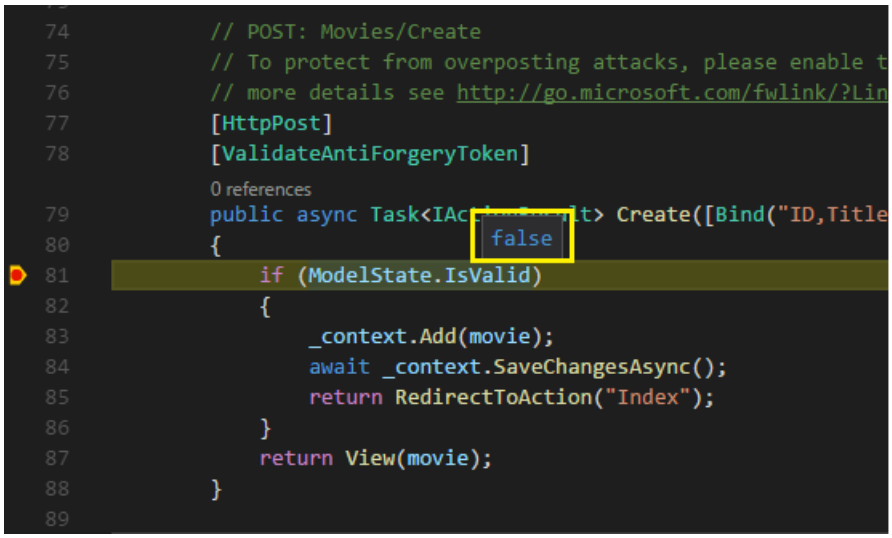
The following image shows how to disable JavaScript in the Firefox browser.



The following image shows how to disable JavaScript in the Chrome browser.



After you disable JavaScript, post invalid data and step through the debugger.



The portion of the *Create.cshtml* view template is shown in the following markup:

```
<h4>Movie</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Create">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Title" class="control-label"></label>
                <input asp-for="Title" class="form-control" />
                <span asp-validation-for="Title" class="text-danger"></span>
            </div>

        @*Markup removed for brevity.*@
```

The preceding markup is used by the action methods to display the initial form and to redisplay it in the event of an error.

The Input Tag Helper uses the DataAnnotations attributes and produces HTML attributes needed for jQuery Validation on the client side. The Validation Tag Helper displays validation errors. See Validation for more information.

What's really nice about this approach is that neither the controller nor the `Create` view template knows anything about the actual validation rules being enforced or about the specific error messages displayed. The validation rules and the error strings are specified only in the `Movie` class. These same validation rules are automatically applied to the `Edit` view and any other views templates you might create that edit your model.

When you need to change validation logic, you can do so in exactly one place by adding validation attributes to the model (in this example, the `Movie` class). You won't have to worry about different parts of the application being inconsistent with how the rules are enforced — all validation logic will be defined in one place and used everywhere. This keeps the code very clean, and makes it easy to maintain and evolve. And it means that you'll be fully honoring the DRY principle.

Using DataType Attributes

Open the *Movie.cs* file and examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. We've already applied a `DataType` enumeration value to the release date and to the price fields. The following code shows the `ReleaseDate` and `Price` properties with the appropriate `DataType` attribute.

```
[Display(Name = "Release Date")]
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[Range(1, 100)]
[DataType(DataType.Currency)]
public decimal Price { get; set; }
```

The `DataType` attributes only provide hints for the view engine to format the data (and supplies elements/attributes such as `<a>` for URL's and `<a href="mailto:EmailAddress.com">` for email. You can use the `RegularExpression` attribute to validate the format of the data. The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type, they're not validation attributes. In this case we only want to keep track of the date, not the time. The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`, and a date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attributes emit HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers can understand. The `DataType` attributes do **not** provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's `CultureInfo`.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
public DateTime ReleaseDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some fields — for example, for currency values, you probably don't want the currency symbol in the text box for editing.)

You can use the `DisplayFormat` attribute by itself, but it's generally a good idea to use the `DataType` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with DisplayFormat:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.)
- By default, the browser will render data using the correct format based on your locale.
- The `DataType` attribute can enable MVC to choose the right field template to render the data (the `DisplayFormat` if used by itself uses the string template).

> **NOTE**
> jQuery validation doesn't work with the `Range` attribute and `DateTime`. For example, the following code will always display a client side validation error, even when the date is in the specified range:
>
> `[Range(typeof(DateTime), "1/1/1966", "1/1/2020")]`

You will need to disable jQuery date validation to use the `Range` attribute with `DateTime`. It's generally not a good practice to compile hard dates in your models, so using the `Range` attribute and `DateTime` is discouraged.

The following code shows combining attributes on one line:

```
public class Movie
{
    public int Id { get; set; }

    [StringLength(60, MinimumLength = 3)]
    public string Title { get; set; }

    [Display(Name = "Release Date"), DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z]*$"), Required, StringLength(30)]
    public string Genre { get; set; }

    [Range(1, 100), DataType(DataType.Currency)]
    [Column(TypeName = "decimal(18, 2)")]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z0-9""'\s-]*$"), StringLength(5)]
    public string Rating { get; set; }
}
```

In the next part of the series, we review the app and make some improvements to the automatically generated `Details` and `Delete` methods.

Part 10, examine the Details and Delete methods of an ASP.NET Core app

9/22/2020 • 3 minutes to read • Edit Online

By Rick Anderson

Open the Movie controller and examine the `Details` method:

```
// GET: Movies/Details/5
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}
```

The MVC scaffolding engine that created this action method adds a comment showing an HTTP request that invokes the method. In this case it's a GET request with three URL segments, the `Movies` controller, the `Details` method, and an `id` value. Recall these segments are defined in *Startup.cs*.

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

EF makes it easy to search for data using the `FirstOrDefaultAsync` method. An important security feature built into the method is that the code verifies that the search method has found a movie before it tries to do anything with it. For example, a hacker could introduce errors into the site by changing the URL created by the links from `http://localhost:{PORT}/Movies/Details/1` to something like `http://localhost:{PORT}/Movies/Details/12345` (or some other value that doesn't represent an actual movie). If you didn't check for a null movie, the app would throw an exception.

Examine the `Delete` and `DeleteConfirmed` methods.

```
// GET: Movies/Delete/5
public async Task<IActionResult> Delete(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var movie = await _context.Movie
        .FirstOrDefaultAsync(m => m.Id == id);
    if (movie == null)
    {
        return NotFound();
    }

    return View(movie);
}

// POST: Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    var movie = await _context.Movie.FindAsync(id);
    _context.Movie.Remove(movie);
    await _context.SaveChangesAsync();
    return RedirectToAction(nameof(Index));
}
```

Note that the `HTTP GET Delete` method doesn't delete the specified movie, it returns a view of the movie where you can submit (HttpPost) the deletion. Performing a delete operation in response to a GET request (or for that matter, performing an edit operation, create operation, or any other operation that changes data) opens up a security hole.

The `[HttpPost]` method that deletes the data is named `DeleteConfirmed` to give the HTTP POST method a unique signature or name. The two method signatures are shown below:

```
// GET: Movies/Delete/5
public async Task<IActionResult> Delete(int? id)
{
```

```
// POST: Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
```

The common language runtime (CLR) requires overloaded methods to have a unique parameter signature (same method name but different list of parameters). However, here you need two `Delete` methods -- one for GET and one for POST -- that both have the same parameter signature. (They both need to accept a single integer as a parameter.)

There are two approaches to this problem, one is to give the methods different names. That's what the scaffolding mechanism did in the preceding example. However, this introduces a small problem: ASP.NET maps segments of a URL to action methods by name, and if you rename a method, routing normally wouldn't be able to find that method. The solution is what you see in the example, which is to add the `ActionName("Delete")` attribute to the `DeleteConfirmed` method. That attribute performs mapping for the routing system so that a URL that includes /Delete/ for a POST request will find the `DeleteConfirmed` method.

Another common work around for methods that have identical names and signatures is to artificially change the

signature of the POST method to include an extra (unused) parameter. That's what we did in a previous post when we added the `notUsed` parameter. You could do the same thing here for the `[HttpPost] Delete` method:

```
// POST: Movies/Delete/6
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Delete(int id, bool notUsed)
```

Publish to Azure

Build a Blazor todo list app

9/22/2020 • 4 minutes to read • Edit Online

By Daniel Roth and Luke Latham

This tutorial shows you how to build and modify a Blazor app. You learn how to:

- Create a todo list Blazor app project
- Modify Razor components
- Use event handling and data binding in components
- Use routing in a Blazor app

At the end of this tutorial, you'll have a working todo list app.

Prerequisites

.NET Core 3.1 SDK or later

Create a todo list Blazor app

1. Create a new Blazor app named `TodoList` in a command shell:

   ```
   dotnet new blazorserver -o TodoList
   ```

   The preceding command creates a folder named `TodoList` to hold the app. The `TodoList` folder is the *root folder* of the project. Change directories to the `TodoList` folder with the following command:

   ```
   cd TodoList
   ```

2. Add a new `Todo` Razor component to the app in the `Pages` folder using the following command:

   ```
   dotnet new razorcomponent -n Todo -o Pages
   ```

   > **IMPORTANT**
   > Razor component file names require a capitalized first letter. Open the `Pages` folder and confirm that the `Todo` component file name starts with a capital letter `T`. The file name should be `Todo.razor`.

3. In `Pages/Todo.razor` provide the initial markup for the component:

   ```
   @page "/todo"

   <h3>Todo</h3>
   ```

4. Add the `Todo` component to the navigation bar.

   The `NavMenu` component (`Shared/NavMenu.razor`) is used in the app's layout. Layouts are components that allow you to avoid duplication of content in the app.

Add a `<NavLink>` element for the `Todo` component by adding the following list item markup below the existing list items in the `Shared/NavMenu.razor` file:

```
<li class="nav-item px-3">
    <NavLink class="nav-link" href="todo">
        <span class="oi oi-list-rich" aria-hidden="true"></span> Todo
    </NavLink>
</li>
```

5. Build and run the app by executing the `dotnet run` command in the command shell from the `TodoList` folder. Visit the new Todo page to confirm that the link to the `Todo` component works.

6. Add a `TodoItem.cs` file to the root of the project (the `TodoList` folder) to hold a class that represents a todo item. Use the following C# code for the `TodoItem` class:

```
public class TodoItem
{
    public string Title { get; set; }
    public bool IsDone { get; set; }
}
```

7. Return to the `Todo` component (`Pages/Todo.razor`):

   - Add a field for the todo items in an `@code` block. The `Todo` component uses this field to maintain the state of the todo list.
   - Add unordered list markup and a `foreach` loop to render each todo item as a list item (`<li>`).

```
@page "/todo"

<h3>Todo</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>@todo.Title</li>
    }
</ul>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();
}
```

8. The app requires UI elements for adding todo items to the list. Add a text input (`<input>`) and a button (`<button>`) below the unordered list (`<ul>...</ul>`):

```
@page "/todo"

<h3>Todo</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>@todo.Title</li>
    }
</ul>

<input placeholder="Something todo" />
<button>Add todo</button>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();
}
```

9. Stop the running app in the command shell. Many command shells accept the keyboard command `Ctrl+c` to stop an app. Rebuild and run the app with the `dotnet run` command. When the `Add todo` button is selected, nothing happens because an event handler isn't wired up to the button.

10. Add an `AddTodo` method to the `Todo` component and register it for button selections using the `@onclick` attribute. The `AddTodo` C# method is called when the button is selected:

```
<input placeholder="Something todo" />
<button @onclick="AddTodo">Add todo</button>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();

    private void AddTodo()
    {
        // Todo: Add the todo
    }
}
```

11. To get the title of the new todo item, add a `newTodo` string field at the top of the `@code` block and bind it to the value of the text input using the `bind` attribute in the `<input>` element:

```
private IList<TodoItem> todos = new List<TodoItem>();
private string newTodo;
```

```
<input placeholder="Something todo" @bind="newTodo" />
```

12. Update the `AddTodo` method to add the `TodoItem` with the specified title to the list. Clear the value of the text input by setting `newTodo` to an empty string:

```
@page "/todo"

<h3>Todo</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>@todo.Title</li>
    }
</ul>

<input placeholder="Something todo" @bind="newTodo" />
<button @onclick="AddTodo">Add todo</button>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();
    private string newTodo;

    private void AddTodo()
    {
        if (!string.IsNullOrWhiteSpace(newTodo))
        {
            todos.Add(new TodoItem { Title = newTodo });
            newTodo = string.Empty;
        }
    }
}
```

13. Stop the running app in the command shell. Rebuild and run the app with the `dotnet run` command. Add some todo items to the todo list to test the new code.

14. The title text for each todo item can be made editable, and a check box can help the user keep track of completed items. Add a check box input for each todo item and bind its value to the `IsDone` property. Change `@todo.Title` to an `<input>` element bound to `@todo.Title`:

```
<ul>
    @foreach (var todo in todos)
    {
        <li>
            <input type="checkbox" @bind="todo.IsDone" />
            <input @bind="todo.Title" />
        </li>
    }
</ul>
```

15. To verify that these values are bound, update the `<h3>` header to show a count of the number of todo items that aren't complete (`IsDone` is `false`).

```
<h3>Todo (@todos.Count(todo => !todo.IsDone))</h3>
```

16. The completed `Todo` component (`Pages/Todo.razor`):

```
@page "/todo"

<h3>Todo (@todos.Count(todo => !todo.IsDone))</h3>

<ul>
    @foreach (var todo in todos)
    {
        <li>
            <input type="checkbox" @bind="todo.IsDone" />
            <input @bind="todo.Title" />
        </li>
    }
</ul>

<input placeholder="Something todo" @bind="newTodo" />
<button @onclick="AddTodo">Add todo</button>

@code {
    private IList<TodoItem> todos = new List<TodoItem>();
    private string newTodo;

    private void AddTodo()
    {
        if (!string.IsNullOrWhiteSpace(newTodo))
        {
            todos.Add(new TodoItem { Title = newTodo });
            newTodo = string.Empty;
        }
    }
}
```

17. Stop the running app in the command shell. Rebuild and run the app with the `dotnet run` command. Add todo items to test the new code.

Next steps

In this tutorial, you learned how to:

- Create a todo list Blazor app project
- Modify Razor components
- Use event handling and data binding in components
- Use routing in a Blazor app

Learn about tooling for ASP.NET Core Blazor:

Tooling for ASP.NET Core Blazor

Tutorial: Create a web API with ASP.NET Core

9/22/2020 • 47 minutes to read • Edit Online

By Rick Anderson, Kirk Larkin, and Mike Wasson

This tutorial teaches the basics of building a web API with ASP.NET Core.

In this tutorial, you learn how to:

- Create a web API project.
- Add a model class and a database context.
- Scaffold a controller with CRUD methods.
- Configure routing, URL paths, and return values.
- Call the web API with Postman.

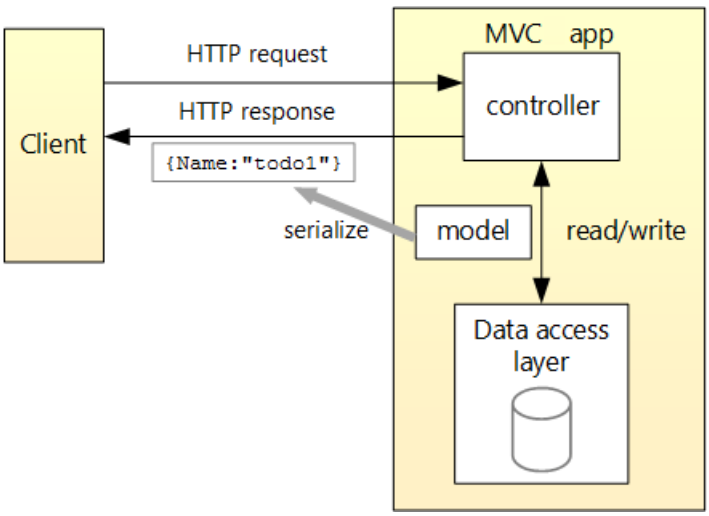
At the end, you have a web API that can manage "to-do" items stored in a database.

Overview

This tutorial creates the following API:

API	DESCRIPTION	REQUEST BODY	RESPONSE BODY
`GET /api/TodoItems`	Get all to-do items	None	Array of to-do items
`GET /api/TodoItems/{id}`	Get an item by ID	None	To-do item
`POST /api/TodoItems`	Add a new item	To-do item	To-do item
`PUT /api/TodoItems/{id}`	Update an existing item	To-do item	None
`DELETE /api/TodoItems/{id}`	Delete an item	None	None

The following diagram shows the design of the app.



Prerequisites

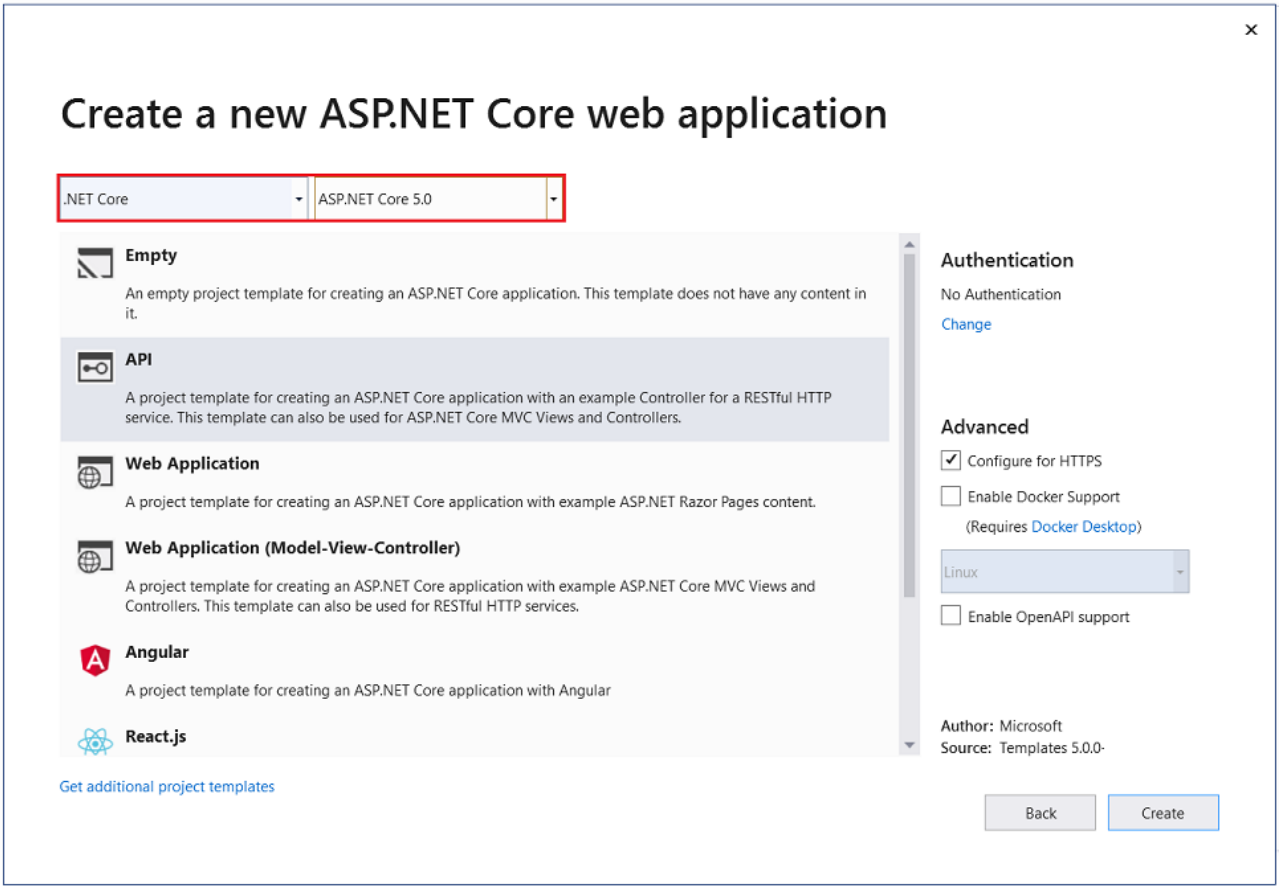
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.8 or later with the **ASP.NET and web development** workload
- .NET 5.0 SDK or later

Create a web project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the **File** menu, select **New** > **Project**.
- Select the **ASP.NET Core Web Application** template and click **Next**.
- Name the project *TodoApi* and click **Create**.
- In the **Create a new ASP.NET Core Web Application** dialog, confirm that **.NET Core** and **ASP.NET Core 5.0** are selected. Select the **API** template and click **Create**.



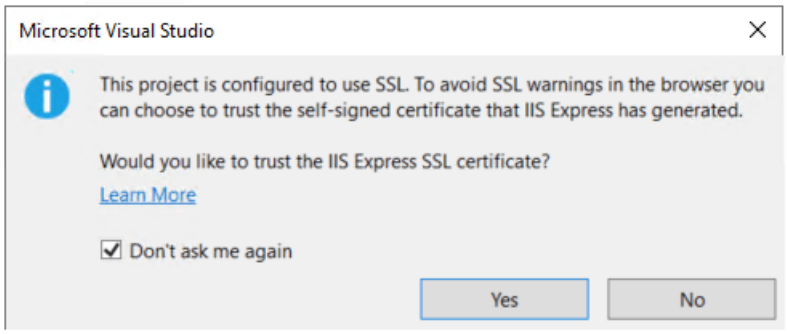
Test the project

The project template creates a `WeatherForecast` API with support for Swagger.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

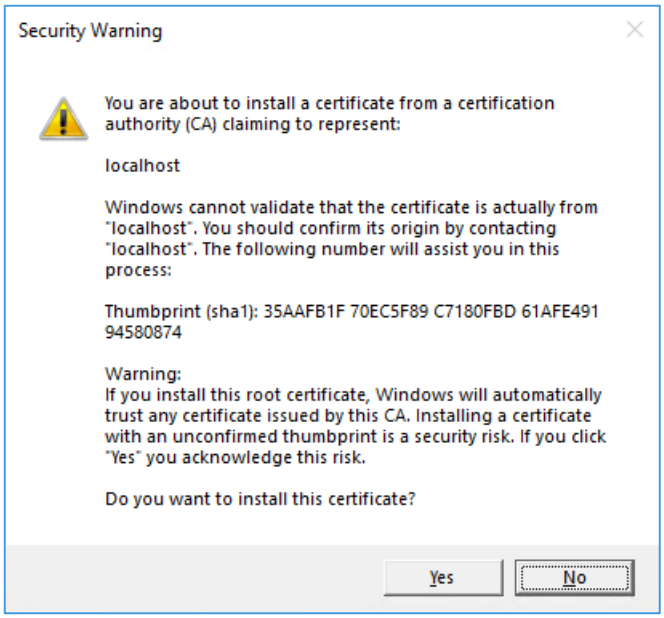
Press Ctrl+F5 to run without the debugger.

Visual Studio displays the following dialog:



Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:



Select **Yes** if you agree to trust the development certificate.

Visual Studio launches:

- The IIS Express web server.
- The default browser and navigates to `https://localhost:<port>/https://localhost:5001/swagger/index.html`, where `<port>` is a randomly chosen port number.

The Swagger page `/swagger/index.html` is displayed. Select **GET** > **Try it out** > **Execute**. The page displays:

- The Curl command to test the WeatherForecast API.
- The URL to test the WeatherForecast API.
- The response code, body, and headers.
- A drop down list box with media types and the example value and schema.

Swagger is used to generate useful documentation and help pages for web APIs. This tutorial focuses on creating a web API. For more information on Swagger, see ASP.NET Core Web API help pages with Swagger / OpenAPI.

Copy and past the **Request URL** in the browser: `https://localhost:<port>/WeatherForecast`

JSON similar to the following is returned:

```
[
    {
        "date": "2019-07-16T19:04:05.7257911-06:00",
        "temperatureC": 52,
        "temperatureF": 125,
        "summary": "Mild"
    },
    {
        "date": "2019-07-17T19:04:05.7258461-06:00",
        "temperatureC": 36,
        "temperatureF": 96,
        "summary": "Warm"
    },
    {
        "date": "2019-07-18T19:04:05.7258467-06:00",
        "temperatureC": 39,
        "temperatureF": 102,
        "summary": "Cool"
    },
    {
        "date": "2019-07-19T19:04:05.7258471-06:00",
        "temperatureC": 10,
        "temperatureF": 49,
        "summary": "Bracing"
    },
    {
        "date": "2019-07-20T19:04:05.7258474-06:00",
        "temperatureC": -1,
        "temperatureF": 31,
        "summary": "Chilly"
    }
]
```

Update the launchUrl

In *Properties\launchSettings.json*, update `launchUrl` from `"swagger"` to `"api/TodoItems"`:

```
"launchUrl": "api/TodoItems",
```

Because Swagger has been removed, the preceding markup changes the URL that is launched to the GET method of the controller added in the following sections.

Add a model class

A *model* is a set of classes that represent the data that the app manages. The model for this app is a single `TodoItem` class.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project. Select **Add** > **New Folder**. Name the folder *Models*.
- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoItem* and select **Add**.
- Replace the template code with the following:

```
namespace TodoApi.Models
{
    public class TodoItem
    {
        public long Id { get; set; }
        public string Name { get; set; }
        public bool IsComplete { get; set; }
    }
}
```

The `Id` property functions as the unique key in a relational database.

Model classes can go anywhere in the project, but the *Models* folder is used by convention.

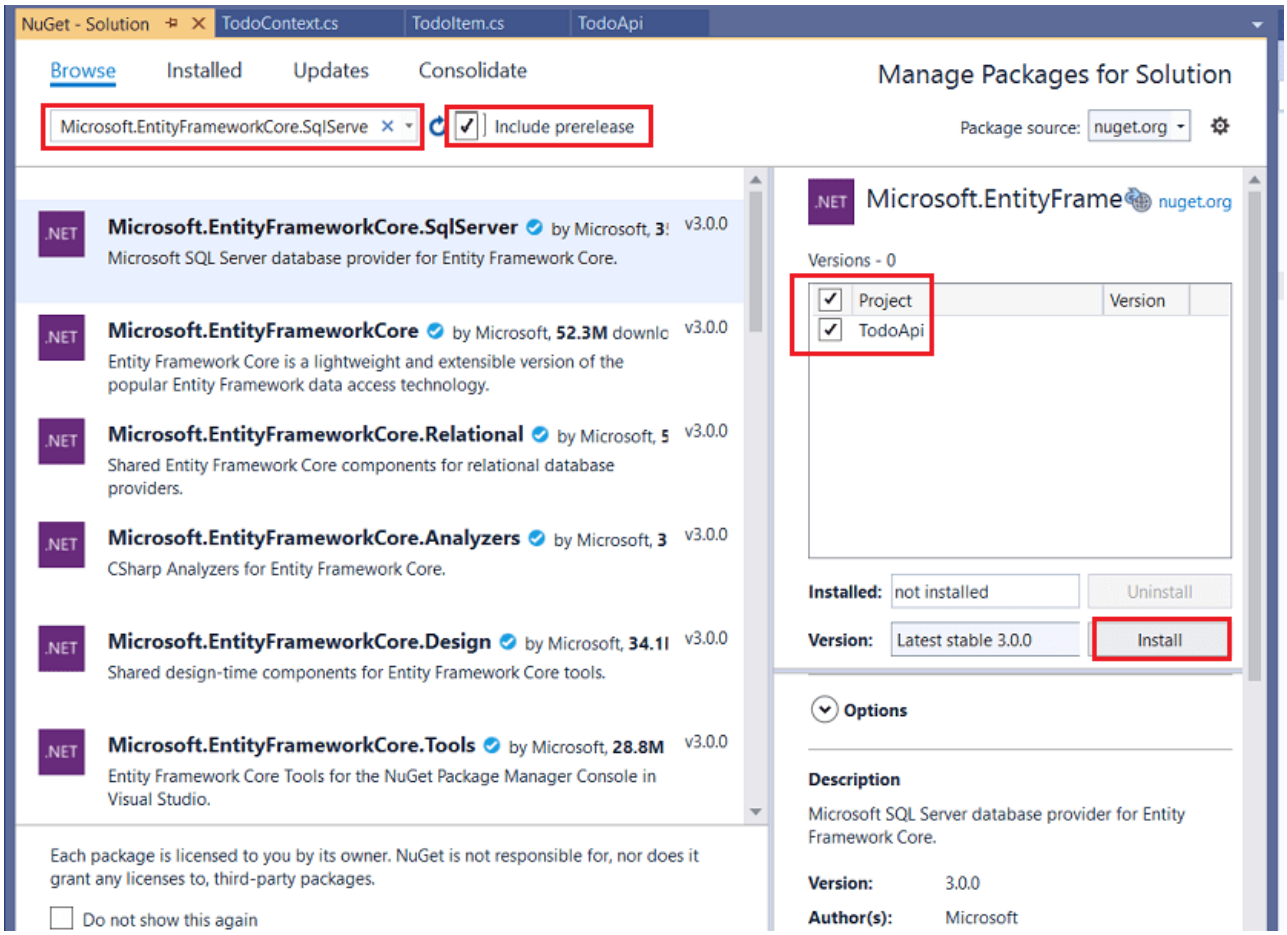
Add a database context

The *database context* is the main class that coordinates Entity Framework functionality for a data model. This class is created by deriving from the Microsoft.EntityFrameworkCore.DbContext class.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Add NuGet packages

- From the **Tools** menu, select **NuGet Package Manager > Manage NuGet Packages for Solution**.
- Select the **Browse** tab, and then enter **Microsoft. **EntityFrameworkCore.SqlServer** in the search box.
- Select the **Include prerelease** checkbox so the 5.0 RC version is available.
- Select **Microsoft.EntityFrameworkCore.SqlServer** in the left pane.
- Select the **Project** check box in the right pane and then select **Install**.
- Use the preceding instructions to add the **Microsoft.EntityFrameworkCore.InMemory** NuGet package.



Add the TodoContext database context

- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoContext* and click **Add**.
- Enter the following code:

```
using Microsoft.EntityFrameworkCore;

namespace TodoApi.Models
{
    public class TodoContext : DbContext
    {
        public TodoContext(DbContextOptions<TodoContext> options)
            : base(options)
        {
        }

        public DbSet<TodoItem> TodoItems { get; set; }
    }
}
```

Register the database context

In ASP.NET Core, services such as the DB context must be registered with the dependency injection (DI) container. The container provides the service to controllers.

Update *Startup.cs* with the following code:

```
// Unused usings removed
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

namespace TodoApi
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.AddDbContext<TodoContext>(opt =>
                                               opt.UseInMemoryDatabase("TodoList"));
            services.AddControllers();
        }

        public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }

            app.UseHttpsRedirection();
            app.UseRouting();

            app.UseAuthorization();

            app.UseEndpoints(endpoints =>
            {
                endpoints.MapControllers();
            });
        }
    }
}
```

The preceding code:

- Removes the Swagger calls.
- Removes unused `using` declarations.
- Adds the database context to the DI container.
- Specifies that the database context will use an in-memory database.

Scaffold a controller

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Right-click the *Controllers* folder.
- Select **Add** > **New Scaffolded Item**.

- Select **API Controller with actions, using Entity Framework**, and then select **Add**.
- In the **Add API Controller with actions, using Entity Framework** dialog:
  - Select **TodoItem (TodoApi.Models)** in the **Model class**.
  - Select **TodoContext (TodoApi.Models)** in the **Data context class**.
  - Select **Add**.

The generated code:

- Marks the class with the `[ApiController]` attribute. This attribute indicates that the controller responds to web API requests. For information about specific behaviors that the attribute enables, see Create web APIs with ASP.NET Core.
- Uses DI to inject the database context (`TodoContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

The ASP.NET Core templates for:

- Controllers with views include `[action]` in the route template.
- API controllers don't include `[action]` in the route template.

When the `[action]` token isn't in the route template, the action name is excluded from the route. That is, the action's associated method name isn't used in the matching route.

Update the PostTodoItem create method

Replace the return statement in the `PostTodoItem` to use the nameof operator:

```
// POST: api/TodoItems
[HttpPost]
public async Task<ActionResult<TodoItem>> PostTodoItem(TodoItem todoItem)
{
    _context.TodoItems.Add(todoItem);
    await _context.SaveChangesAsync();

    //return CreatedAtAction("GetTodoItem", new { id = todoItem.Id }, todoItem);
    return CreatedAtAction(nameof(GetTodoItem), new { id = todoItem.Id }, todoItem);
}
```

The preceding code is an HTTP POST method, as indicated by the `[HttpPost]` attribute. The method gets the value of the to-do item from the body of the HTTP request.

For more information, see Attribute routing with Http[Verb] attributes.

The CreatedAtAction method:

- Returns an HTTP 201 status code if successful. HTTP 201 is the standard response for an HTTP POST method that creates a new resource on the server.
- Adds a Location header to the response. The `Location` header specifies the URI of the newly created to-do item. For more information, see 10.2.2 201 Created.
- References the `GetTodoItem` action to create the `Location` header's URI. The C# `nameof` keyword is used to avoid hard-coding the action name in the `CreatedAtAction` call.

Install Postman

This tutorial uses Postman to test the web API.

- Install Postman

- Start the web app.
- Start Postman.
- Disable **SSL certificate verification**
  - From **File** > **Settings** (**General** tab), disable **SSL certificate verification**.

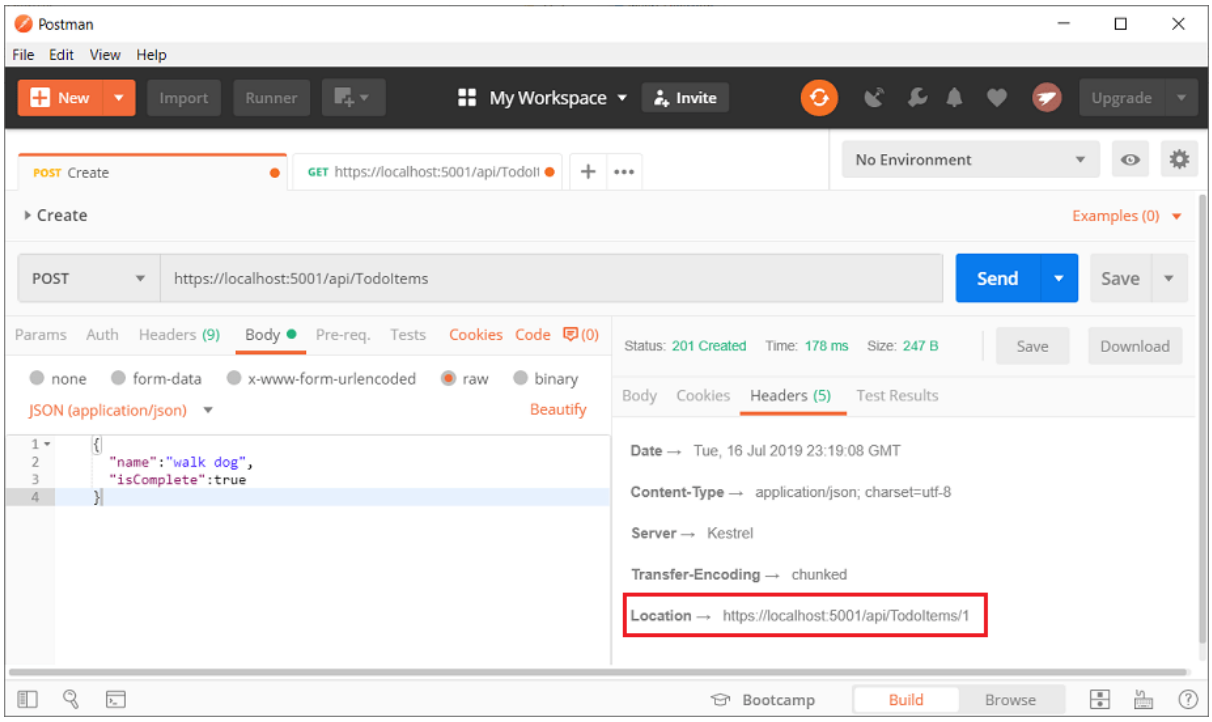
> **WARNING**
> Re-enable SSL certificate verification after testing the controller.

Test PostTodoItem with Postman

- Create a new request.
- Set the HTTP method to `POST`.
- Set the URI to `https://localhost:<port>/api/TodoItems`. For example, `https://localhost:5001/api/TodoItems`.
- Select the **Body** tab.
- Select the **raw** radio button.
- Set the type to **JSON (application/json)**.
- In the request body enter JSON for a to-do item:

```
{
  "name":"walk dog",
  "isComplete":true
}
```

- Select **Send**.



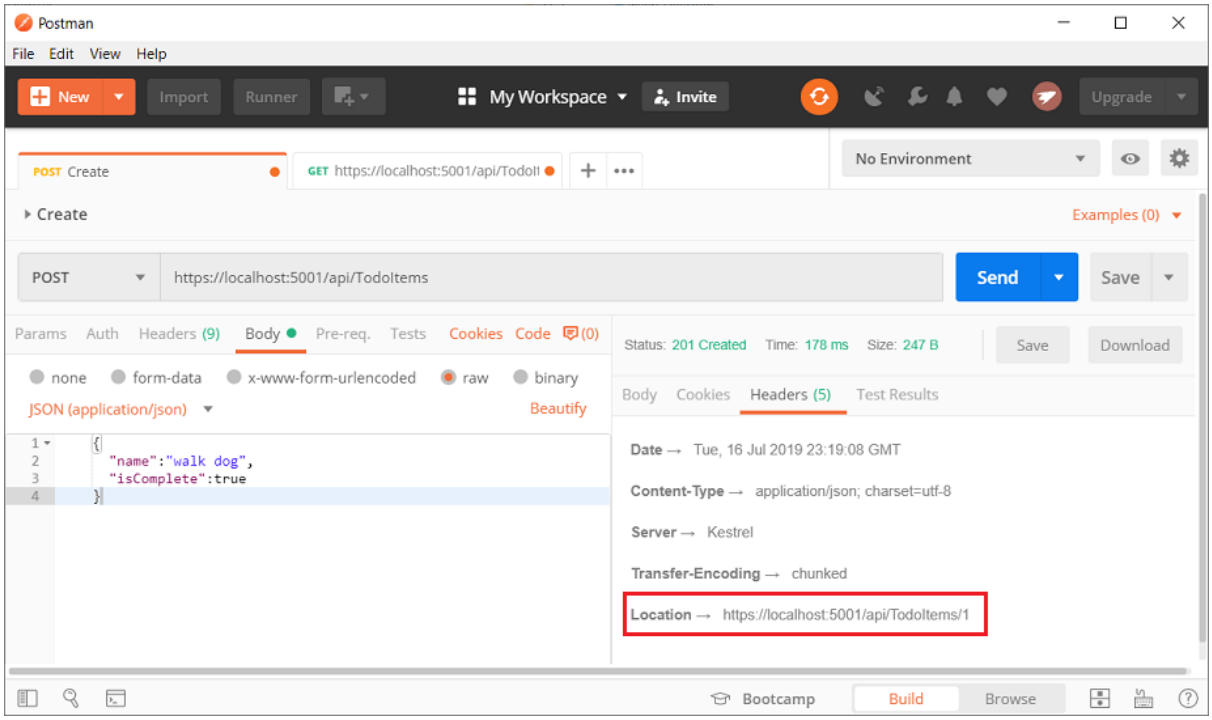
Test the location header URI

The location header URI can be tested in the browser. Copy and paste the location header URI into the browser.

To test in Postman:

- Select the **Headers** tab in the **Response** pane.

- Copy the **Location** header value:



- Set the HTTP method to `GET`.
- Set the URI to `https://localhost:<port>/api/TodoItems/1`. For example, `https://localhost:5001/api/TodoItems/1`.
- Select **Send**.

Examine the GET methods

Two GET endpoints are implemented:

- `GET /api/TodoItems`
- `GET /api/TodoItems/{id}`

Test the app by calling the two endpoints from a browser or Postman. For example:

- `https://localhost:5001/api/TodoItems`
- `https://localhost:5001/api/TodoItems/1`

A response similar to the following is produced by the call to `GetTodoItems`:

```
[
  {
    "id": 1,
    "name": "Item1",
    "isComplete": false
  }
]
```

Test Get with Postman

- Create a new request.
- Set the HTTP method to **GET**.
- Set the request URI to `https://localhost:<port>/api/TodoItems`. For example, `https://localhost:5001/api/TodoItems`.

- Set **Two pane view** in Postman.
- Select **Send**.

This app uses an in-memory database. If the app is stopped and started, the preceding GET request will not return any data. If no data is returned, POST data to the app.

Routing and URL paths

The `[HttpGet]` attribute denotes a method that responds to an HTTP GET request. The URL path for each method is constructed as follows:

- Start with the template string in the controller's `Route` attribute:

```
[Route("api/[controller]")]
[ApiController]
public class TodoItemsController : ControllerBase
{
    private readonly TodoContext _context;

    public TodoItemsController(TodoContext context)
    {
        _context = context;
    }
```

- Replace `[controller]` with the name of the controller, which by convention is the controller class name minus the "Controller" suffix. For this sample, the controller class name is **TodoItems**Controller, so the controller name is "TodoItems". ASP.NET Core routing is case insensitive.
- If the `[HttpGet]` attribute has a route template (for example, `[HttpGet("products")]`), append that to the path. This sample doesn't use a template. For more information, see Attribute routing with Http[Verb] attributes.

In the following `GetTodoItem` method, `"{id}"` is a placeholder variable for the unique identifier of the to-do item. When `GetTodoItem` is invoked, the value of `"{id}"` in the URL is provided to the method in its `id` parameter.

```
// GET: api/TodoItems/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

Return values

The return type of the `GetTodoItems` and `GetTodoItem` methods is ActionResult<T> type. ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200 OK, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

`ActionResult` return types can represent a wide range of HTTP status codes. For example, `GetTodoItem` can return two different status values:

- If no item matches the requested ID, the method returns a 404 status NotFound error code.
- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an HTTP 200 response.

The PutTodoItem method

Examine the `PutTodoItem` method:

```
// PUT: api/TodoItems/5
[HttpPut("{id}")]
public async Task<IActionResult> PutTodoItem(long id, TodoItem todoItem)
{
    if (id != todoItem.Id)
    {
        return BadRequest();
    }

    _context.Entry(todoItem).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!TodoItemExists(id))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return NoContent();
}
```

`PutTodoItem` is similar to `PostTodoItem`, except it uses HTTP PUT. The response is 204 (No Content). According to the HTTP specification, a PUT request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

If you get an error calling `PutTodoItem`, call `GET` to ensure there's an item in the database.

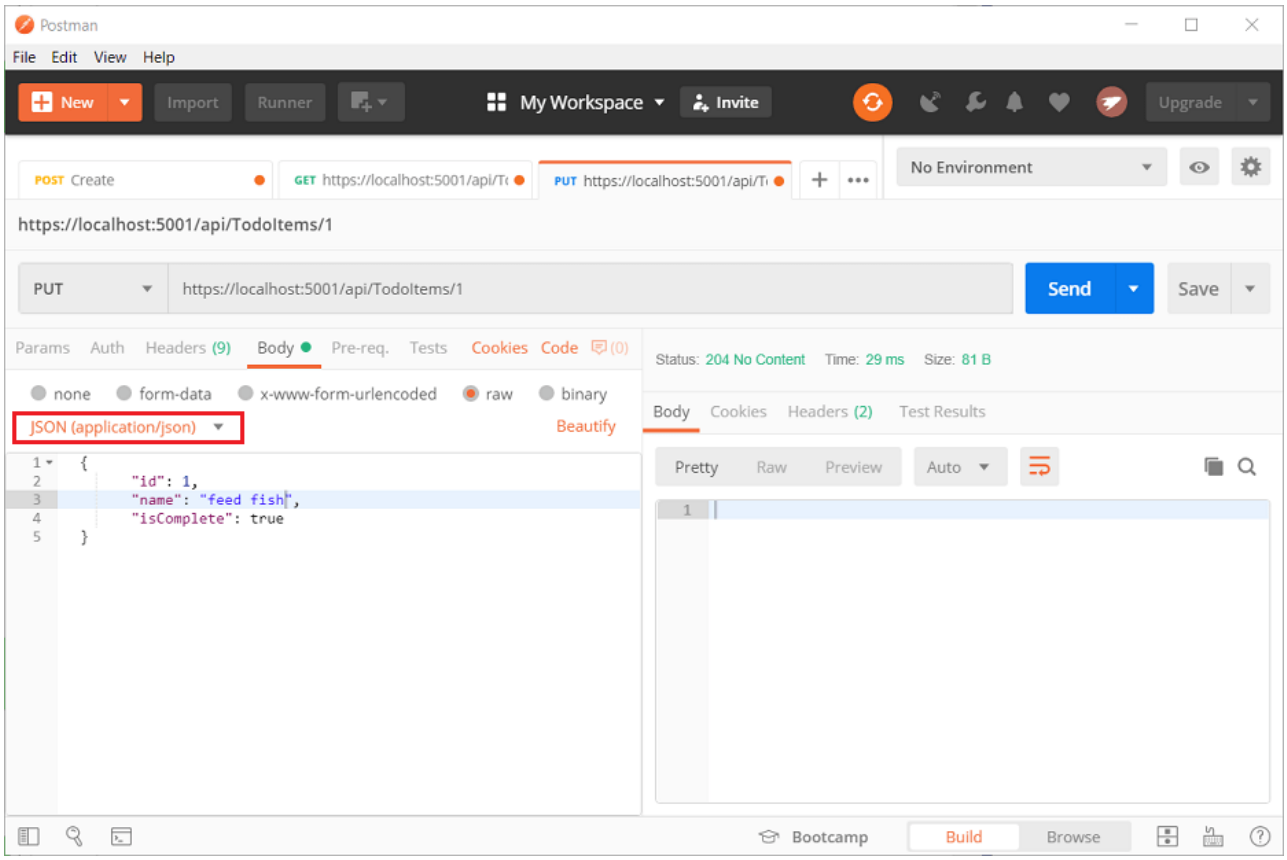
Test the PutTodoItem method

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Update the to-do item that has Id = 1 and set its name to `"feed fish"`:

```
{
  "Id":1,
  "name":"feed fish",
  "isComplete":true
}
```

The following image shows the Postman update:



The DeleteTodoItem method

Examine the `DeleteTodoItem` method:

```
// DELETE: api/TodoItems/5
[HttpDelete("{id}")]
public async Task<IActionResult> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);
    if (todoItem == null)
    {
        return NotFound();
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return NoContent();
}
```

Test the DeleteTodoItem method

Use Postman to delete a to-do item:

- Set the method to `DELETE`.
- Set the URI of the object to delete (for example `https://localhost:5001/api/TodoItems/1`).
- Select **Send**.

Prevent over-posting

Currently the sample app exposes the entire `TodoItem` object. Production apps typically limit the data that's input and returned using a subset of the model. There are multiple reasons behind this and security is a major one. The subset of a model is usually referred to as a Data Transfer Object (DTO), input model, or view model. **DTO** is used in this article.

A DTO may be used to:

- Prevent over-posting.
- Hide properties that clients are not supposed to view.
- Omit some properties in order to reduce payload size.
- Flatten object graphs that contain nested objects. Flattened object graphs can be more convenient for clients.

To demonstrate the DTO approach, update the `TodoItem` class to include a secret field:

```
namespace TodoApi.Models
{
    public class TodoItem
    {
        public long Id { get; set; }
        public string Name { get; set; }
        public bool IsComplete { get; set; }
        public string Secret { get; set; }
    }
}
```

The secret field needs to be hidden from this app, but an administrative app could choose to expose it.

Verify you can post and get the secret field.

Create a DTO model:

```
public class TodoItemDTO
{
    public long Id { get; set; }
    public string Name { get; set; }
    public bool IsComplete { get; set; }
}
```

Update the `TodoItemsController` to use `TodoItemDTO`:

```
// GET: api/TodoItems
[HttpGet]
public async Task<ActionResult<IEnumerable<TodoItemDTO>>> GetTodoItems()
{
    return await _context.TodoItems
        .Select(x => ItemToDTO(x))
        .ToListAsync();
}

[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return ItemToDTO(todoItem);
}

[HttpPut("{id}")]
public async Task<IActionResult> UpdateTodoItem(long id, TodoItemDTO todoItemDTO)
{
    if (id != todoItemDTO.Id)
    {
```

```
    {
        return BadRequest();
    }

    var todoItem = await _context.TodoItems.FindAsync(id);
    if (todoItem == null)
    {
        return NotFound();
    }

    todoItem.Name = todoItemDTO.Name;
    todoItem.IsComplete = todoItemDTO.IsComplete;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException) when (!TodoItemExists(id))
    {
        return NotFound();
    }

    return NoContent();
}

[HttpPost]
public async Task<ActionResult<TodoItemDTO>> CreateTodoItem(TodoItemDTO todoItemDTO)
{
    var todoItem = new TodoItem
    {
        IsComplete = todoItemDTO.IsComplete,
        Name = todoItemDTO.Name
    };

    _context.TodoItems.Add(todoItem);
    await _context.SaveChangesAsync();

    return CreatedAtAction(
        nameof(GetTodoItem),
        new { id = todoItem.Id },
        ItemToDTO(todoItem));
}

[HttpDelete("{id}")]
public async Task<IActionResult> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return NoContent();
}

private bool TodoItemExists(long id) =>
     _context.TodoItems.Any(e => e.Id == id);

private static TodoItemDTO ItemToDTO(TodoItem todoItem) =>
    new TodoItemDTO
    {
        Id = todoItem.Id,
        Name = todoItem.Name,
        IsComplete = todoItem.IsComplete
    };
```

Verify you can't post or get the secret field.

Call the web API with JavaScript

See Tutorial: Call an ASP.NET Core web API with JavaScript.

In this tutorial, you learn how to:

- Create a web API project.
- Add a model class and a database context.
- Scaffold a controller with CRUD methods.
- Configure routing, URL paths, and return values.
- Call the web API with Postman.

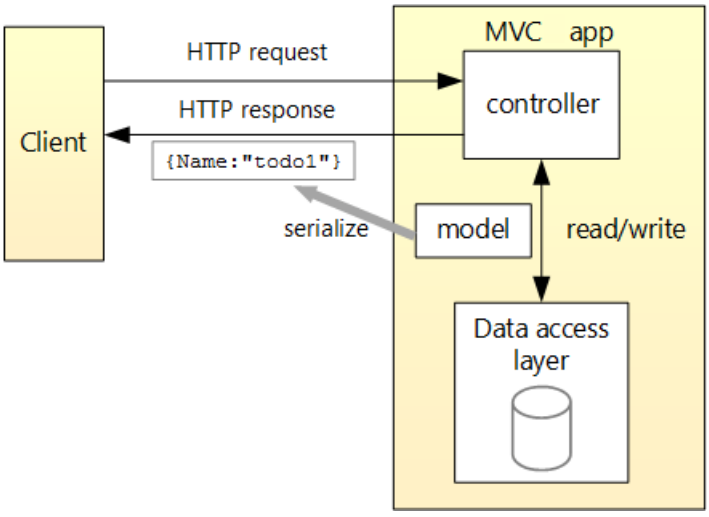
At the end, you have a web API that can manage "to-do" items stored in a database.

Overview

This tutorial creates the following API:

API	DESCRIPTION	REQUEST BODY	RESPONSE BODY
`GET /api/TodoItems`	Get all to-do items	None	Array of to-do items
`GET /api/TodoItems/{id}`	Get an item by ID	None	To-do item
`POST /api/TodoItems`	Add a new item	To-do item	To-do item
`PUT /api/TodoItems/{id}`	Update an existing item	To-do item	None
`DELETE /api/TodoItems/{id}`	Delete an item	None	None

The following diagram shows the design of the app.



Prerequisites

- Visual Studio

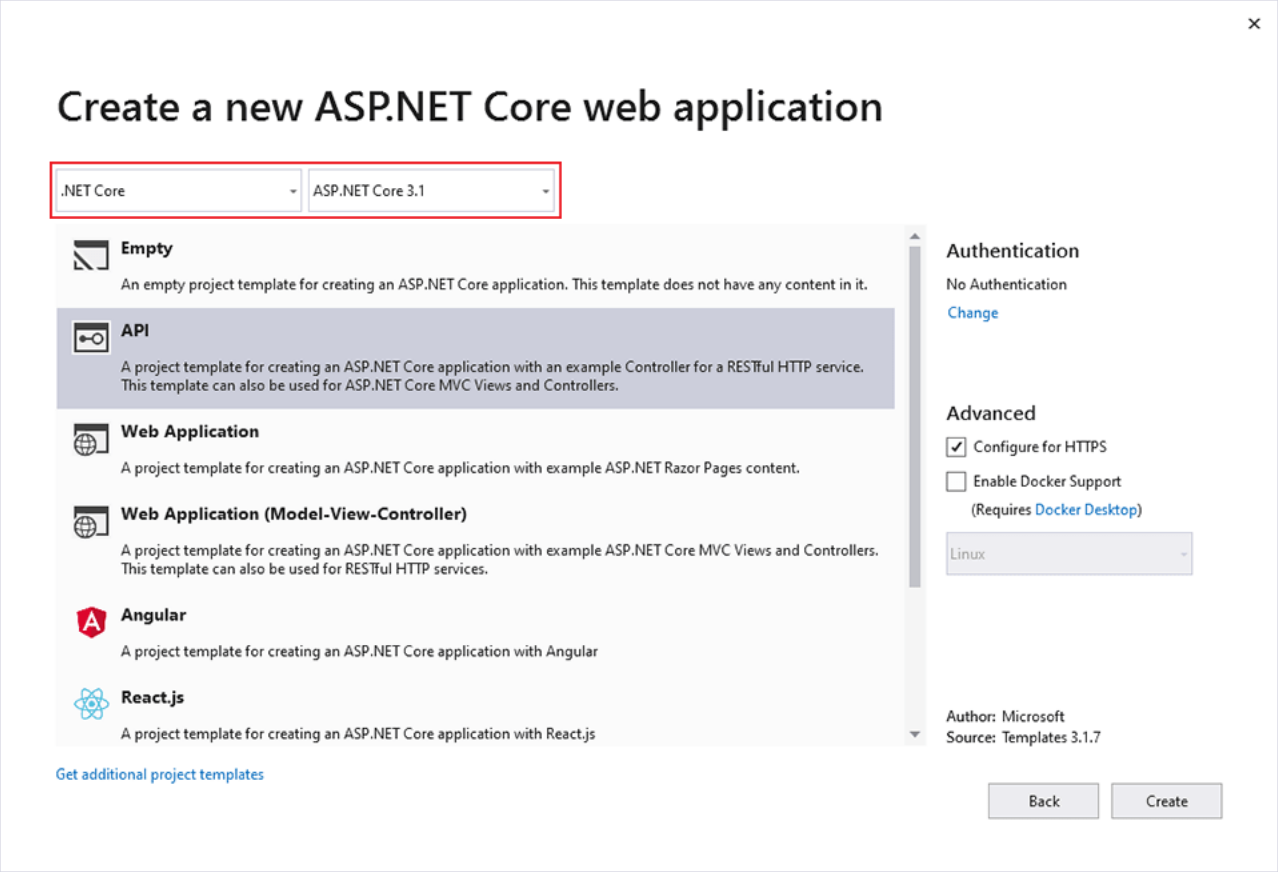
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Create a web project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the **File** menu, select **New** > **Project**.
- Select the **ASP.NET Core Web Application** template and click **Next**.
- Name the project *TodoApi* and click **Create**.
- In the **Create a new ASP.NET Core Web Application** dialog, confirm that **.NET Core** and **ASP.NET Core 3.1** are selected. Select the **API** template and click **Create**.



Test the API

The project template creates a `WeatherForecast` API. Call the `Get` method from a browser to test the app.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Press Ctrl+F5 to run the app. Visual Studio launches a browser and navigates to `https://localhost:<port>/WeatherForecast`, where `<port>` is a randomly chosen port number.

If you get a dialog box that asks if you should trust the IIS Express certificate, select **Yes**. In the **Security Warning** dialog that appears next, select **Yes**.

JSON similar to the following is returned:

```
[
    {
        "date": "2019-07-16T19:04:05.7257911-06:00",
        "temperatureC": 52,
        "temperatureF": 125,
        "summary": "Mild"
    },
    {
        "date": "2019-07-17T19:04:05.7258461-06:00",
        "temperatureC": 36,
        "temperatureF": 96,
        "summary": "Warm"
    },
    {
        "date": "2019-07-18T19:04:05.7258467-06:00",
        "temperatureC": 39,
        "temperatureF": 102,
        "summary": "Cool"
    },
    {
        "date": "2019-07-19T19:04:05.7258471-06:00",
        "temperatureC": 10,
        "temperatureF": 49,
        "summary": "Bracing"
    },
    {
        "date": "2019-07-20T19:04:05.7258474-06:00",
        "temperatureC": -1,
        "temperatureF": 31,
        "summary": "Chilly"
    }
]
```

Add a model class

A *model* is a set of classes that represent the data that the app manages. The model for this app is a single `TodoItem` class.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project. Select **Add** > **New Folder**. Name the folder *Models*.
- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoItem* and select **Add**.
- Replace the template code with the following code:

```
public class TodoItem
{
    public long Id { get; set; }
    public string Name { get; set; }
    public bool IsComplete { get; set; }
}
```

The `Id` property functions as the unique key in a relational database.

Model classes can go anywhere in the project, but the *Models* folder is used by convention.

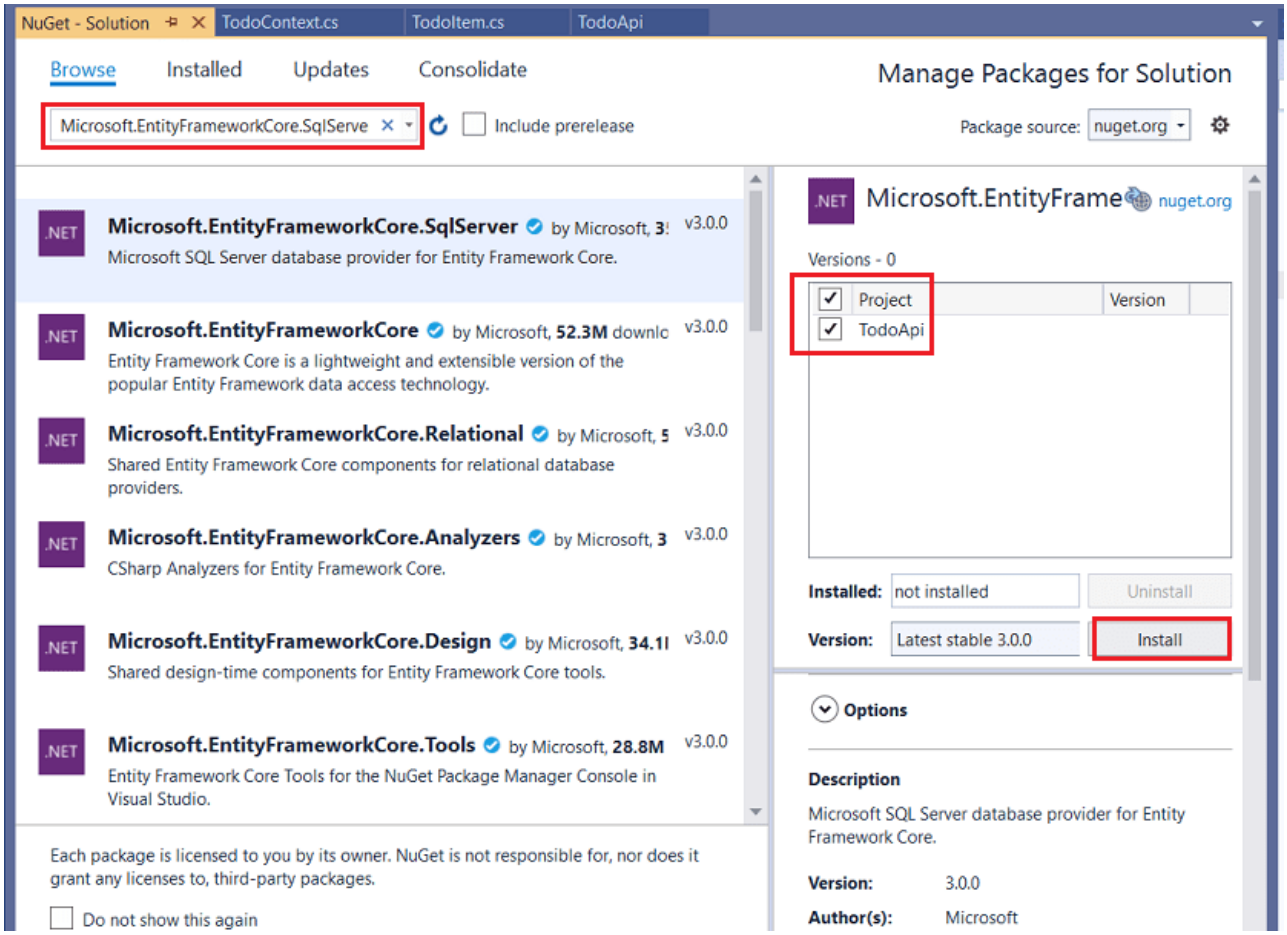
Add a database context

The *database context* is the main class that coordinates Entity Framework functionality for a data model. This class is created by deriving from the `Microsoft.EntityFrameworkCore.DbContext` class.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

Add NuGet packages

- From the **Tools** menu, select **NuGet Package Manager** > **Manage NuGet Packages for Solution**.
- Select the **Browse** tab, and then enter **Microsoft.EntityFrameworkCore.SqlServer** in the search box.
- Select **Microsoft.EntityFrameworkCore.SqlServer** in the left pane.
- Select the **Project** check box in the right pane and then select **Install**.
- Use the preceding instructions to add the **Microsoft.EntityFrameworkCore.InMemory** NuGet package.



Add the TodoContext database context

- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoContext* and click **Add**.
- Enter the following code:

```
using Microsoft.EntityFrameworkCore;

namespace TodoApi.Models
{
    public class TodoContext : DbContext
    {
        public TodoContext(DbContextOptions<TodoContext> options)
            : base(options)
        {
        }

        public DbSet<TodoItem> TodoItems { get; set; }
    }
}
```

Register the database context

In ASP.NET Core, services such as the DB context must be registered with the dependency injection (DI) container. The container provides the service to controllers.

Update *Startup.cs* with the following highlighted code:

```
// Unused usings removed
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

namespace TodoApi
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.AddDbContext<TodoContext>(opt =>
               opt.UseInMemoryDatabase("TodoList"));
            services.AddControllers();
        }

        public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }

            app.UseHttpsRedirection();

            app.UseRouting();

            app.UseAuthorization();

            app.UseEndpoints(endpoints =>
            {
                endpoints.MapControllers();
            });
        }
    }
}
```

The preceding code:

- Removes unused `using` declarations.
- Adds the database context to the DI container.
- Specifies that the database context will use an in-memory database.

Scaffold a controller

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Right-click the *Controllers* folder.
- Select **Add** > **New Scaffolded Item**.
- Select **API Controller with actions, using Entity Framework**, and then select **Add**.

- In the **Add API Controller with actions, using Entity Framework** dialog:
  - Select **TodoItem (TodoApi.Models)** in the **Model class**.
  - Select **TodoContext (TodoApi.Models)** in the **Data context class**.
  - Select **Add**.

The generated code:

- Marks the class with the `[ApiController]` attribute. This attribute indicates that the controller responds to web API requests. For information about specific behaviors that the attribute enables, see Create web APIs with ASP.NET Core.
- Uses DI to inject the database context (`TodoContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

The ASP.NET Core templates for:

- Controllers with views include `[action]` in the route template.
- API controllers don't include `[action]` in the route template.

When the `[action]` token isn't in the route template, the action name is excluded from the route. That is, the action's associated method name isn't used in the matching route.

Examine the PostTodoItem create method

Replace the return statement in the `PostTodoItem` to use the nameof operator:

```
// POST: api/TodoItems
[HttpPost]
public async Task<ActionResult<TodoItem>> PostTodoItem(TodoItem todoItem)
{
    _context.TodoItems.Add(todoItem);
    await _context.SaveChangesAsync();

    //return CreatedAtAction("GetTodoItem", new { id = todoItem.Id }, todoItem);
    return CreatedAtAction(nameof(GetTodoItem), new { id = todoItem.Id }, todoItem);
}
```

The preceding code is an HTTP POST method, as indicated by the `[HttpPost]` attribute. The method gets the value of the to-do item from the body of the HTTP request.

For more information, see Attribute routing with Http[Verb] attributes.

The CreatedAtAction method:

- Returns an HTTP 201 status code if successful. HTTP 201 is the standard response for an HTTP POST method that creates a new resource on the server.
- Adds a Location header to the response. The `Location` header specifies the URI of the newly created to-do item. For more information, see 10.2.2 201 Created.
- References the `GetTodoItem` action to create the `Location` header's URI. The C# `nameof` keyword is used to avoid hard-coding the action name in the `CreatedAtAction` call.

Install Postman

This tutorial uses Postman to test the web API.

- Install Postman
- Start the web app.
- Start Postman.

- Disable **SSL certificate verification**
  - From **File** > **Settings** (**General** tab), disable **SSL certificate verification**.

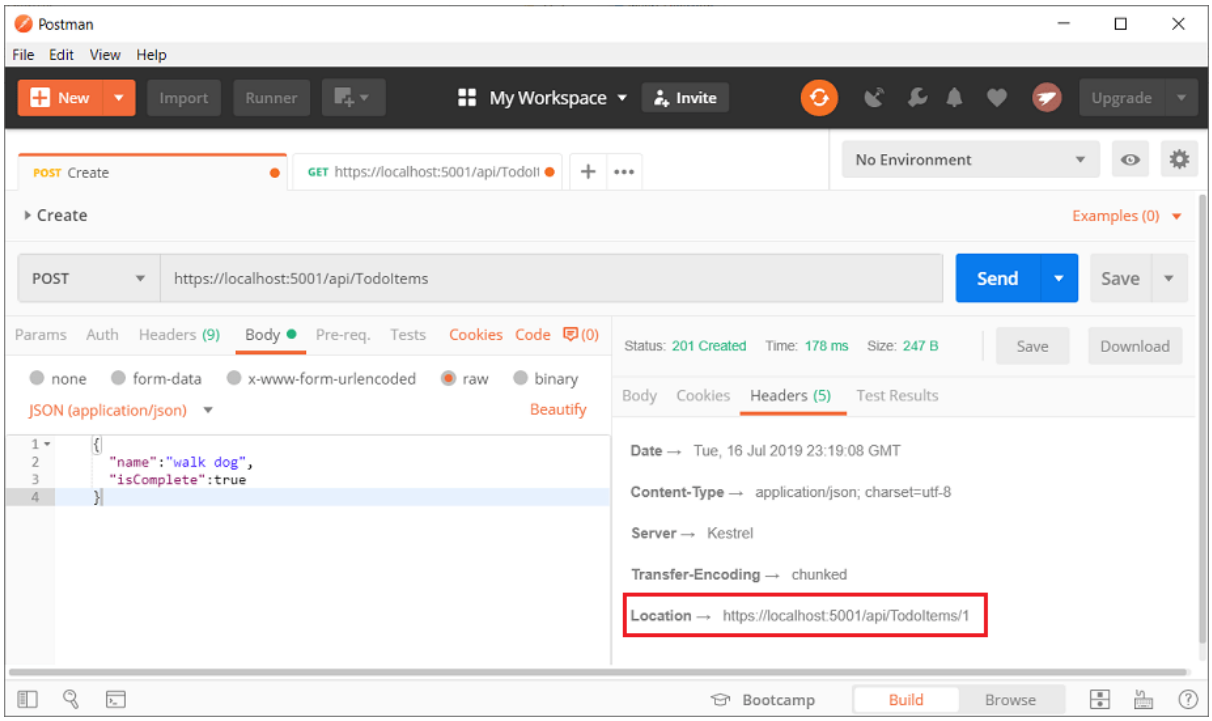
> **WARNING**
> Re-enable SSL certificate verification after testing the controller.

Test PostTodoItem with Postman

- Create a new request.
- Set the HTTP method to `POST`.
- Set the URI to `https://localhost:<port>/api/TodoItems`. For example, `https://localhost:5001/api/TodoItems`.
- Select the **Body** tab.
- Select the **raw** radio button.
- Set the type to **JSON (application/json)**.
- In the request body enter JSON for a to-do item:

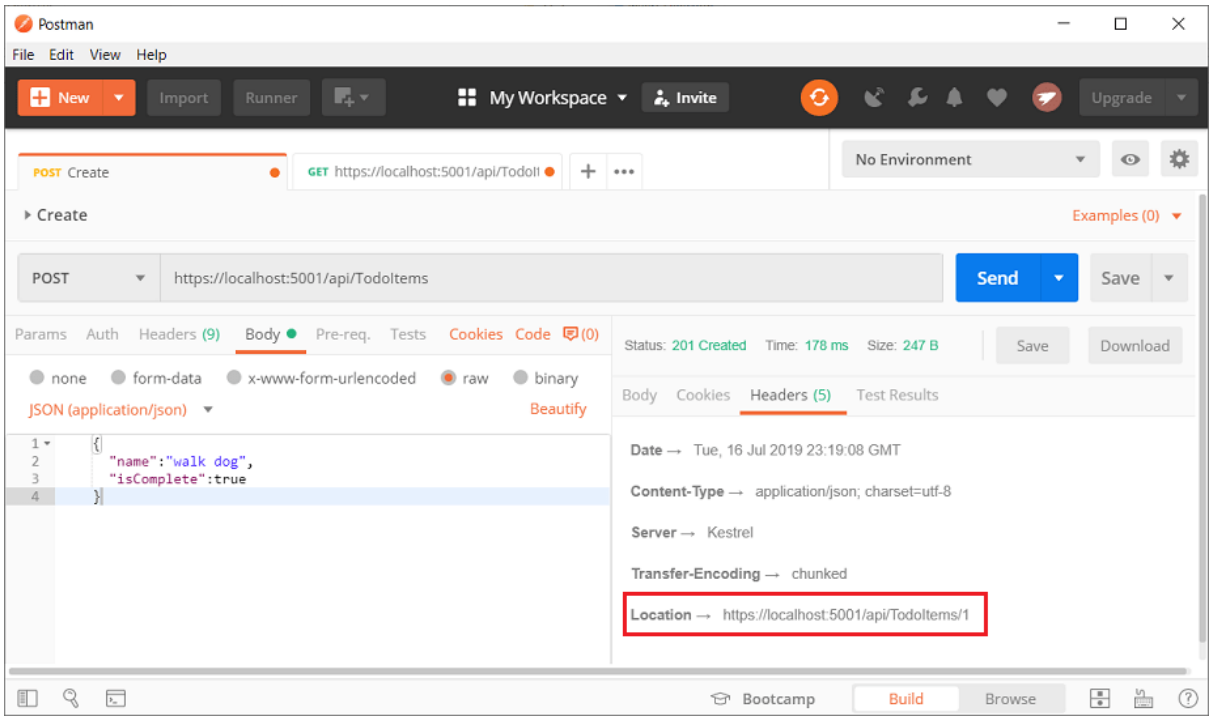
```
{
  "name":"walk dog",
  "isComplete":true
}
```

- Select **Send**.



Test the location header URI with Postman

- Select the **Headers** tab in the **Response** pane.
- Copy the **Location** header value:



- Set the HTTP method to `GET`.
- Set the URI to `https://localhost:<port>/api/TodoItems/1`. For example, `https://localhost:5001/api/TodoItems/1`.
- Select **Send**.

Examine the GET methods

These methods implement two GET endpoints:

- `GET /api/TodoItems`
- `GET /api/TodoItems/{id}`

Test the app by calling the two endpoints from a browser or Postman. For example:

- `https://localhost:5001/api/TodoItems`
- `https://localhost:5001/api/TodoItems/1`

A response similar to the following is produced by the call to `GetTodoItems`:

```
[
  {
    "id": 1,
    "name": "Item1",
    "isComplete": false
  }
]
```

Test Get with Postman

- Create a new request.
- Set the HTTP method to **GET**.
- Set the request URI to `https://localhost:<port>/api/TodoItems`. For example, `https://localhost:5001/api/TodoItems`.
- Set **Two pane view** in Postman.
- Select **Send**.

This app uses an in-memory database. If the app is stopped and started, the preceding GET request will not return any data. If no data is returned, POST data to the app.

Routing and URL paths

The `[HttpGet]` attribute denotes a method that responds to an HTTP GET request. The URL path for each method is constructed as follows:

- Start with the template string in the controller's `Route` attribute:

```
[Route("api/[controller]")]
[ApiController]
public class TodoItemsController : ControllerBase
{
    private readonly TodoContext _context;

    public TodoItemsController(TodoContext context)
    {
        _context = context;
    }
```

- Replace `[controller]` with the name of the controller, which by convention is the controller class name minus the "Controller" suffix. For this sample, the controller class name is **TodoItems**Controller, so the controller name is "TodoItems". ASP.NET Core routing is case insensitive.
- If the `[HttpGet]` attribute has a route template (for example, `[HttpGet("products")]`), append that to the path. This sample doesn't use a template. For more information, see Attribute routing with Http[Verb] attributes.

In the following `GetTodoItem` method, `"{id}"` is a placeholder variable for the unique identifier of the to-do item. When `GetTodoItem` is invoked, the value of `"{id}"` in the URL is provided to the method in its `id` parameter.

```
// GET: api/TodoItems/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

Return values

The return type of the `GetTodoItems` and `GetTodoItem` methods is ActionResult<T> type. ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

`ActionResult` return types can represent a wide range of HTTP status codes. For example, `GetTodoItem` can return two different status values:

- If no item matches the requested ID, the method returns a 404 NotFound error code.
- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an HTTP 200

response.

The PutTodoItem method

Examine the `PutTodoItem` method:

```
// PUT: api/TodoItems/5
[HttpPut("{id}")]
public async Task<IActionResult> PutTodoItem(long id, TodoItem todoItem)
{
    if (id != todoItem.Id)
    {
        return BadRequest();
    }

    _context.Entry(todoItem).State = EntityState.Modified;

    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!TodoItemExists(id))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return NoContent();
}
```

`PutTodoItem` is similar to `PostTodoItem`, except it uses HTTP PUT. The response is 204 (No Content). According to the HTTP specification, a PUT request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

If you get an error calling `PutTodoItem`, call `GET` to ensure there's an item in the database.

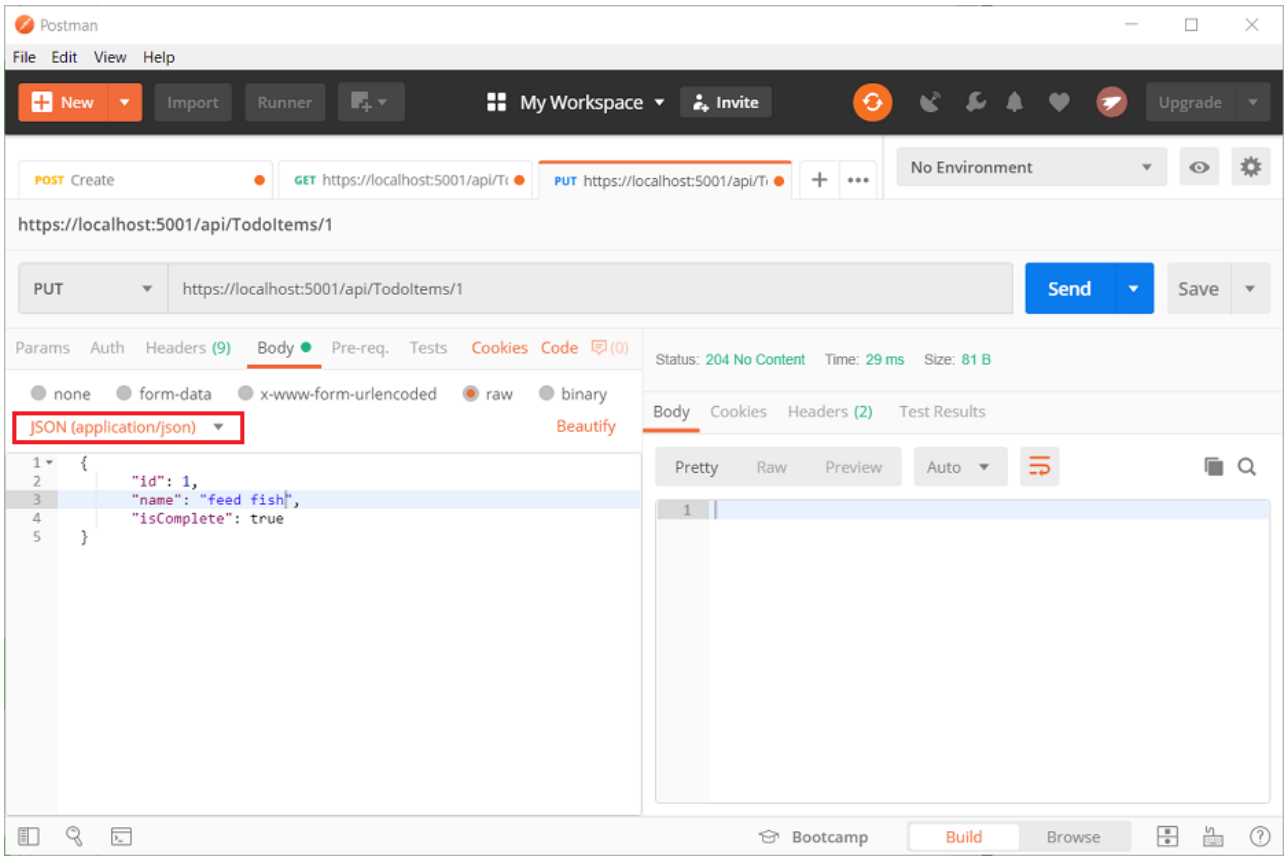
Test the PutTodoItem method

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Update the to-do item that has Id = 1 and set its name to "feed fish":

```
{
  "Id":1,
  "name":"feed fish",
  "isComplete":true
}
```

The following image shows the Postman update:



The DeleteTodoItem method

Examine the `DeleteTodoItem` method:

```
// DELETE: api/TodoItems/5
[HttpDelete("{id}")]
public async Task<ActionResult<TodoItem>> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);
    if (todoItem == null)
    {
        return NotFound();
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return todoItem;
}
```

Test the DeleteTodoItem method

Use Postman to delete a to-do item:

- Set the method to `DELETE`.
- Set the URI of the object to delete (for example `https://localhost:5001/api/TodoItems/1`).
- Select **Send**.

Prevent over-posting

Currently the sample app exposes the entire `TodoItem` object. Production apps typically limit the data that's input and returned using a subset of the model. There are multiple reasons behind this and security is a major one. The subset of a model is usually referred to as a Data Transfer Object (DTO), input model, or view model. **DTO** is used in this article.

A DTO may be used to:

- Prevent over-posting.
- Hide properties that clients are not supposed to view.
- Omit some properties in order to reduce payload size.
- Flatten object graphs that contain nested objects. Flattened object graphs can be more convenient for clients.

To demonstrate the DTO approach, update the `TodoItem` class to include a secret field:

```
public class TodoItem
{
    public long Id { get; set; }
    public string Name { get; set; }
    public bool IsComplete { get; set; }
    public string Secret { get; set; }
}
```

The secret field needs to be hidden from this app, but an administrative app could choose to expose it.

Verify you can post and get the secret field.

Create a DTO model:

```
public class TodoItemDTO
{
    public long Id { get; set; }
    public string Name { get; set; }
    public bool IsComplete { get; set; }
}
```

Update the `TodoItemsController` to use `TodoItemDTO`:

```
    [HttpGet]
    public async Task<ActionResult<IEnumerable<TodoItemDTO>>> GetTodoItems()
    {
        return await _context.TodoItems
            .Select(x => ItemToDTO(x))
            .ToListAsync();
    }

    [HttpGet("{id}")]
    public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
    {
        var todoItem = await _context.TodoItems.FindAsync(id);

        if (todoItem == null)
        {
            return NotFound();
        }

        return ItemToDTO(todoItem);
    }

    [HttpPut("{id}")]
    public async Task<IActionResult> UpdateTodoItem(long id, TodoItemDTO todoItemDTO)
    {
        if (id != todoItemDTO.Id)
        {
            return BadRequest();
        }

        var todoItem = await _context.TodoItems.FindAsync(id);
```

```
        var todoItem = await _context.TodoItems.FindAsync(id);
        if (todoItem == null)
        {
            return NotFound();
        }

        todoItem.Name = todoItemDTO.Name;
        todoItem.IsComplete = todoItemDTO.IsComplete;

        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateConcurrencyException) when (!TodoItemExists(id))
        {
            return NotFound();
        }

        return NoContent();
    }

    [HttpPost]
    public async Task<ActionResult<TodoItemDTO>> CreateTodoItem(TodoItemDTO todoItemDTO)
    {
        var todoItem = new TodoItem
        {
            IsComplete = todoItemDTO.IsComplete,
            Name = todoItemDTO.Name
        };

        _context.TodoItems.Add(todoItem);
        await _context.SaveChangesAsync();

        return CreatedAtAction(
            nameof(GetTodoItem),
            new { id = todoItem.Id },
            ItemToDTO(todoItem));
    }

    [HttpDelete("{id}")]
    public async Task<IActionResult> DeleteTodoItem(long id)
    {
        var todoItem = await _context.TodoItems.FindAsync(id);

        if (todoItem == null)
        {
            return NotFound();
        }

        _context.TodoItems.Remove(todoItem);
        await _context.SaveChangesAsync();

        return NoContent();
    }

    private bool TodoItemExists(long id) =>
         _context.TodoItems.Any(e => e.Id == id);

    private static TodoItemDTO ItemToDTO(TodoItem todoItem) =>
        new TodoItemDTO
        {
            Id = todoItem.Id,
            Name = todoItem.Name,
            IsComplete = todoItem.IsComplete
        };
}
```

Verify you can't post or get the secret field.

Call the web API with JavaScript

See Tutorial: Call an ASP.NET Core web API with JavaScript.

In this tutorial, you learn how to:

- Create a web API project.
- Add a model class and a database context.
- Add a controller.
- Add CRUD methods.
- Configure routing and URL paths.
- Specify return values.
- Call the web API with Postman.
- Call the web API with JavaScript.

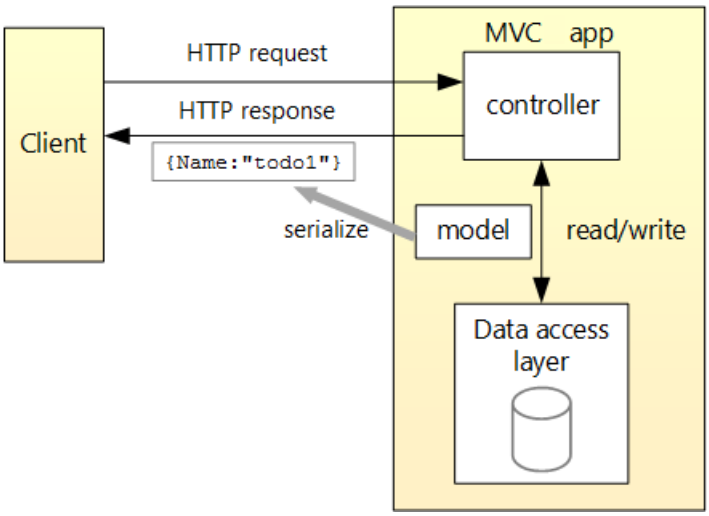
At the end, you have a web API that can manage "to-do" items stored in a relational database.

Overview 2.1

This tutorial creates the following API:

API	DESCRIPTION	REQUEST BODY	RESPONSE BODY
GET /api/TodoItems	Get all to-do items	None	Array of to-do items
GET /api/TodoItems/{id}	Get an item by ID	None	To-do item
POST /api/TodoItems	Add a new item	To-do item	To-do item
PUT /api/TodoItems/{id}	Update an existing item	To-do item	None
DELETE /api/TodoItems/{id}	Delete an item	None	None

The following diagram shows the design of the app.



Prerequisites 2.1

- Visual Studio
- Visual Studio Code

- Visual Studio for Mac

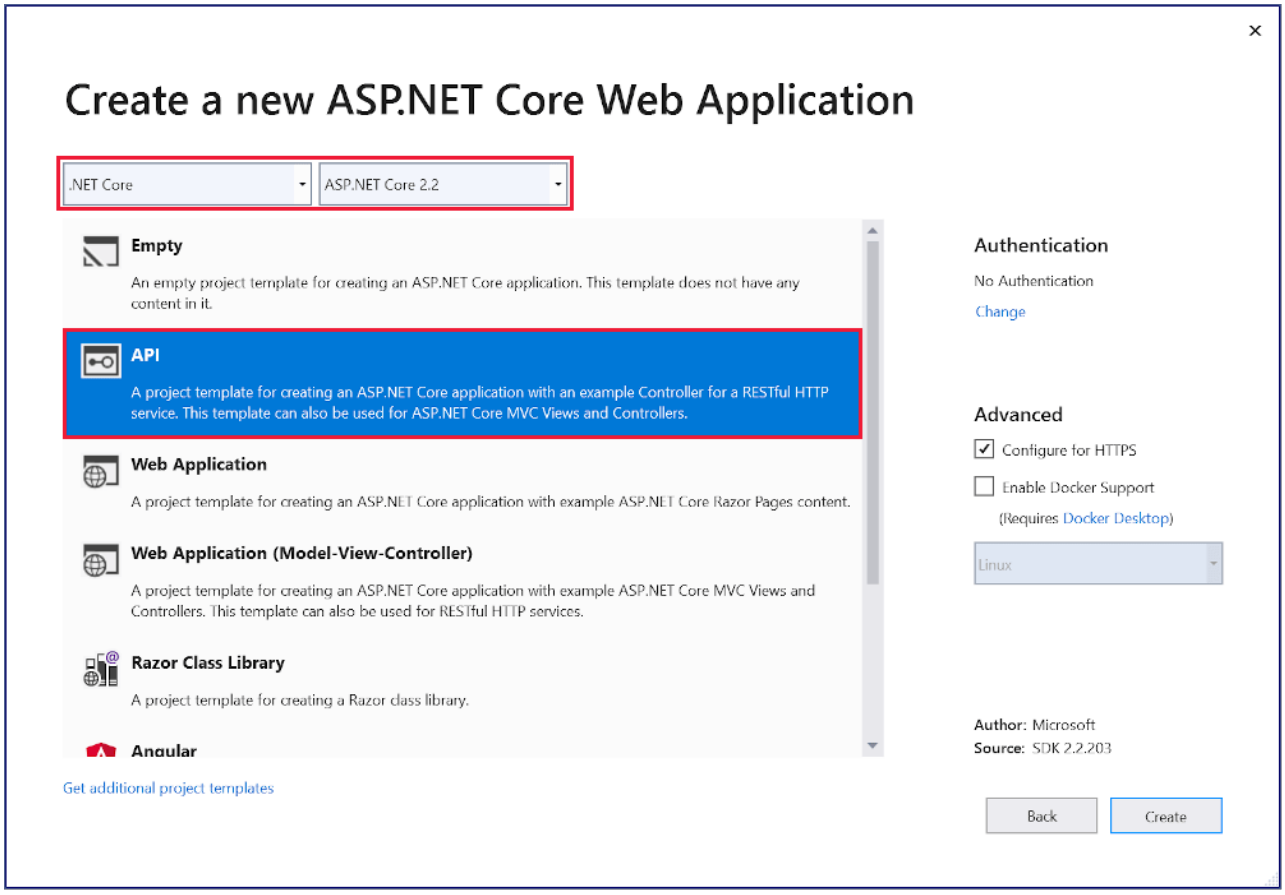
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later

> **WARNING**
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

Create a web project 2.1

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the **File** menu, select **New** > **Project**.
- Select the **ASP.NET Core Web Application** template and click **Next**.
- Name the project *TodoApi* and click **Create**.
- In the **Create a new ASP.NET Core Web Application** dialog, confirm that **.NET Core** and **ASP.NET Core 2.2** are selected. Select the **API** template and click **Create**. **Don't** select **Enable Docker Support**.



Test the API 2.1

The project template creates a `values` API. Call the `Get` method from a browser to test the app.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Press Ctrl+F5 to run the app. Visual Studio launches a browser and navigates to `https://localhost:<port>/api/values`, where `<port>` is a randomly chosen port number.

If you get a dialog box that asks if you should trust the IIS Express certificate, select **Yes**. In the **Security Warning** dialog that appears next, select **Yes**.

The following JSON is returned:

```
["value1","value2"]
```

Add a model class 2.1

A *model* is a set of classes that represent the data that the app manages. The model for this app is a single `TodoItem` class.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project. Select **Add** > **New Folder**. Name the folder *Models*.
- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoItem* and select **Add**.
- Replace the template code with the following code:

```
namespace TodoApi.Models
{
    public class TodoItem
    {
        public long Id { get; set; }
        public string Name { get; set; }
        public bool IsComplete { get; set; }
    }
}
```

The `Id` property functions as the unique key in a relational database.

Model classes can go anywhere in the project, but the *Models* folder is used by convention.

Add a database context 2.1

The *database context* is the main class that coordinates Entity Framework functionality for a data model. This class is created by deriving from the `Microsoft.EntityFrameworkCore.DbContext` class.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Right-click the *Models* folder and select **Add** > **Class**. Name the class *TodoContext* and click **Add**.
- Replace the template code with the following code:

```
using Microsoft.EntityFrameworkCore;

namespace TodoApi.Models
{
    public class TodoContext : DbContext
    {
        public TodoContext(DbContextOptions<TodoContext> options)
            : base(options)
        {
        }

        public DbSet<TodoItem> TodoItems { get; set; }
    }
}
```

Register the database context 2.1

In ASP.NET Core, services such as the DB context must be registered with the dependency injection (DI) container. The container provides the service to controllers.

Update *Startup.cs* with the following highlighted code:

```
// Unused usings removed
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using TodoApi.Models;

namespace TodoApi
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        // This method gets called by the runtime. Use this method to add services to the
        //container.
        public void ConfigureServices(IServiceCollection services)
        {
            services.AddDbContext<TodoContext>(opt =>
                opt.UseInMemoryDatabase("TodoList"));
            services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
        }

        // This method gets called by the runtime. Use this method to configure the HTTP
        //request pipeline.
        public void Configure(IApplicationBuilder app, IHostingEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                // The default HSTS value is 30 days. You may want to change this for
                // production scenarios, see https://aka.ms/aspnetcore-hsts.
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseMvc();
        }
    }
}
```

The preceding code:

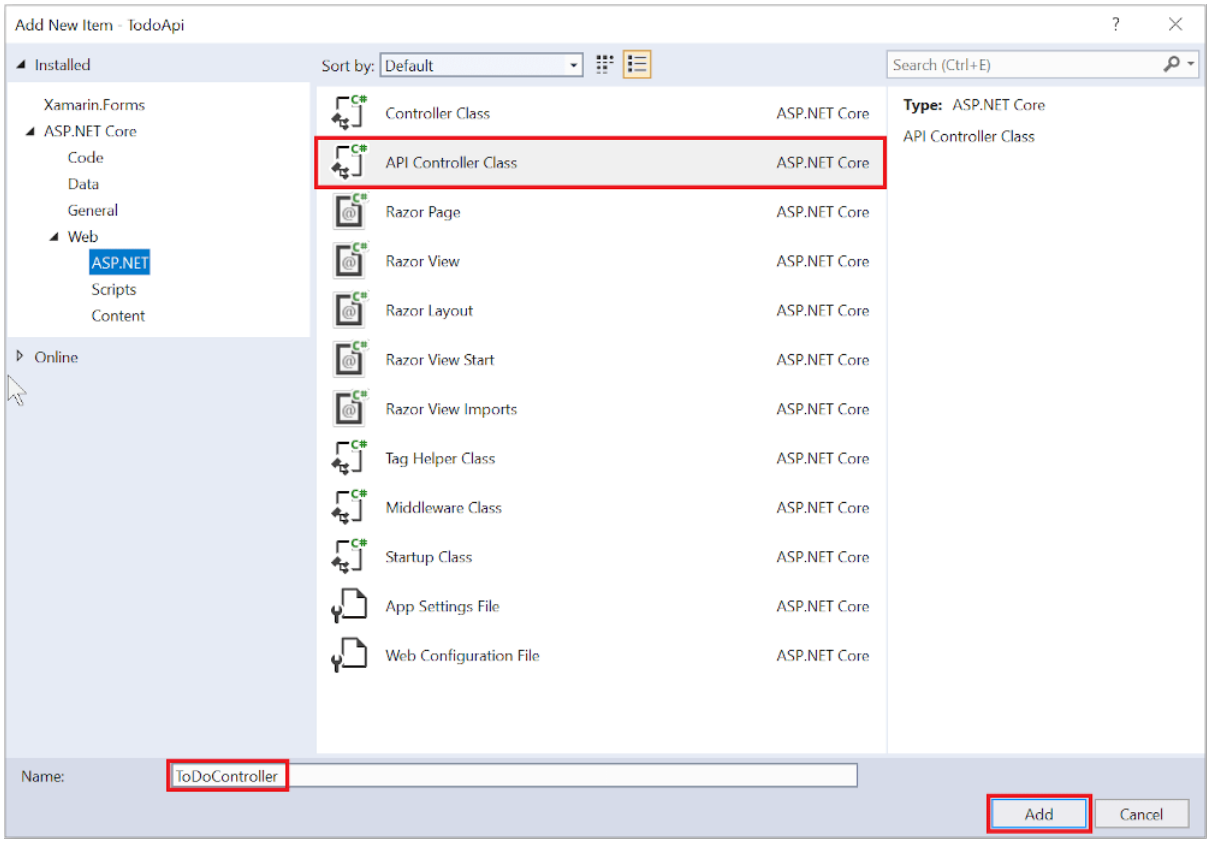
- Removes unused `using` declarations.
- Adds the database context to the DI container.
- Specifies that the database context will use an in-memory database.

Add a controller 2.1

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- Right-click the *Controllers* folder.
- Select **Add** > **New Item**.

- In the **Add New Item** dialog, select the **API Controller Class** template.
- Name the class *TodoController*, and select **Add**.



- Replace the template code with the following code:

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using TodoApi.Models;

namespace TodoApi.Controllers
{
    [Route("api/[controller]")]
    [ApiController]
    public class TodoController : ControllerBase
    {
        private readonly TodoContext _context;

        public TodoController(TodoContext context)
        {
            _context = context;

            if (_context.TodoItems.Count() == 0)
            {
                // Create a new TodoItem if collection is empty,
                // which means you can't delete all TodoItems.
                _context.TodoItems.Add(new TodoItem { Name = "Item1" });
                _context.SaveChanges();
            }
        }
    }
}
```

The preceding code:

- Defines an API controller class without methods.
- Marks the class with the `[ApiController]` attribute. This attribute indicates that the controller responds to web API requests. For information about specific behaviors that the attribute enables, see Create web APIs with ASP.NET Core.
- Uses DI to inject the database context (`TodoContext`) into the controller. The database context is used in each of the CRUD methods in the controller.
- Adds an item named `Item1` to the database if the database is empty. This code is in the constructor, so it runs every time there's a new HTTP request. If you delete all items, the constructor creates `Item1` again the next time an API method is called. So it may look like the deletion didn't work when it actually did work.

Add Get methods 2.1

To provide an API that retrieves to-do items, add the following methods to the `TodoController` class:

```
// GET: api/Todo
[HttpGet]
public async Task<ActionResult<IEnumerable<TodoItem>>> GetTodoItems()
{
    return await _context.TodoItems.ToListAsync();
}

// GET: api/Todo/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

These methods implement two GET endpoints:

- `GET /api/todo`
- `GET /api/todo/{id}`

Stop the app if it's still running. Then run it again to include the latest changes.

Test the app by calling the two endpoints from a browser. For example:

- `https://localhost:<port>/api/todo`
- `https://localhost:<port>/api/todo/1`

The following HTTP response is produced by the call to `GetTodoItems` :

```
[
  {
    "id": 1,
    "name": "Item1",
    "isComplete": false
  }
]
```

Routing and URL paths 2.1

The `[HttpGet]` attribute denotes a method that responds to an HTTP GET request. The URL path for each method is constructed as follows:

- Start with the template string in the controller's `Route` attribute:

```
namespace TodoApi.Controllers
{
    [Route("api/[controller]")]
    [ApiController]
    public class TodoController : ControllerBase
    {
        private readonly TodoContext _context;
```

- Replace `[controller]` with the name of the controller, which by convention is the controller class name minus the "Controller" suffix. For this sample, the controller class name is **Todo**Controller, so the controller name is "todo". ASP.NET Core routing is case insensitive.
- If the `[HttpGet]` attribute has a route template (for example, `[HttpGet("products")]`), append that to the path. This sample doesn't use a template. For more information, see Attribute routing with Http[Verb] attributes.

In the following `GetTodoItem` method, `"{id}"` is a placeholder variable for the unique identifier of the to-do item. When `GetTodoItem` is invoked, the value of `"{id}"` in the URL is provided to the method in its `id` parameter.

```
// GET: api/Todo/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

Return values 2.1

The return type of the `GetTodoItems` and `GetTodoItem` methods is ActionResult<T> type. ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

`ActionResult` return types can represent a wide range of HTTP status codes. For example, `GetTodoItem` can return two different status values:

- If no item matches the requested ID, the method returns a 404 NotFound error code.
- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an HTTP 200 response.

Test the GetTodoItems method 2.1

This tutorial uses Postman to test the web API.

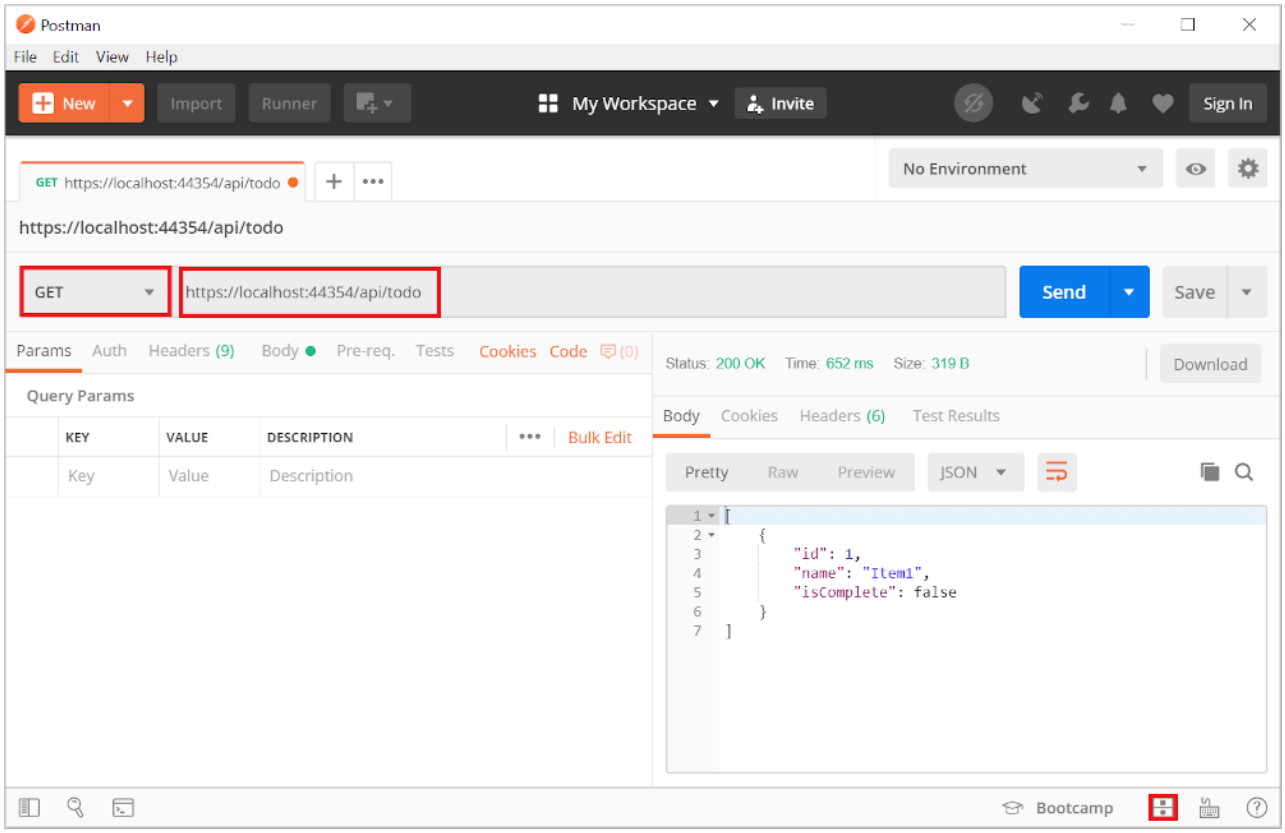
- Install Postman.
- Start the web app.
- Start Postman.
- Disable **SSL certificate verification**.

- Visual Studio
- Visual Studio Code / Visual Studio for Mac

- From **File** > **Settings** (**General** tab), disable **SSL certificate verification**.

> **WARNING**
> Re-enable SSL certificate verification after testing the controller.

- Create a new request.
  - Set the HTTP method to **GET**.
  - Set the request URI to `https://localhost:<port>/api/todo`. For example, `https://localhost:5001/api/todo`.
- Set **Two pane view** in Postman.
- Select **Send**.



Add a Create method 2.1

Add the following `PostTodoItem` method inside of *Controllers/TodoController.cs*:

```
// POST: api/Todo
[HttpPost]
public async Task<ActionResult<TodoItem>> PostTodoItem(TodoItem item)
{
    _context.TodoItems.Add(item);
    await _context.SaveChangesAsync();

    return CreatedAtAction(nameof(GetTodoItem), new { id = item.Id }, item);
}
```

The preceding code is an HTTP POST method, as indicated by the `[HttpPost]` attribute. The method gets the value of the to-do item from the body of the HTTP request.

The `CreatedAtAction` method:

- Returns an HTTP 201 status code, if successful. HTTP 201 is the standard response for an HTTP POST method that creates a new resource on the server.
- Adds a `Location` header to the response. The `Location` header specifies the URI of the newly created to-do item. For more information, see 10.2.2 201 Created.
- References the `GetTodoItem` action to create the `Location` header's URI. The C# `nameof` keyword is used to avoid hard-coding the action name in the `CreatedAtAction` call.

```
// GET: api/Todo/5
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

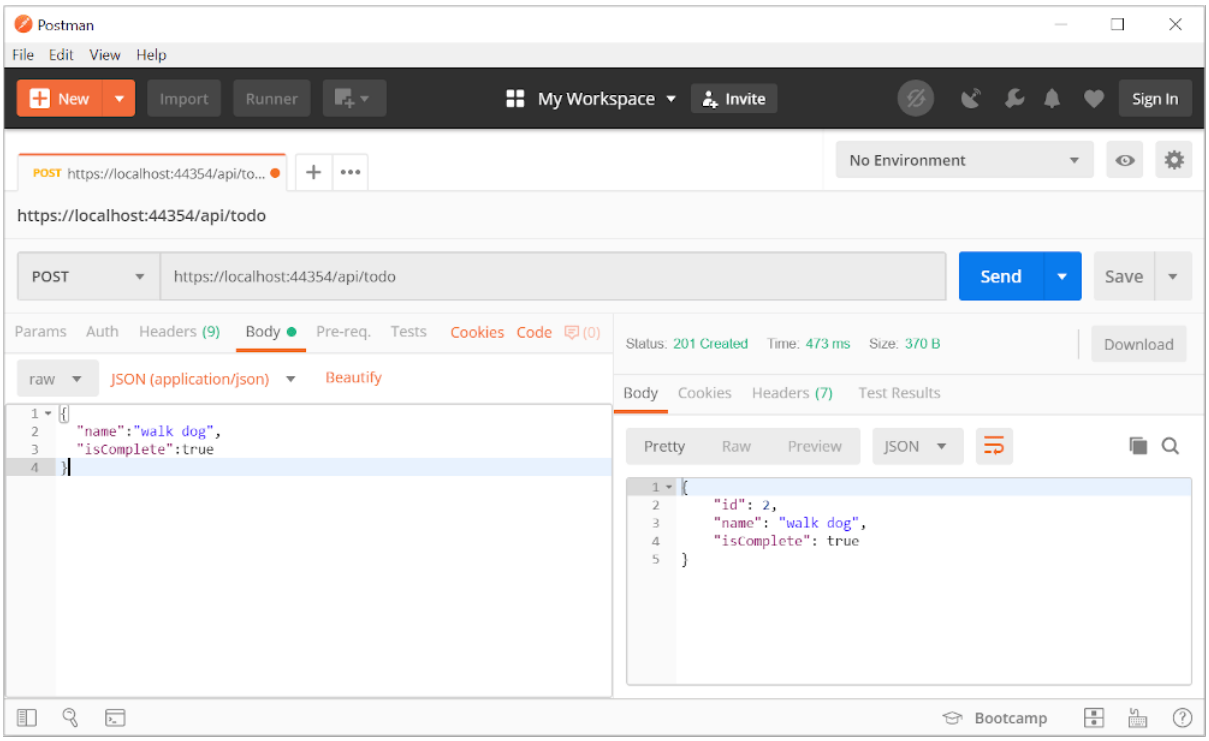
    return todoItem;
}
```

Test the PostTodoItem method 2.1

- Build the project.
- In Postman, set the HTTP method to `POST`.
- Set the URI to `https://localhost:<port>/api/TodoItem`. For example, `https://localhost:5001/api/TodoItem`.
- Select the **Body** tab.
- Select the **raw** radio button.
- Set the type to **JSON (application/json)**.
- In the request body enter JSON for a to-do item:

```
{
  "name":"walk dog",
  "isComplete":true
}
```

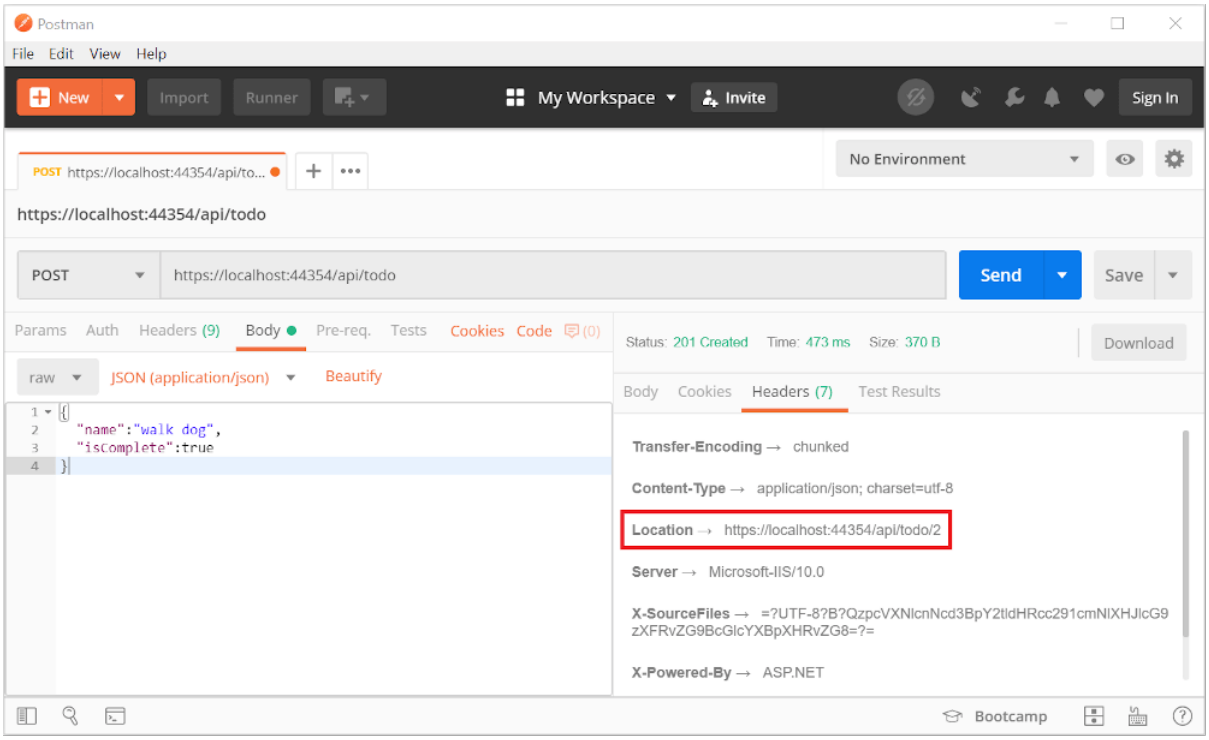
- Select **Send**.



If you get a 405 Method Not Allowed error, it's probably the result of not compiling the project after adding the `PostTodoItem` method.

Test the location header URI 2.1

- Select the **Headers** tab in the **Response** pane.
- Copy the **Location** header value:



- Set the method to GET. * Set the URI to `https://localhost:<port>/api/TodoItems/2`. For example, `https://localhost:5001/api/TodoItems/2`.
- Select **Send**.

Add a PutTodoItem method 2.1

Add the following `PutTodoItem` method:

```
// PUT: api/Todo/5
[HttpPut("{id}")]
public async Task<IActionResult> PutTodoItem(long id, TodoItem item)
{
    if (id != item.Id)
    {
        return BadRequest();
    }

    _context.Entry(item).State = EntityState.Modified;
    await _context.SaveChangesAsync();

    return NoContent();
}
```

`PutTodoItem` is similar to `PostTodoItem`, except it uses HTTP PUT. The response is 204 (No Content). According to the HTTP specification, a PUT request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

If you get an error calling `PutTodoItem`, call `GET` to ensure there's an item in the database.

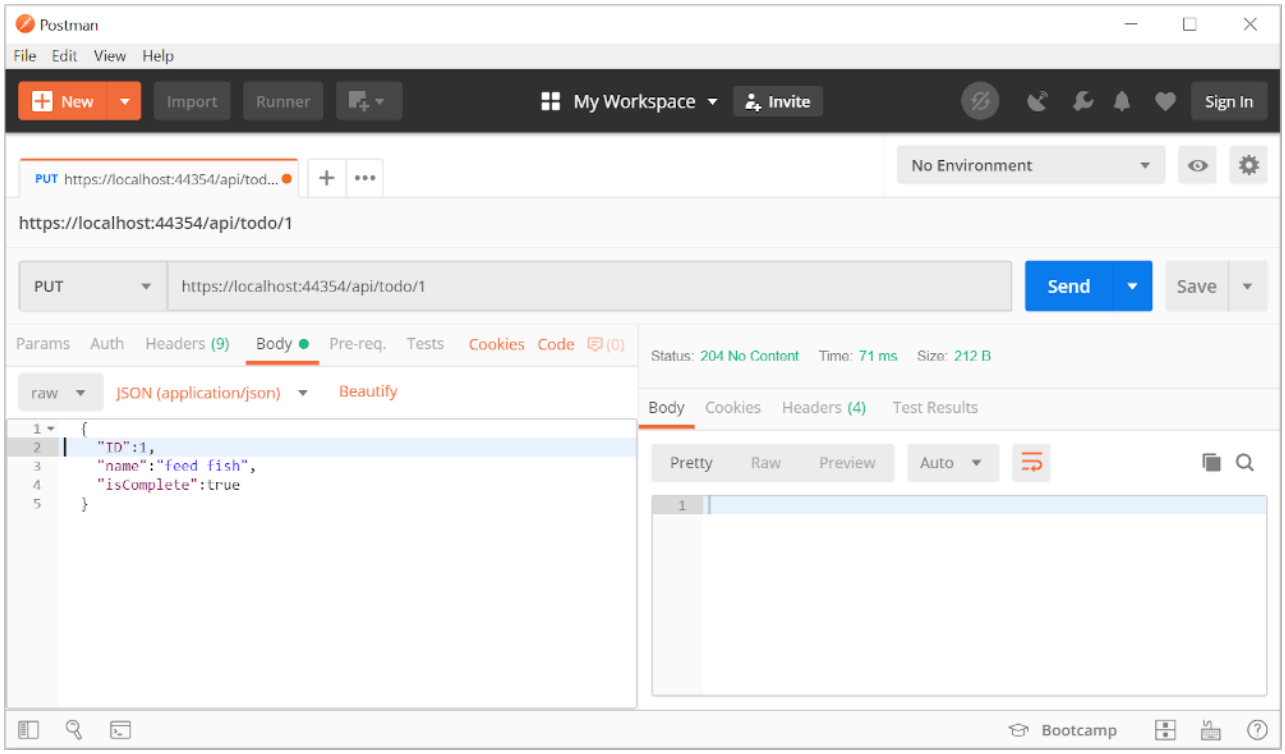
Test the PutTodoItem method 2.1

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Update the to-do item that has Id = 1 and set its name to "feed fish":

```
{
  "Id":1,
  "name":"feed fish",
  "isComplete":true
}
```

The following image shows the Postman update:



Add a DeleteTodoItem method 2.1

Add the following `DeleteTodoItem` method:

```
// DELETE: api/Todo/5
[HttpDelete("{id}")]
public async Task<IActionResult> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return NoContent();
}
```

The `DeleteTodoItem` response is 204 (No Content).

Test the DeleteTodoItem method 2.1

Use Postman to delete a to-do item:

- Set the method to `DELETE`.
- Set the URI of the object to delete (for example, `https://localhost:5001/api/todo/1`).
- Select **Send**.

The sample app allows you to delete all the items. However, when the last item is deleted, a new one is created by the model class constructor the next time the API is called.

Call the web API with JavaScript 2.1

In this section, an HTML page is added that uses JavaScript to call the web API. jQuery initiates the request. JavaScript updates the page with the details from the web API's response.

Configure the app to serve static files and enable default file mapping by updating *Startup.cs* with the following highlighted code:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        // The default HSTS value is 30 days. You may want to change this for
        // production scenarios, see https://aka.ms/aspnetcore-hsts.
        app.UseHsts();
    }

    app.UseDefaultFiles();
    app.UseStaticFiles();
    app.UseHttpsRedirection();
    app.UseMvc();
}
```

Create a *wwwroot* folder in the project directory.

Add an HTML file named *index.html* to the *wwwroot* directory. Replace its contents with the following markup:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="UTF-8">
    <title>To-do CRUD</title>
    <style>
        input[type='submit'], button, [aria-label] {
            cursor: pointer;
        }

        #spoiler {
            display: none;
        }

        table {
            font-family: Arial, sans-serif;
            border: 1px solid;
            border-collapse: collapse;
        }

        th {
            background-color: #0066CC;
            color: white;
        }

        td {
            border: 1px solid;
            padding: 5px;
        }
    </style>
</head>
<body>
    <h1>To-do CRUD</h1>
    <h3>Add</h3>
    <form action="javascript:void(0);" method="POST" onsubmit="addItem()">
        <input type="text" id="add-name" placeholder="New to-do">
        <input type="submit" value="Add">
    </form>

    <div id="spoiler">
        <h3>Edit</h3>
        <form class="my-form">
            <input type="hidden" id="edit-id">
            <input type="checkbox" id="edit-isComplete">
            <input type="text" id="edit-name">
            <input type="submit" value="Save">
            <a onclick="closeInput()" aria-label="Close">&#10006;</a>
        </form>
    </div>

    <p id="counter"></p>

    <table>
        <tr>
            <th>Is Complete</th>
            <th>Name</th>
            <th></th>
            <th></th>
        </tr>
        <tbody id="todos"></tbody>
    </table>

    <script src="https://code.jquery.com/jquery-3.3.1.min.js"
            integrity="sha256-FgpCb/KJQlLNfOu91ta32o/NMZxltwRo8QtmkMRdAu8="
```

```
            integrity="sha256-[illegible]"
            crossorigin="anonymous"></script>
    <script src="site.js"></script>
</body>
</html>
```

Add a JavaScript file named *site.js* to the *wwwroot* directory. Replace its contents with the following code:

```
const uri = "api/todo";
let todos = null;
function getCount(data) {
  const el = $("#counter");
  let name = "to-do";
  if (data) {
    if (data > 1) {
      name = "to-dos";
    }
    el.text(data + " " + name);
  } else {
    el.text("No " + name);
  }
}

$(document).ready(function() {
  getData();
});

function getData() {
  $.ajax({
    type: "GET",
    url: uri,
    cache: false,
    success: function(data) {
      const tBody = $("#todos");

      $(tBody).empty();

      getCount(data.length);

      $.each(data, function(key, item) {
        const tr = $("<tr></tr>")
          .append(
            $("<td></td>").append(
              $("<input/>", {
                type: "checkbox",
                disabled: true,
                checked: item.isComplete
              })
            )
          )
          .append($("<td></td>").text(item.name))
          .append(
            $("<td></td>").append(
              $("<button>Edit</button>").on("click", function() {
                editItem(item.id);
              })
            )
          )
          .append(
            $("<td></td>").append(
              $("<button>Delete</button>").on("click", function() {
                deleteItem(item.id);
              })
            )
          );

        tr.appendTo(tBody);
      });
```

```
      todos = data;
    }
  });
}

function addItem() {
  const item = {
    name: $("#add-name").val(),
    isComplete: false
  };

  $.ajax({
    type: "POST",
    accepts: "application/json",
    url: uri,
    contentType: "application/json",
    data: JSON.stringify(item),
    error: function(jqXHR, textStatus, errorThrown) {
      alert("Something went wrong!");
    },
    success: function(result) {
      getData();
      $("#add-name").val("");
    }
  });
}

function deleteItem(id) {
  $.ajax({
    url: uri + "/" + id,
    type: "DELETE",
    success: function(result) {
      getData();
    }
  });
}

function editItem(id) {
  $.each(todos, function(key, item) {
    if (item.id === id) {
      $("#edit-name").val(item.name);
      $("#edit-id").val(item.id);
      $("#edit-isComplete")[0].checked = item.isComplete;
    }
  });
  $("#spoiler").css({ display: "block" });
}

$(".my-form").on("submit", function() {
  const item = {
    name: $("#edit-name").val(),
    isComplete: $("#edit-isComplete").is(":checked"),
    id: $("#edit-id").val()
  };

  $.ajax({
    url: uri + "/" + $("#edit-id").val(),
    type: "PUT",
    accepts: "application/json",
    contentType: "application/json",
    data: JSON.stringify(item),
    success: function(result) {
      getData();
    }
  });

  closeInput();
  return false;
```

```
  return false;
});

function closeInput() {
  $("#spoiler").css({ display: "none" });
}
```

A change to the ASP.NET Core project's launch settings may be required to test the HTML page locally:

- Open *Properties\launchSettings.json*.
- Remove the `launchUrl` property to force the app to open at *index.html*—the project's default file.

This sample calls all of the CRUD methods of the web API. Following are explanations of the calls to the API.

Get a list of to-do items 2.1

jQuery sends an HTTP GET request to the web API, which returns JSON representing an array of to-do items. The `success` callback function is invoked if the request succeeds. In the callback, the DOM is updated with the to-do information.

```
$(document).ready(function() {
  getData();
});

function getData() {
  $.ajax({
    type: "GET",
    url: uri,
    cache: false,
    success: function(data) {
      const tBody = $("#todos");

      $(tBody).empty();

      getCount(data.length);

      $.each(data, function(key, item) {
        const tr = $("<tr></tr>")
          .append(
            $("<td></td>").append(
              $("<input/>", {
                type: "checkbox",
                disabled: true,
                checked: item.isComplete
              })
            )
          )
          .append($("<td></td>").text(item.name))
          .append(
            $("<td></td>").append(
              $("<button>Edit</button>").on("click", function() {
                editItem(item.id);
              })
            )
          )
          .append(
            $("<td></td>").append(
              $("<button>Delete</button>").on("click", function() {
                deleteItem(item.id);
              })
            )
          );

        tr.appendTo(tBody);
      });

      todos = data;
    }
  });
}
```

Add a to-do item 2.1

jQuery sends an HTTP POST request with the to-do item in the request body. The `accepts` and `contentType` options are set to `application/json` to specify the media type being received and sent. The to-do item is converted to JSON by using JSON.stringify. When the API returns a successful status code, the `getData` function is invoked to update the HTML table.

```
function addItem() {
  const item = {
    name: $("#add-name").val(),
    isComplete: false
  };

  $.ajax({
    type: "POST",
    accepts: "application/json",
    url: uri,
    contentType: "application/json",
    data: JSON.stringify(item),
    error: function(jqXHR, textStatus, errorThrown) {
      alert("Something went wrong!");
    },
    success: function(result) {
      getData();
      $("#add-name").val("");
    }
  });
}
```

Update a to-do item 2.1

Updating a to-do item is similar to adding one. The `url` changes to add the unique identifier of the item, and the `type` is `PUT`.

```
$.ajax({
  url: uri + "/" + $("#edit-id").val(),
  type: "PUT",
  accepts: "application/json",
  contentType: "application/json",
  data: JSON.stringify(item),
  success: function(result) {
    getData();
  }
});
```

Delete a to-do item 2.1

Deleting a to-do item is accomplished by setting the `type` on the AJAX call to `DELETE` and specifying the item's unique identifier in the URL.

```
$.ajax({
  url: uri + "/" + id,
  type: "DELETE",
  success: function(result) {
    getData();
  }
});
```

Add authentication support to a web API 2.1

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Azure Active Directory
- Azure Active Directory B2C (Azure AD B2C)
- IdentityServer4

IdentityServer4 is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. IdentityServer4 enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

For more information, see Welcome to IdentityServer4.

Additional resources 2.1

View or download sample code for this tutorial. See how to download.

Create a web API with ASP.NET Core and MongoDB

9/22/2020 • 21 minutes to read • Edit Online

By Pratik Khandelwal and Scott Addie

This tutorial creates a web API that performs Create, Read, Update, and Delete (CRUD) operations on a MongoDB NoSQL database.

In this tutorial, you learn how to:

- Configure MongoDB
- Create a MongoDB database
- Define a MongoDB collection and schema
- Perform MongoDB CRUD operations from a web API
- Customize JSON serialization

View or download sample code (how to download)

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- .NET Core SDK 3.0 or later
- Visual Studio 2019 with the **ASP.NET and web development** workload
- MongoDB

Configure MongoDB

If using Windows, MongoDB is installed at *C:\Program Files\MongoDB* by default. Add *C:\Program Files\MongoDB\Server\<version_number>\bin* to the `Path` environment variable. This change enables MongoDB access from anywhere on your development machine.

Use the mongo Shell in the following steps to create a database, make collections, and store documents. For more information on mongo Shell commands, see Working with the mongo Shell.

1. Choose a directory on your development machine for storing the data. For example, *C:\BooksData* on Windows. Create the directory if it doesn't exist. The mongo Shell doesn't create new directories.

2. Open a command shell. Run the following command to connect to MongoDB on default port 27017. Remember to replace `<data_directory_path>` with the directory you chose in the previous step.

   ```
   mongod --dbpath <data_directory_path>
   ```

3. Open another command shell instance. Connect to the default test database by running the following command:

   ```
   mongo
   ```

4. Run the following in a command shell:

```
use BookstoreDb
```

   If it doesn't already exist, a database named *BookstoreDb* is created. If the database does exist, its connection is opened for transactions.

5. Create a `Books` collection using following command:

```
db.createCollection('Books')
```

   The following result is displayed:

```
{ "ok" : 1 }
```

6. Define a schema for the `Books` collection and insert two documents using the following command:

```
db.Books.insertMany([{'Name':'Design Patterns','Price':54.93,'Category':'Computers','Author':'Ralph
Johnson'}, {'Name':'Clean Code','Price':43.15,'Category':'Computers','Author':'Robert C. Martin'}])
```

   The following result is displayed:

```
{
  "acknowledged" : true,
  "insertedIds" : [
    ObjectId("5bfd996f7b8e48dc15ff215d"),
    ObjectId("5bfd996f7b8e48dc15ff215e")
  ]
}
```

   NOTE

   The ID's shown in this article will not match the IDs when you run this sample.

7. View the documents in the database using the following command:

```
db.Books.find({}).pretty()
```

   The following result is displayed:

```
{
  "_id" : ObjectId("5bfd996f7b8e48dc15ff215d"),
  "Name" : "Design Patterns",
  "Price" : 54.93,
  "Category" : "Computers",
  "Author" : "Ralph Johnson"
}
{
  "_id" : ObjectId("5bfd996f7b8e48dc15ff215e"),
  "Name" : "Clean Code",
  "Price" : 43.15,
  "Category" : "Computers",
  "Author" : "Robert C. Martin"
}
```

The schema adds an autogenerated `_id` property of type `ObjectId` for each document.

The database is ready. You can start creating the ASP.NET Core web API.

Create the ASP.NET Core web API project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

1. Go to **File** > **New** > **Project**.
2. Select the **ASP.NET Core Web Application** project type, and select **Next**.
3. Name the project *BooksApi*, and select **Create**.
4. Select the **.NET Core** target framework and **ASP.NET Core 3.0**. Select the **API** project template, and select **Create**.
5. Visit the NuGet Gallery: MongoDB.Driver to determine the latest stable version of the .NET driver for MongoDB. In the **Package Manager Console** window, navigate to the project root. Run the following command to install the .NET driver for MongoDB:

```
Install-Package MongoDB.Driver -Version {VERSION}
```

Add an entity model

1. Add a *Models* directory to the project root.
2. Add a `Book` class to the *Models* directory with the following code:

```
using MongoDB.Bson;
using MongoDB.Bson.Serialization.Attributes;

namespace BooksApi.Models
{
    public class Book
    {
        [BsonId]
        [BsonRepresentation(BsonType.ObjectId)]
        public string Id { get; set; }

        [BsonElement("Name")]
        public string BookName { get; set; }

        public decimal Price { get; set; }

        public string Category { get; set; }

        public string Author { get; set; }
    }
}
```

In the preceding class, the `Id` property:

- Is required for mapping the Common Language Runtime (CLR) object to the MongoDB collection.
- Is annotated with `[BsonId]` to designate this property as the document's primary key.
- Is annotated with `[BsonRepresentation(BsonType.ObjectId)]` to allow passing the parameter as type `string` instead of an ObjectId structure. Mongo handles the conversion from `string` to `ObjectId`.

The `BookName` property is annotated with the `[BsonElement]` attribute. The attribute's value of `Name` represents the property name in the MongoDB collection.

Add a configuration model

1. Add the following database configuration values to *appsettings.json*:

```
{
  "BookstoreDatabaseSettings": {
    "BooksCollectionName": "Books",
    "ConnectionString": "mongodb://localhost:27017",
    "DatabaseName": "BookstoreDb"
  },
  "Logging": {
    "IncludeScopes": false,
    "Debug": {
      "LogLevel": {
        "Default": "Warning"
      }
    },
    "Console": {
      "LogLevel": {
        "Default": "Warning"
      }
    }
  }
}
```

2. Add a *BookstoreDatabaseSettings.cs* file to the *Models* directory with the following code:

```
namespace BooksApi.Models
{
    public class BookstoreDatabaseSettings : IBookstoreDatabaseSettings
    {
        public string BooksCollectionName { get; set; }
        public string ConnectionString { get; set; }
        public string DatabaseName { get; set; }
    }

    public interface IBookstoreDatabaseSettings
    {
        string BooksCollectionName { get; set; }
        string ConnectionString { get; set; }
        string DatabaseName { get; set; }
    }
}
```

The preceding `BookstoreDatabaseSettings` class is used to store the *appsettings.json* file's `BookstoreDatabaseSettings` property values. The JSON and C# property names are named identically to ease the mapping process.

3. Add the following highlighted code to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    // requires using Microsoft.Extensions.Options
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddControllers();
}
```

In the preceding code:

- The configuration instance to which the *appsettings.json* file's `BookstoreDatabaseSettings` section binds is registered in the Dependency Injection (DI) container. For example, a `BookstoreDatabaseSettings` object's `ConnectionString` property is populated with the `BookstoreDatabaseSettings:ConnectionString` property in *appsettings.json*.
- The `IBookstoreDatabaseSettings` interface is registered in DI with a singleton service lifetime. When injected, the interface instance resolves to a `BookstoreDatabaseSettings` object.

4. Add the following code to the top of *Startup.cs* to resolve the `BookstoreDatabaseSettings` and `IBookstoreDatabaseSettings` references:

```
using BooksApi.Models;
```

Add a CRUD operations service

1. Add a *Services* directory to the project root.
2. Add a `BookService` class to the *Services* directory with the following code:

```
using BooksApi.Models;
using MongoDB.Driver;
using System.Collections.Generic;
using System.Linq;

namespace BooksApi.Services
{
    public class BookService
    {
        private readonly IMongoCollection<Book> _books;

        public BookService(IBookstoreDatabaseSettings settings)
        {
            var client = new MongoClient(settings.ConnectionString);
            var database = client.GetDatabase(settings.DatabaseName);

            _books = database.GetCollection<Book>(settings.BooksCollectionName);
        }

        public List<Book> Get() =>
            _books.Find(book => true).ToList();

        public Book Get(string id) =>
            _books.Find<Book>(book => book.Id == id).FirstOrDefault();

        public Book Create(Book book)
        {
            _books.InsertOne(book);
            return book;
        }

        public void Update(string id, Book bookIn) =>
            _books.ReplaceOne(book => book.Id == id, bookIn);

        public void Remove(Book bookIn) =>
            _books.DeleteOne(book => book.Id == bookIn.Id);

        public void Remove(string id) =>
            _books.DeleteOne(book => book.Id == id);
    }
}
```

In the preceding code, an `IBookstoreDatabaseSettings` instance is retrieved from DI via constructor injection. This technique provides access to the *appsettings.json* configuration values that were added in the Add a configuration model section.

3. Add the following highlighted code to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddSingleton<BookService>();

    services.AddControllers();
}
```

In the preceding code, the `BookService` class is registered with DI to support constructor injection in consuming classes. The singleton service lifetime is most appropriate because `BookService` takes a direct

dependency on `MongoClient`. Per the official Mongo Client reuse guidelines, `MongoClient` should be registered in DI with a singleton service lifetime.

4. Add the following code to the top of *Startup.cs* to resolve the `BookService` reference:

```
using BooksApi.Services;
```

The `BookService` class uses the following `MongoDB.Driver` members to perform CRUD operations against the database:

- MongoClient: Reads the server instance for performing database operations. The constructor of this class is provided the MongoDB connection string:

```
public BookService(IBookstoreDatabaseSettings settings)
{
    var client = new MongoClient(settings.ConnectionString);
    var database = client.GetDatabase(settings.DatabaseName);

    _books = database.GetCollection<Book>(settings.BooksCollectionName);
}
```

- IMongoDatabase: Represents the Mongo database for performing operations. This tutorial uses the generic GetCollection<TDocument>(collection) method on the interface to gain access to data in a specific collection. Perform CRUD operations against the collection after this method is called. In the `GetCollection<TDocument>(collection)` method call:
  - `collection` represents the collection name.
  - `TDocument` represents the CLR object type stored in the collection.

`GetCollection<TDocument>(collection)` returns a MongoCollection object representing the collection. In this tutorial, the following methods are invoked on the collection:

- DeleteOne: Deletes a single document matching the provided search criteria.
- Find<TDocument>: Returns all documents in the collection matching the provided search criteria.
- InsertOne: Inserts the provided object as a new document in the collection.
- ReplaceOne: Replaces the single document matching the provided search criteria with the provided object.

Add a controller

Add a `BooksController` class to the *Controllers* directory with the following code:

```
using BooksApi.Models;
using BooksApi.Services;
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;

namespace BooksApi.Controllers
{
    [Route("api/[controller]")]
    [ApiController]
    public class BooksController : ControllerBase
    {
        private readonly BookService _bookService;

        public BooksController(BookService bookService)
        {
            _bookService = bookService;
        }
```

```
        [HttpGet]
        public ActionResult<List<Book>> Get() =>
            _bookService.Get();

        [HttpGet("{id:length(24)}", Name = "GetBook")]
        public ActionResult<Book> Get(string id)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            return book;
        }

        [HttpPost]
        public ActionResult<Book> Create(Book book)
        {
            _bookService.Create(book);

            return CreatedAtRoute("GetBook", new { id = book.Id.ToString() }, book);
        }

        [HttpPut("{id:length(24)}")]
        public IActionResult Update(string id, Book bookIn)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            _bookService.Update(id, bookIn);

            return NoContent();
        }

        [HttpDelete("{id:length(24)}")]
        public IActionResult Delete(string id)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            _bookService.Remove(book.Id);

            return NoContent();
        }
    }
}
```

The preceding web API controller:

- Uses the `BookService` class to perform CRUD operations.
- Contains action methods to support GET, POST, PUT, and DELETE HTTP requests.
- Calls CreatedAtRoute in the `Create` action method to return an HTTP 201 response. Status code 201 is the standard response for an HTTP POST method that creates a new resource on the server. `CreatedAtRoute` also adds a `Location` header to the response. The `Location` header specifies the URI of the newly created book.

Test the web API

1. Build and run the app.
2. Navigate to `http://localhost:<port>/api/books` to test the controller's parameterless `Get` action method. The following JSON response is displayed:

```
[
  {
    "id":"5bfd996f7b8e48dc15ff215d",
    "bookName":"Design Patterns",
    "price":54.93,
    "category":"Computers",
    "author":"Ralph Johnson"
  },
  {
    "id":"5bfd996f7b8e48dc15ff215e",
    "bookName":"Clean Code",
    "price":43.15,
    "category":"Computers",
    "author":"Robert C. Martin"
  }
]
```

3. Navigate to `http://localhost:<port>/api/books/{id here}` to test the controller's overloaded `Get` action method. The following JSON response is displayed:

```
{
  "id":"{ID}",
  "bookName":"Clean Code",
  "price":43.15,
  "category":"Computers",
  "author":"Robert C. Martin"
}
```

Configure JSON serialization options

There are two details to change about the JSON responses returned in the Test the web API section:

- The property names' default camel casing should be changed to match the Pascal casing of the CLR object's property names.
- The `bookName` property should be returned as `Name`.

To satisfy the preceding requirements, make the following changes:

1. JSON.NET has been removed from ASP.NET shared framework. Add a package reference to `Microsoft.AspNetCore.Mvc.NewtonsoftJson`.
2. In `Startup.ConfigureServices`, chain the following highlighted code on to the `AddControllers` method call:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddSingleton<BookService>();

    services.AddControllers()
        .AddNewtonsoftJson(options => options.UseMemberCasing());
}
```

With the preceding change, property names in the web API's serialized JSON response match their corresponding property names in the CLR object type. For example, the `Book` class's `Author` property serializes as `Author`.

3. In *Models/Book.cs*, annotate the `BookName` property with the following `[JsonProperty]` attribute:

```
[BsonElement("Name")]
[JsonProperty("Name")]
public string BookName { get; set; }
```

The `[JsonProperty]` attribute's value of `Name` represents the property name in the web API's serialized JSON response.

4. Add the following code to the top of *Models/Book.cs* to resolve the `[JsonProperty]` attribute reference:

```
using Newtonsoft.Json;
```

5. Repeat the steps defined in the Test the web API section. Notice the difference in JSON property names.

This tutorial creates a web API that performs Create, Read, Update, and Delete (CRUD) operations on a MongoDB NoSQL database.

In this tutorial, you learn how to:

- Configure MongoDB
- Create a MongoDB database
- Define a MongoDB collection and schema
- Perform MongoDB CRUD operations from a web API
- Customize JSON serialization

View or download sample code (how to download)

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- .NET Core SDK 2.2
- Visual Studio 2019 with the **ASP.NET and web development** workload
- MongoDB

Configure MongoDB

If using Windows, MongoDB is installed at *C:\Program Files\MongoDB* by default. Add *C:\Program Files\MongoDB\Server\<version_number>\bin* to the `Path` environment variable. This change enables MongoDB access from anywhere on your development machine.

Use the mongo Shell in the following steps to create a database, make collections, and store documents. For more information on mongo Shell commands, see Working with the mongo Shell.

1. Choose a directory on your development machine for storing the data. For example, *C:\BooksData* on Windows. Create the directory if it doesn't exist. The mongo Shell doesn't create new directories.

2. Open a command shell. Run the following command to connect to MongoDB on default port 27017. Remember to replace `<data_directory_path>` with the directory you chose in the previous step.

   ```
   mongod --dbpath <data_directory_path>
   ```

3. Open another command shell instance. Connect to the default test database by running the following command:

   ```
   mongo
   ```

4. Run the following in a command shell:

   ```
   use BookstoreDb
   ```

   If it doesn't already exist, a database named *BookstoreDb* is created. If the database does exist, its connection is opened for transactions.

5. Create a `Books` collection using following command:

   ```
   db.createCollection('Books')
   ```

   The following result is displayed:

   ```
   { "ok" : 1 }
   ```

6. Define a schema for the `Books` collection and insert two documents using the following command:

   ```
   db.Books.insertMany([{'Name':'Design Patterns','Price':54.93,'Category':'Computers','Author':'Ralph
   Johnson'}, {'Name':'Clean Code','Price':43.15,'Category':'Computers','Author':'Robert C. Martin'}])
   ```

   The following result is displayed:

   ```
   {
     "acknowledged" : true,
     "insertedIds" : [
       ObjectId("5bfd996f7b8e48dc15ff215d"),
       ObjectId("5bfd996f7b8e48dc15ff215e")
     ]
   }
   ```

> **NOTE**
> The ID's shown in this article will not match the IDs when you run this sample.

7. View the documents in the database using the following command:

```
db.Books.find({}).pretty()
```

   The following result is displayed:

```
{
  "_id" : ObjectId("5bfd996f7b8e48dc15ff215d"),
  "Name" : "Design Patterns",
  "Price" : 54.93,
  "Category" : "Computers",
  "Author" : "Ralph Johnson"
}
{
  "_id" : ObjectId("5bfd996f7b8e48dc15ff215e"),
  "Name" : "Clean Code",
  "Price" : 43.15,
  "Category" : "Computers",
  "Author" : "Robert C. Martin"
}
```

   The schema adds an autogenerated `_id` property of type `ObjectId` for each document.

The database is ready. You can start creating the ASP.NET Core web API.

Create the ASP.NET Core web API project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

1. Go to **File** > **New** > **Project**.
2. Select the **ASP.NET Core Web Application** project type, and select **Next**.
3. Name the project *BooksApi*, and select **Create**.
4. Select the **.NET Core** target framework and **ASP.NET Core 2.2**. Select the **API** project template, and select **Create**.
5. Visit the NuGet Gallery: MongoDB.Driver to determine the latest stable version of the .NET driver for MongoDB. In the **Package Manager Console** window, navigate to the project root. Run the following command to install the .NET driver for MongoDB:

```
Install-Package MongoDB.Driver -Version {VERSION}
```

Add an entity model

1. Add a *Models* directory to the project root.
2. Add a `Book` class to the *Models* directory with the following code:

```
using MongoDB.Bson;
using MongoDB.Bson.Serialization.Attributes;

namespace BooksApi.Models
{
    public class Book
    {
        [BsonId]
        [BsonRepresentation(BsonType.ObjectId)]
        public string Id { get; set; }

        [BsonElement("Name")]
        public string BookName { get; set; }

        public decimal Price { get; set; }

        public string Category { get; set; }

        public string Author { get; set; }
    }
}
```

In the preceding class, the `Id` property:

- Is required for mapping the Common Language Runtime (CLR) object to the MongoDB collection.
- Is annotated with `[BsonId]` to designate this property as the document's primary key.
- Is annotated with `[BsonRepresentation(BsonType.ObjectId)]` to allow passing the parameter as type `string` instead of an ObjectId structure. Mongo handles the conversion from `string` to `ObjectId`.

The `BookName` property is annotated with the `[BsonElement]` attribute. The attribute's value of `Name` represents the property name in the MongoDB collection.

Add a configuration model

1. Add the following database configuration values to *appsettings.json*:

```
{
  "BookstoreDatabaseSettings": {
    "BooksCollectionName": "Books",
    "ConnectionString": "mongodb://localhost:27017",
    "DatabaseName": "BookstoreDb"
  },
  "Logging": {
    "IncludeScopes": false,
    "Debug": {
      "LogLevel": {
        "Default": "Warning"
      }
    },
    "Console": {
      "LogLevel": {
        "Default": "Warning"
      }
    }
  }
}
```

2. Add a *BookstoreDatabaseSettings.cs* file to the *Models* directory with the following code:

```
namespace BooksApi.Models
{
    public class BookstoreDatabaseSettings : IBookstoreDatabaseSettings
    {
        public string BooksCollectionName { get; set; }
        public string ConnectionString { get; set; }
        public string DatabaseName { get; set; }
    }

    public interface IBookstoreDatabaseSettings
    {
        string BooksCollectionName { get; set; }
        string ConnectionString { get; set; }
        string DatabaseName { get; set; }
    }
}
```

The preceding `BookstoreDatabaseSettings` class is used to store the *appsettings.json* file's `BookstoreDatabaseSettings` property values. The JSON and C# property names are named identically to ease the mapping process.

3. Add the following highlighted code to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

In the preceding code:

- The configuration instance to which the *appsettings.json* file's `BookstoreDatabaseSettings` section binds is registered in the Dependency Injection (DI) container. For example, a `BookstoreDatabaseSettings` object's `ConnectionString` property is populated with the `BookstoreDatabaseSettings:ConnectionString` property in *appsettings.json*.
- The `IBookstoreDatabaseSettings` interface is registered in DI with a singleton service lifetime. When injected, the interface instance resolves to a `BookstoreDatabaseSettings` object.

4. Add the following code to the top of *Startup.cs* to resolve the `BookstoreDatabaseSettings` and `IBookstoreDatabaseSettings` references:

```
using BooksApi.Models;
```

Add a CRUD operations service

1. Add a *Services* directory to the project root.
2. Add a `BookService` class to the *Services* directory with the following code:

```
using BooksApi.Models;
using MongoDB.Driver;
using System.Collections.Generic;
using System.Linq;

namespace BooksApi.Services
{
    public class BookService
    {
        private readonly IMongoCollection<Book> _books;

        public BookService(IBookstoreDatabaseSettings settings)
        {
            var client = new MongoClient(settings.ConnectionString);
            var database = client.GetDatabase(settings.DatabaseName);

            _books = database.GetCollection<Book>(settings.BooksCollectionName);
        }

        public List<Book> Get() =>
            _books.Find(book => true).ToList();

        public Book Get(string id) =>
            _books.Find<Book>(book => book.Id == id).FirstOrDefault();

        public Book Create(Book book)
        {
            _books.InsertOne(book);
            return book;
        }

        public void Update(string id, Book bookIn) =>
            _books.ReplaceOne(book => book.Id == id, bookIn);

        public void Remove(Book bookIn) =>
            _books.DeleteOne(book => book.Id == bookIn.Id);

        public void Remove(string id) =>
            _books.DeleteOne(book => book.Id == id);
    }
}
```

In the preceding code, an `IBookstoreDatabaseSettings` instance is retrieved from DI via constructor injection. This technique provides access to the *appsettings.json* configuration values that were added in the Add a configuration model section.

3. Add the following highlighted code to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddSingleton<BookService>();

    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

In the preceding code, the `BookService` class is registered with DI to support constructor injection in

consuming classes. The singleton service lifetime is most appropriate because `BookService` takes a direct dependency on `MongoClient`. Per the official Mongo Client reuse guidelines, `MongoClient` should be registered in DI with a singleton service lifetime.

4. Add the following code to the top of *Startup.cs* to resolve the `BookService` reference:

```
using BooksApi.Services;
```

The `BookService` class uses the following `MongoDB.Driver` members to perform CRUD operations against the database:

- MongoClient: Reads the server instance for performing database operations. The constructor of this class is provided the MongoDB connection string:

```
public BookService(IBookstoreDatabaseSettings settings)
{
    var client = new MongoClient(settings.ConnectionString);
    var database = client.GetDatabase(settings.DatabaseName);

    _books = database.GetCollection<Book>(settings.BooksCollectionName);
}
```

- IMongoDatabase: Represents the Mongo database for performing operations. This tutorial uses the generic GetCollection<TDocument>(collection) method on the interface to gain access to data in a specific collection. Perform CRUD operations against the collection after this method is called. In the `GetCollection<TDocument>(collection)` method call:
  - `collection` represents the collection name.
  - `TDocument` represents the CLR object type stored in the collection.

`GetCollection<TDocument>(collection)` returns a MongoCollection object representing the collection. In this tutorial, the following methods are invoked on the collection:

- DeleteOne: Deletes a single document matching the provided search criteria.
- Find<TDocument>: Returns all documents in the collection matching the provided search criteria.
- InsertOne: Inserts the provided object as a new document in the collection.
- ReplaceOne: Replaces the single document matching the provided search criteria with the provided object.

Add a controller

Add a `BooksController` class to the *Controllers* directory with the following code:

```
using BooksApi.Models;
using BooksApi.Services;
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;

namespace BooksApi.Controllers
{
    [Route("api/[controller]")]
    [ApiController]
    public class BooksController : ControllerBase
    {
        private readonly BookService _bookService;

        public BooksController(BookService bookService)
        {
            _bookService = bookService;
```

```
        }

        [HttpGet]
        public ActionResult<List<Book>> Get() =>
            _bookService.Get();

        [HttpGet("{id:length(24)}", Name = "GetBook")]
        public ActionResult<Book> Get(string id)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            return book;
        }

        [HttpPost]
        public ActionResult<Book> Create(Book book)
        {
            _bookService.Create(book);

            return CreatedAtRoute("GetBook", new { id = book.Id.ToString() }, book);
        }

        [HttpPut("{id:length(24)}")]
        public IActionResult Update(string id, Book bookIn)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            _bookService.Update(id, bookIn);

            return NoContent();
        }

        [HttpDelete("{id:length(24)}")]
        public IActionResult Delete(string id)
        {
            var book = _bookService.Get(id);

            if (book == null)
            {
                return NotFound();
            }

            _bookService.Remove(book.Id);

            return NoContent();
        }
    }
}
```

The preceding web API controller:

- Uses the `BookService` class to perform CRUD operations.
- Contains action methods to support GET, POST, PUT, and DELETE HTTP requests.
- Calls CreatedAtRoute in the `Create` action method to return an HTTP 201 response. Status code 201 is the standard response for an HTTP POST method that creates a new resource on the server. `CreatedAtRoute` also

adds a `Location` header to the response. The `Location` header specifies the URI of the newly created book.

Test the web API

1. Build and run the app.
2. Navigate to `http://localhost:<port>/api/books` to test the controller's parameterless `Get` action method. The following JSON response is displayed:

```
[
  {
    "id":"5bfd996f7b8e48dc15ff215d",
    "bookName":"Design Patterns",
    "price":54.93,
    "category":"Computers",
    "author":"Ralph Johnson"
  },
  {
    "id":"5bfd996f7b8e48dc15ff215e",
    "bookName":"Clean Code",
    "price":43.15,
    "category":"Computers",
    "author":"Robert C. Martin"
  }
]
```

3. Navigate to `http://localhost:<port>/api/books/{id here}` to test the controller's overloaded `Get` action method. The following JSON response is displayed:

```
{
  "id":"{ID}",
  "bookName":"Clean Code",
  "price":43.15,
  "category":"Computers",
  "author":"Robert C. Martin"
}
```

Configure JSON serialization options

There are two details to change about the JSON responses returned in the Test the web API section:

- The property names' default camel casing should be changed to match the Pascal casing of the CLR object's property names.
- The `bookName` property should be returned as `Name`.

To satisfy the preceding requirements, make the following changes:

1. In `Startup.ConfigureServices`, chain the following highlighted code on to the `AddMvc` method call:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<BookstoreDatabaseSettings>(
        Configuration.GetSection(nameof(BookstoreDatabaseSettings)));

    services.AddSingleton<IBookstoreDatabaseSettings>(sp =>
        sp.GetRequiredService<IOptions<BookstoreDatabaseSettings>>().Value);

    services.AddSingleton<BookService>();

    services.AddMvc()
            .AddJsonOptions(options => options.UseMemberCasing())
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
}
```

With the preceding change, property names in the web API's serialized JSON response match their corresponding property names in the CLR object type. For example, the `Book` class's `Author` property serializes as `Author`.

2. In *Models/Book.cs*, annotate the `BookName` property with the following `[JsonProperty]` attribute:

```
[BsonElement("Name")]
[JsonProperty("Name")]
public string BookName { get; set; }
```

The `[JsonProperty]` attribute's value of `Name` represents the property name in the web API's serialized JSON response.

3. Add the following code to the top of *Models/Book.cs* to resolve the `[JsonProperty]` attribute reference:

```
using Newtonsoft.Json;
```

4. Repeat the steps defined in the Test the web API section. Notice the difference in JSON property names.

Add authentication support to a web API

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Azure Active Directory
- Azure Active Directory B2C (Azure AD B2C)
- IdentityServer4

IdentityServer4 is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. IdentityServer4 enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

For more information, see Welcome to IdentityServer4.

Tutorial: Call an ASP.NET Core web API with JavaScript

9/22/2020 • 5 minutes to read • Edit Online

By Rick Anderson

This tutorial shows how to call an ASP.NET Core web API with JavaScript, using the Fetch API.

For ASP.NET Core 2.2, see the 2.2 version of Call the web API with JavaScript.

Prerequisites

- Complete Tutorial: Create a web API
- Familiarity with CSS, HTML, and JavaScript

Call the web API with JavaScript

In this section, you'll add an HTML page containing forms for creating and managing to-do items. Event handlers are attached to elements on the page. The event handlers result in HTTP requests to the web API's action methods. The Fetch API's `fetch` function initiates each HTTP request.

The `fetch` function returns a Promise object, which contains an HTTP response represented as a `Response` object. A common pattern is to extract the JSON response body by invoking the `json` function on the `Response` object. JavaScript updates the page with the details from the web API's response.

The simplest `fetch` call accepts a single parameter representing the route. A second parameter, known as the `init` object, is optional. `init` is used to configure the HTTP request.

1. Configure the app to serve static files and enable default file mapping. The following highlighted code is needed in the `Configure` method of *Startup.cs*:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.UseDefaultFiles();
    app.UseStaticFiles();

    app.UseHttpsRedirection();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
    });
}
```

2. Create a *wwwroot* folder in the project root.

3. Create a *js* folder inside of the *wwwroot* folder.

4. Add an HTML file named *index.html* to the *wwwroot* folder. Replace the contents of *index.html* with the following markup:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="UTF-8">
    <title>To-do CRUD</title>
    <link rel="stylesheet" href="css/site.css" />
</head>
<body>
    <h1>To-do CRUD</h1>
    <h3>Add</h3>
    <form action="javascript:void(0);" method="POST" onsubmit="addItem()">
        <input type="text" id="add-name" placeholder="New to-do">
        <input type="submit" value="Add">
    </form>

    <div id="editForm">
        <h3>Edit</h3>
        <form action="javascript:void(0);" onsubmit="updateItem()">
            <input type="hidden" id="edit-id">
            <input type="checkbox" id="edit-isComplete">
            <input type="text" id="edit-name">
            <input type="submit" value="Save">
            <a onclick="closeInput()" aria-label="Close">&#10006;</a>
        </form>
    </div>

    <p id="counter"></p>

    <table>
        <tr>
            <th>Is Complete?</th>
            <th>Name</th>
            <th></th>
            <th></th>
        </tr>
        <tbody id="todos"></tbody>
    </table>

    <script src="js/site.js" asp-append-version="true"></script>
    <script type="text/javascript">
        getItems();
    </script>
</body>
</html>
```

5. Add a JavaScript file named *site.js* to the *wwwroot/js* folder. Replace the contents of *site.js* with the following code:

```
const uri = 'api/TodoItems';
let todos = [];

function getItems() {
  fetch(uri)
    .then(response => response.json())
    .then(data => _displayItems(data))
    .catch(error => console.error('Unable to get items.', error));
}

function addItem() {
  const addNameTextbox = document.getElementById('add-name');
```

```
  const item = {
    isComplete: false,
    name: addNameTextbox.value.trim()
  };

  fetch(uri, {
    method: 'POST',
    headers: {
      'Accept': 'application/json',
      'Content-Type': 'application/json'
    },
    body: JSON.stringify(item)
  })
    .then(response => response.json())
    .then(() => {
      getItems();
      addNameTextbox.value = '';
    })
    .catch(error => console.error('Unable to add item.', error));
}

function deleteItem(id) {
  fetch(`${uri}/${id}`, {
    method: 'DELETE'
  })
  .then(() => getItems())
  .catch(error => console.error('Unable to delete item.', error));
}

function displayEditForm(id) {
  const item = todos.find(item => item.id === id);

  document.getElementById('edit-name').value = item.name;
  document.getElementById('edit-id').value = item.id;
  document.getElementById('edit-isComplete').checked = item.isComplete;
  document.getElementById('editForm').style.display = 'block';
}

function updateItem() {
  const itemId = document.getElementById('edit-id').value;
  const item = {
    id: parseInt(itemId, 10),
    isComplete: document.getElementById('edit-isComplete').checked,
    name: document.getElementById('edit-name').value.trim()
  };

  fetch(`${uri}/${itemId}`, {
    method: 'PUT',
    headers: {
      'Accept': 'application/json',
      'Content-Type': 'application/json'
    },
    body: JSON.stringify(item)
  })
  .then(() => getItems())
  .catch(error => console.error('Unable to update item.', error));

  closeInput();

  return false;
}

function closeInput() {
  document.getElementById('editForm').style.display = 'none';
}

function _displayCount(itemCount) {
  const name = (itemCount === 1) ? 'to-do' : 'to-dos';
```

```
  document.getElementById('counter').innerText = `${itemCount} ${name}`;
}

function _displayItems(data) {
  const tBody = document.getElementById('todos');
  tBody.innerHTML = '';

  _displayCount(data.length);

  const button = document.createElement('button');

  data.forEach(item => {
    let isCompleteCheckbox = document.createElement('input');
    isCompleteCheckbox.type = 'checkbox';
    isCompleteCheckbox.disabled = true;
    isCompleteCheckbox.checked = item.isComplete;

    let editButton = button.cloneNode(false);
    editButton.innerText = 'Edit';
    editButton.setAttribute('onclick', `displayEditForm(${item.id})`);

    let deleteButton = button.cloneNode(false);
    deleteButton.innerText = 'Delete';
    deleteButton.setAttribute('onclick', `deleteItem(${item.id})`);

    let tr = tBody.insertRow();

    let td1 = tr.insertCell(0);
    td1.appendChild(isCompleteCheckbox);

    let td2 = tr.insertCell(1);
    let textNode = document.createTextNode(item.name);
    td2.appendChild(textNode);

    let td3 = tr.insertCell(2);
    td3.appendChild(editButton);

    let td4 = tr.insertCell(3);
    td4.appendChild(deleteButton);
  });

  todos = data;
}
```

A change to the ASP.NET Core project's launch settings may be required to test the HTML page locally:

1. Open *Properties\launchSettings.json*.
2. Remove the `launchUrl` property to force the app to open at *index.html*—the project's default file.

This sample calls all of the CRUD methods of the web API. Following are explanations of the web API requests.

Get a list of to-do items

In the following code, an HTTP GET request is sent to the *api/TodoItems* route:

```
fetch(uri)
  .then(response => response.json())
  .then(data => _displayItems(data))
  .catch(error => console.error('Unable to get items.', error));
```

When the web API returns a successful status code, the `_displayItems` function is invoked. Each to-do item in the array parameter accepted by `_displayItems` is added to a table with **Edit** and **Delete** buttons. If the web API request fails, an error is logged to the browser's console.

Add a to-do item

In the following code:

- An `item` variable is declared to construct an object literal representation of the to-do item.
- A Fetch request is configured with the following options:
  - `method` —specifies the POST HTTP action verb.
  - `body` —specifies the JSON representation of the request body. The JSON is produced by passing the object literal stored in `item` to the JSON.stringify function.
  - `headers` —specifies the `Accept` and `Content-Type` HTTP request headers. Both headers are set to `application/json` to specify the media type being received and sent, respectively.
- An HTTP POST request is sent to the *api/TodoItems* route.

```
function addItem() {
  const addNameTextbox = document.getElementById('add-name');

  const item = {
    isComplete: false,
    name: addNameTextbox.value.trim()
  };

  fetch(uri, {
    method: 'POST',
    headers: {
      'Accept': 'application/json',
      'Content-Type': 'application/json'
    },
    body: JSON.stringify(item)
  })
    .then(response => response.json())
    .then(() => {
      getItems();
      addNameTextbox.value = '';
    })
    .catch(error => console.error('Unable to add item.', error));
}
```

When the web API returns a successful status code, the `getItems` function is invoked to update the HTML table. If the web API request fails, an error is logged to the browser's console.

Update a to-do item

Updating a to-do item is similar to adding one; however, there are two significant differences:

- The route is suffixed with the unique identifier of the item to update. For example, *api/TodoItems/1*.
- The HTTP action verb is PUT, as indicated by the `method` option.

```
fetch(`${uri}/${itemId}`, {
  method: 'PUT',
  headers: {
    'Accept': 'application/json',
    'Content-Type': 'application/json'
  },
  body: JSON.stringify(item)
})
.then(() => getItems())
.catch(error => console.error('Unable to update item.', error));
```

Delete a to-do item

To delete a to-do item, set the request's `method` option to `DELETE` and specify the item's unique identifier in the

URL.

```
fetch(`${uri}/${id}`, {
  method: 'DELETE'
})
.then(() => getItems())
.catch(error => console.error('Unable to delete item.', error));
```

Advance to the next tutorial to learn how to generate web API help pages:

Get started with Swashbuckle and ASP.NET Core

Create backend services for native mobile apps with ASP.NET Core

9/22/2020 • 8 minutes to read • Edit Online

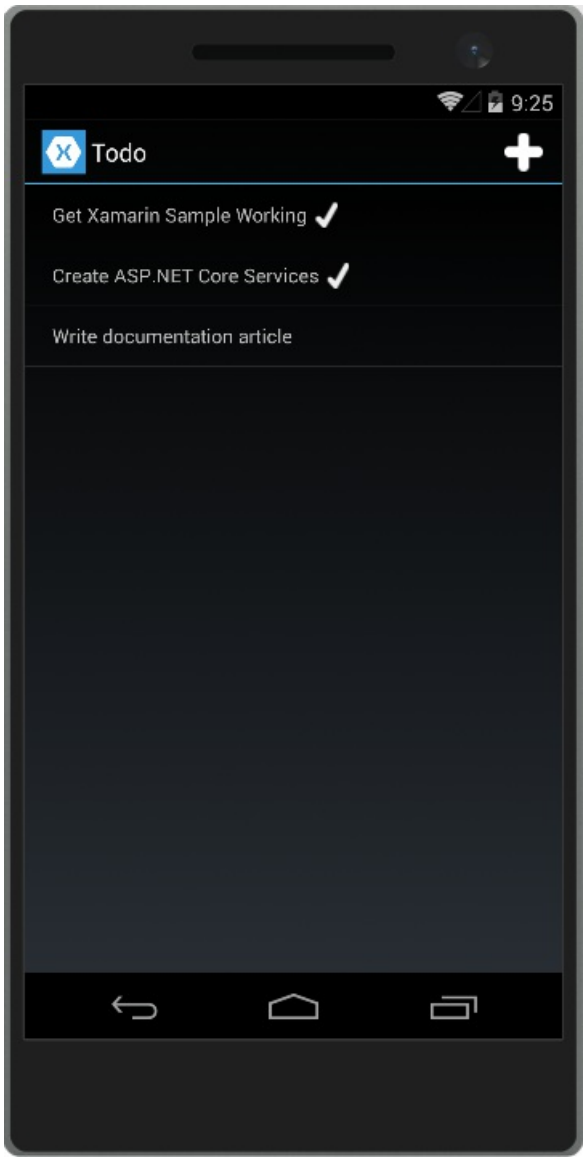
By Steve Smith

Mobile apps can communicate with ASP.NET Core backend services. For instructions on connecting local web services from iOS simulators and Android emulators, see Connect to Local Web Services from iOS Simulators and Android Emulators.

View or download sample backend services code

The Sample Native Mobile App

This tutorial demonstrates how to create backend services using ASP.NET Core MVC to support native mobile apps. It uses the Xamarin Forms ToDoRest app as its native client, which includes separate native clients for Android, iOS, Windows Universal, and Window Phone devices. You can follow the linked tutorial to create the native app (and install the necessary free Xamarin tools), as well as download the Xamarin sample solution. The Xamarin sample includes an ASP.NET Web API 2 services project, which this article's ASP.NET Core app replaces (with no changes required by the client).

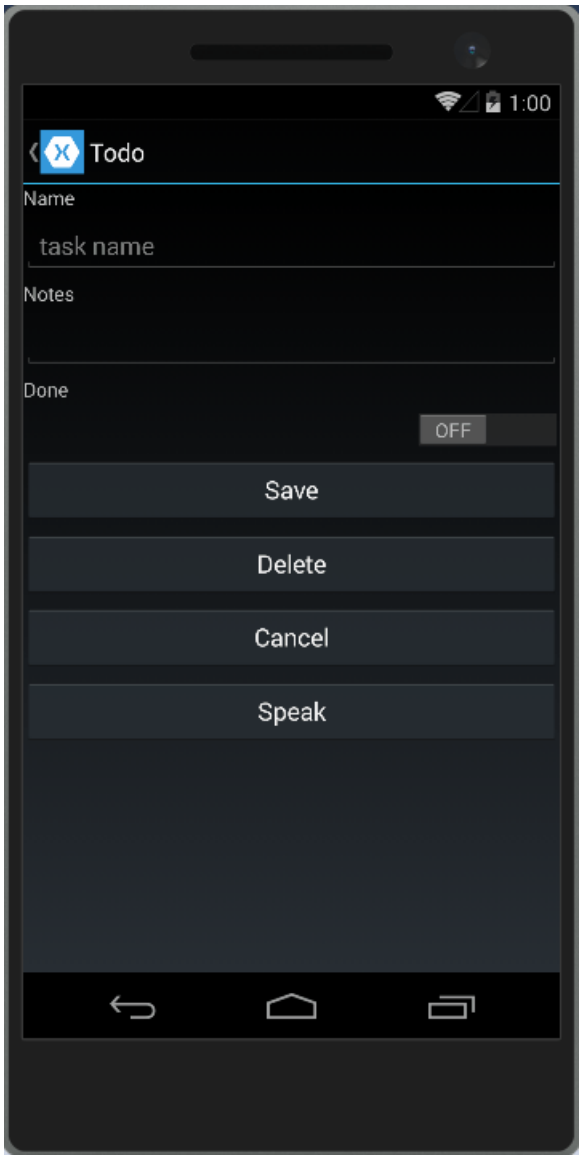


Features

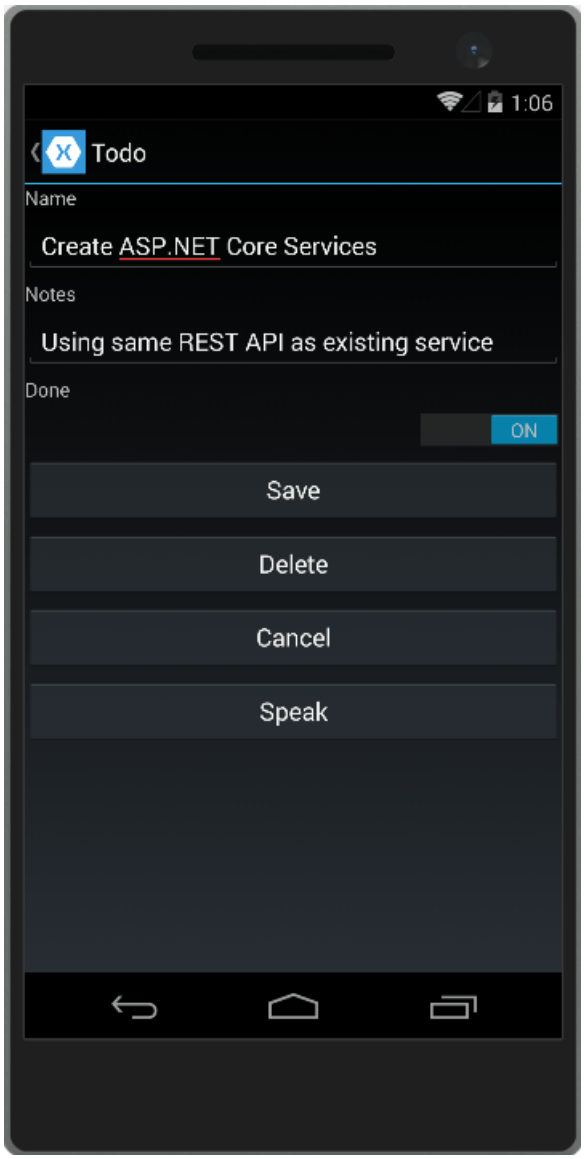
The ToDoRest app supports listing, adding, deleting, and updating To-Do items. Each item has an ID, a Name, Notes, and a property indicating whether it's been Done yet.

The main view of the items, as shown above, lists each item's name and indicates if it's done with a checkmark.

Tapping the `+` icon opens an add item dialog:



Tapping an item on the main list screen opens up an edit dialog where the item's Name, Notes, and Done settings can be modified, or the item can be deleted:



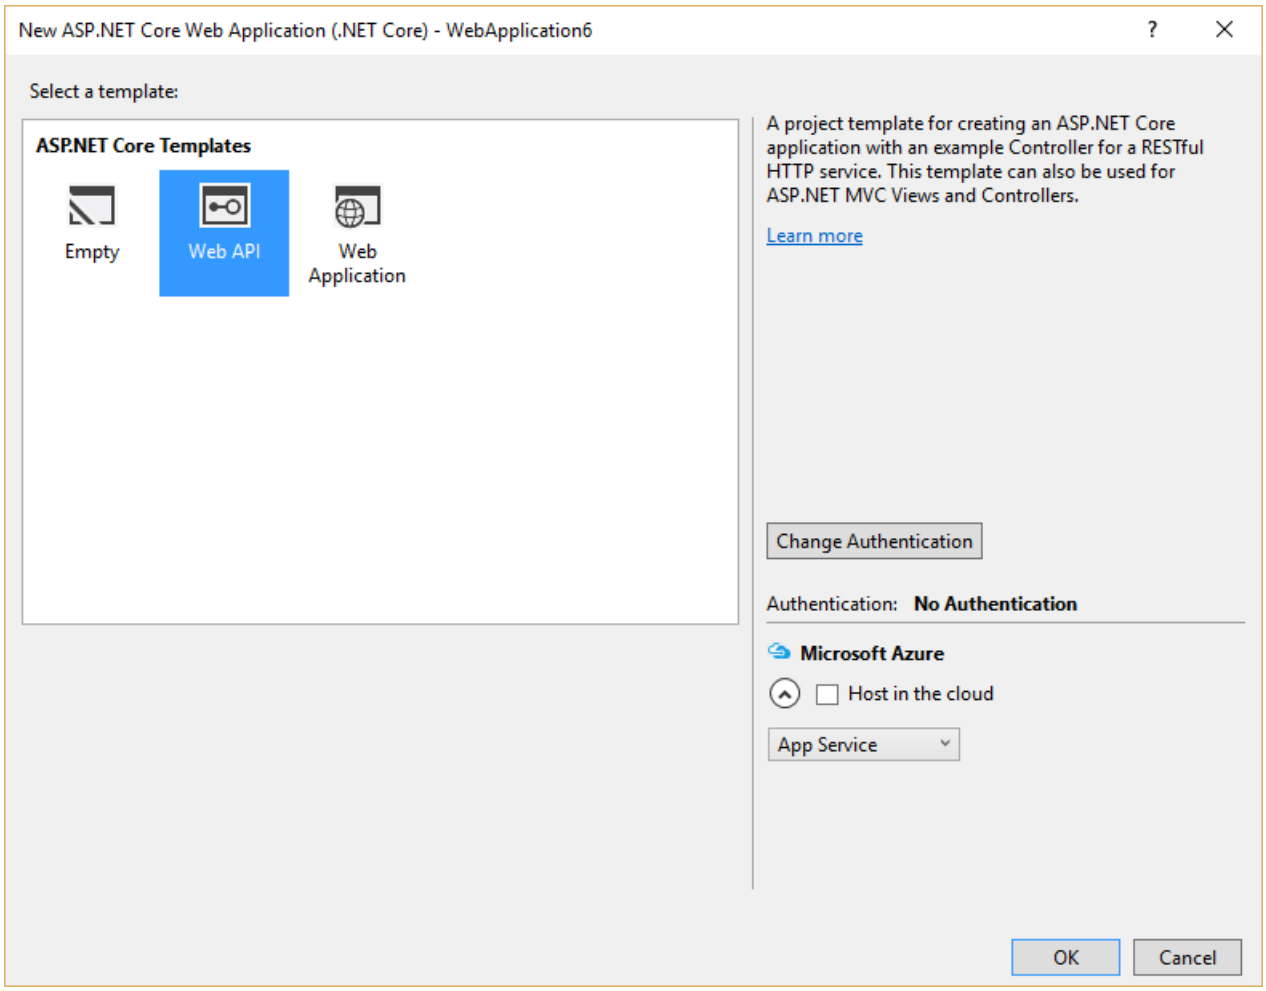
This sample is configured by default to use backend services hosted at developer.xamarin.com, which allow read-only operations. To test it out yourself against the ASP.NET Core app created in the next section running on your computer, you'll need to update the app's `RestUrl` constant. Navigate to the `ToDoREST` project and open the *Constants.cs* file. Replace the `RestUrl` with a URL that includes your machine's IP address (not localhost or 127.0.0.1, since this address is used from the device emulator, not from your machine). Include the port number as well (5000). In order to test that your services work with a device, ensure you don't have an active firewall blocking access to this port.

```
// URL of REST service (Xamarin ReadOnly Service)
//public static string RestUrl = "http://developer.xamarin.com:8081/api/todoitems{0}";

// use your machine's IP address
public static string RestUrl = "http://192.168.1.207:5000/api/todoitems/{0}";
```

Creating the ASP.NET Core Project

Create a new ASP.NET Core Web Application in Visual Studio. Choose the Web API template and No Authentication. Name the project *ToDoApi*.



The application should respond to all requests made to port 5000. Update *Program.cs* to include `.UseUrls("http://*:5000")` to achieve this:

```
var host = new WebHostBuilder()
    .UseKestrel()
    .UseUrls("http://*:5000")
    .UseContentRoot(Directory.GetCurrentDirectory())
    .UseIISIntegration()
    .UseStartup<Startup>()
    .Build();
```

NOTE

Make sure you run the application directly, rather than behind IIS Express, which ignores non-local requests by default. Run dotnet run from a command prompt, or choose the application name profile from the Debug Target dropdown in the Visual Studio toolbar.

Add a model class to represent To-Do items. Mark required fields with the `[Required]` attribute:

```
using System.ComponentModel.DataAnnotations;

namespace ToDoApi.Models
{
    public class ToDoItem
    {
        [Required]
        public string ID { get; set; }

        [Required]
        public string Name { get; set; }

        [Required]
        public string Notes { get; set; }

        public bool Done { get; set; }
    }
}
```

The API methods require some way to work with data. Use the same `IToDoRepository` interface the original Xamarin sample uses:

```
using System.Collections.Generic;
using ToDoApi.Models;

namespace ToDoApi.Interfaces
{
    public interface IToDoRepository
    {
        bool DoesItemExist(string id);
        IEnumerable<ToDoItem> All { get; }
        ToDoItem Find(string id);
        void Insert(ToDoItem item);
        void Update(ToDoItem item);
        void Delete(string id);
    }
}
```

For this sample, the implementation just uses a private collection of items:

```
using System.Collections.Generic;
using System.Linq;
using ToDoApi.Interfaces;
using ToDoApi.Models;

namespace ToDoApi.Services
{
    public class ToDoRepository : IToDoRepository
    {
        private List<ToDoItem> _toDoList;

        public ToDoRepository()
        {
            InitializeData();
        }

        public IEnumerable<ToDoItem> All
        {
            get { return _toDoList; }
        }

        public bool DoesItemExist(string id)
        {
            return _toDoList.Any(item => item.ID == id);
```

```
        }

        public ToDoItem Find(string id)
        {
            return _toDoList.FirstOrDefault(item => item.ID == id);
        }

        public void Insert(ToDoItem item)
        {
            _toDoList.Add(item);
        }

        public void Update(ToDoItem item)
        {
            var todoItem = this.Find(item.ID);
            var index = _toDoList.IndexOf(todoItem);
            _toDoList.RemoveAt(index);
            _toDoList.Insert(index, item);
        }

        public void Delete(string id)
        {
            _toDoList.Remove(this.Find(id));
        }

        private void InitializeData()
        {
            _toDoList = new List<ToDoItem>();

            var todoItem1 = new ToDoItem
            {
                ID = "6bb8a868-dba1-4f1a-93b7-24ebce87e243",
                Name = "Learn app development",
                Notes = "Attend Xamarin University",
                Done = true
            };

            var todoItem2 = new ToDoItem
            {
                ID = "b94afb54-a1cb-4313-8af3-b7511551b33b",
                Name = "Develop apps",
                Notes = "Use Xamarin Studio/Visual Studio",
                Done = false
            };

            var todoItem3 = new ToDoItem
            {
                ID = "ecfa6f80-3671-4911-aabe-63cc442c1ecf",
                Name = "Publish apps",
                Notes = "All app stores",
                Done = false,
            };

            _toDoList.Add(todoItem1);
            _toDoList.Add(todoItem2);
            _toDoList.Add(todoItem3);
        }
    }
}
```

Configure the implementation in *Startup.cs*:

```
public void ConfigureServices(IServiceCollection services)
{
    // Add framework services.
    services.AddMvc();

    services.AddSingleton<IToDoRepository,ToDoRepository>();
}
```

At this point, you're ready to create the *ToDoItemsController*.

TIP

Learn more about creating web APIs in Build your first Web API with ASP.NET Core MVC and Visual Studio.

Creating the Controller

Add a new controller to the project, *ToDoItemsController*. It should inherit from Microsoft.AspNetCore.Mvc.Controller. Add a `Route` attribute to indicate that the controller will handle requests made to paths starting with `api/todoitems`. The `[controller]` token in the route is replaced by the name of the controller (omitting the `Controller` suffix), and is especially helpful for global routes. Learn more about routing.

The controller requires an `IToDoRepository` to function; request an instance of this type through the controller's constructor. At runtime, this instance will be provided using the framework's support for dependency injection.

```
using System;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Mvc;
using ToDoApi.Interfaces;
using ToDoApi.Models;

namespace ToDoApi.Controllers
{
    [Route("api/[controller]")]
    public class ToDoItemsController : Controller
    {
        private readonly IToDoRepository _toDoRepository;

        public ToDoItemsController(IToDoRepository toDoRepository)
        {
            _toDoRepository = toDoRepository;
        }
```

This API supports four different HTTP verbs to perform CRUD (Create, Read, Update, Delete) operations on the data source. The simplest of these is the Read operation, which corresponds to an HTTP GET request.

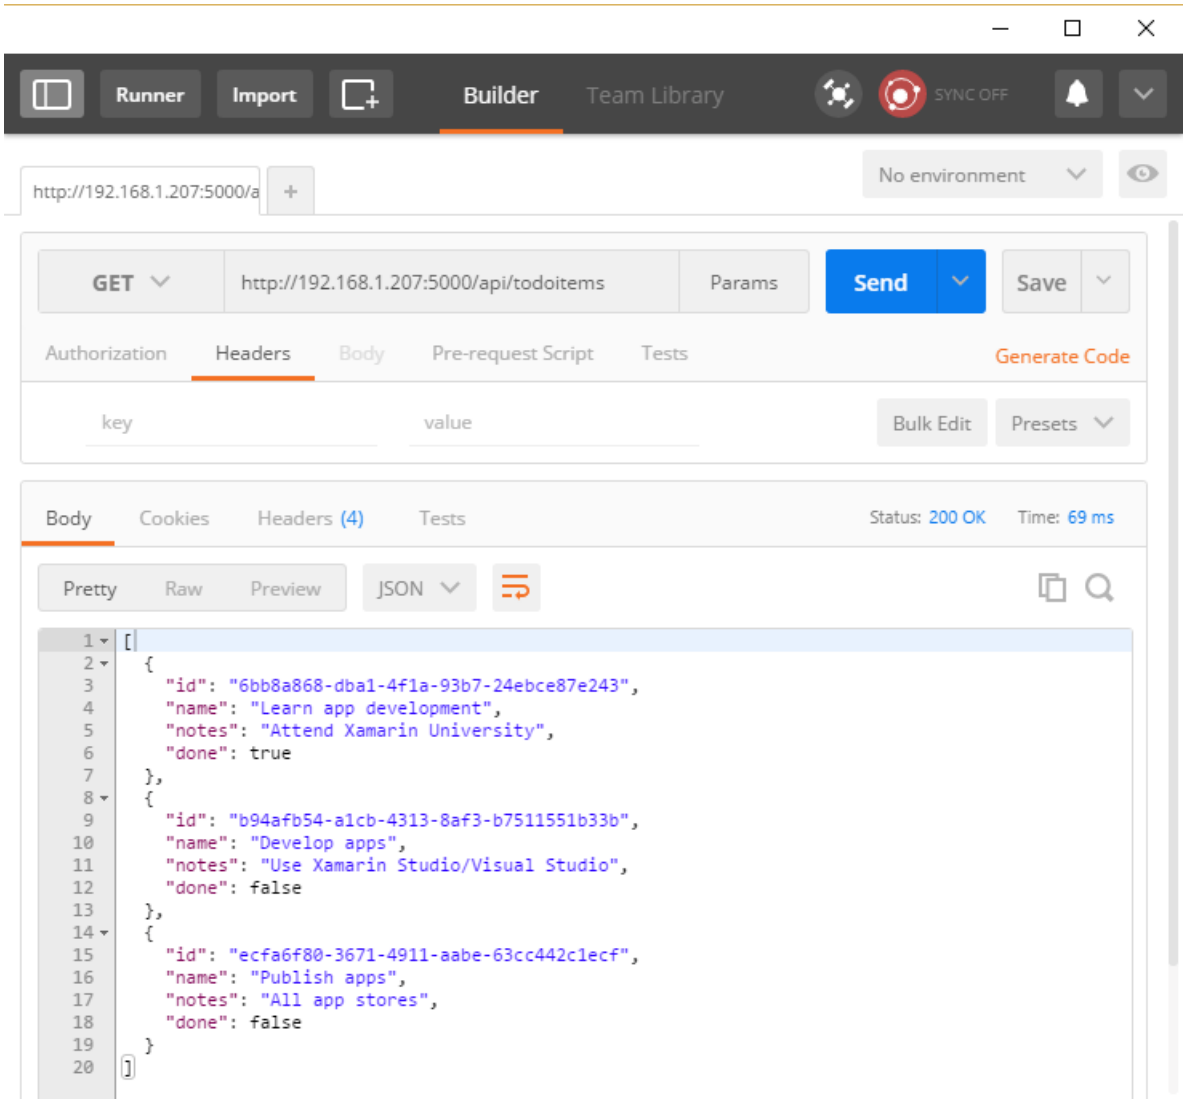
Reading Items

Requesting a list of items is done with a GET request to the `List` method. The `[HttpGet]` attribute on the `List` method indicates that this action should only handle GET requests. The route for this action is the route specified on the controller. You don't necessarily need to use the action name as part of the route. You just need to ensure each action has a unique and unambiguous route. Routing attributes can be applied at both the controller and method levels to build up specific routes.

```
[HttpGet]
public IActionResult List()
{
    return Ok(_toDoRepository.All);
}
```

The `List` method returns a 200 OK response code and all of the ToDo items, serialized as JSON.

You can test your new API method using a variety of tools, such as Postman, shown here:



Creating Items

By convention, creating new data items is mapped to the HTTP POST verb. The `Create` method has an `[HttpPost]` attribute applied to it and accepts a `ToDoItem` instance. Since the `item` argument is passed in the body of the POST, this parameter specifies the `[FromBody]` attribute.

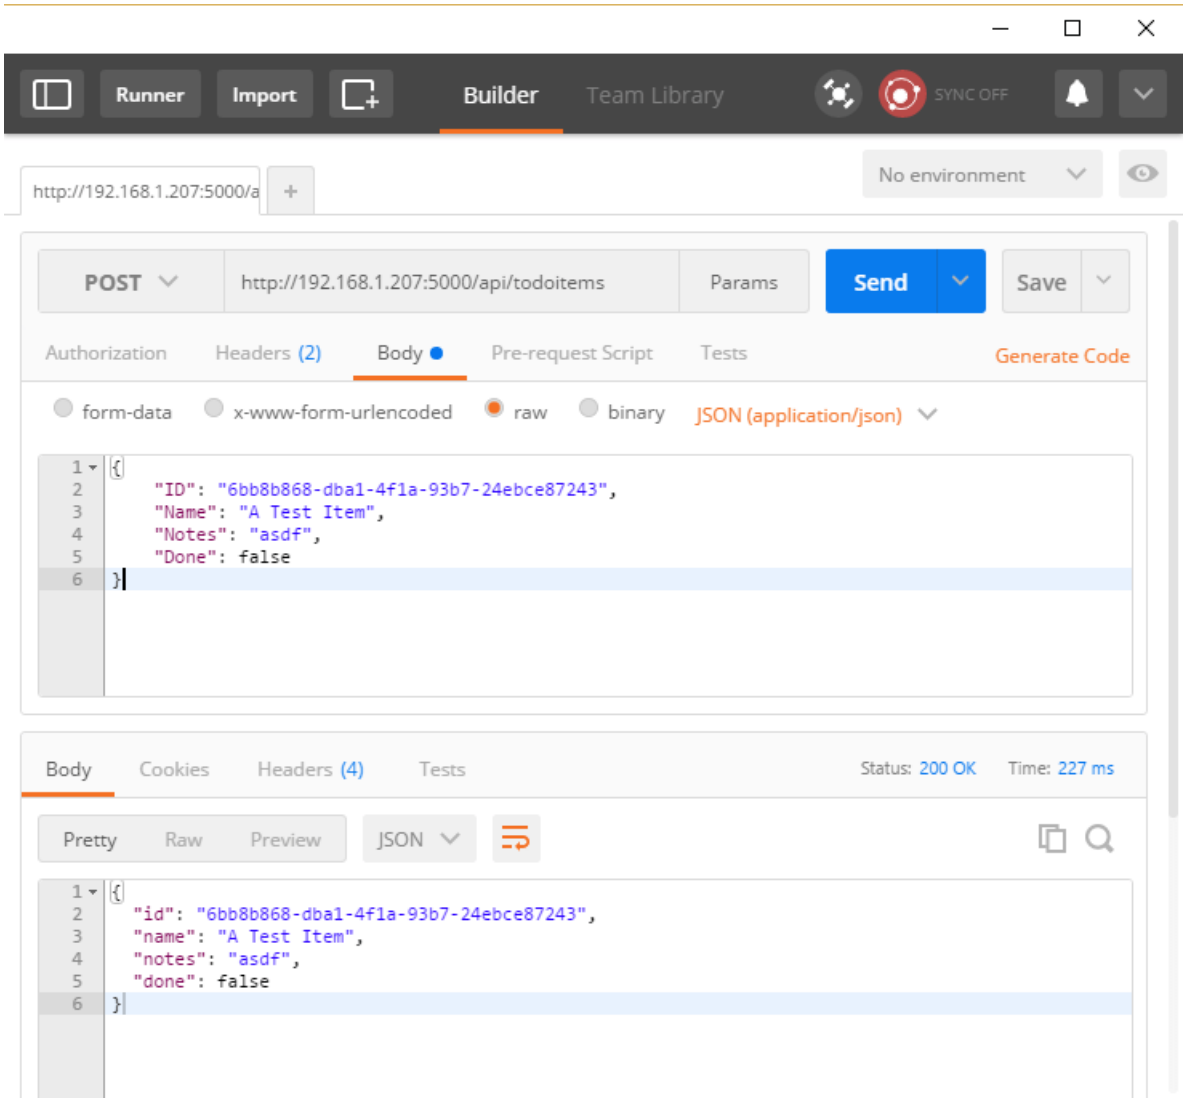
Inside the method, the item is checked for validity and prior existence in the data store, and if no issues occur, it's added using the repository. Checking `ModelState.IsValid` performs model validation, and should be done in every API method that accepts user input.

```
[HttpPost]
public IActionResult Create([FromBody] ToDoItem item)
{
    try
    {
        if (item == null || !ModelState.IsValid)
        {
            return BadRequest(ErrorCode.TodoItemNameAndNotesRequired.ToString());
        }
        bool itemExists = _toDoRepository.DoesItemExist(item.ID);
        if (itemExists)
        {
            return StatusCode(StatusCodes.Status409Conflict, ErrorCode.TodoItemIDInUse.ToString());
        }
        _toDoRepository.Insert(item);
    }
    catch (Exception)
    {
        return BadRequest(ErrorCode.CouldNotCreateItem.ToString());
    }
    return Ok(item);
}
```

The sample uses an enum containing error codes that are passed to the mobile client:

```
public enum ErrorCode
{
    TodoItemNameAndNotesRequired,
    TodoItemIDInUse,
    RecordNotFound,
    CouldNotCreateItem,
    CouldNotUpdateItem,
    CouldNotDeleteItem
}
```

Test adding new items using Postman by choosing the POST verb providing the new object in JSON format in the Body of the request. You should also add a request header specifying a `Content-Type` of `application/json`.



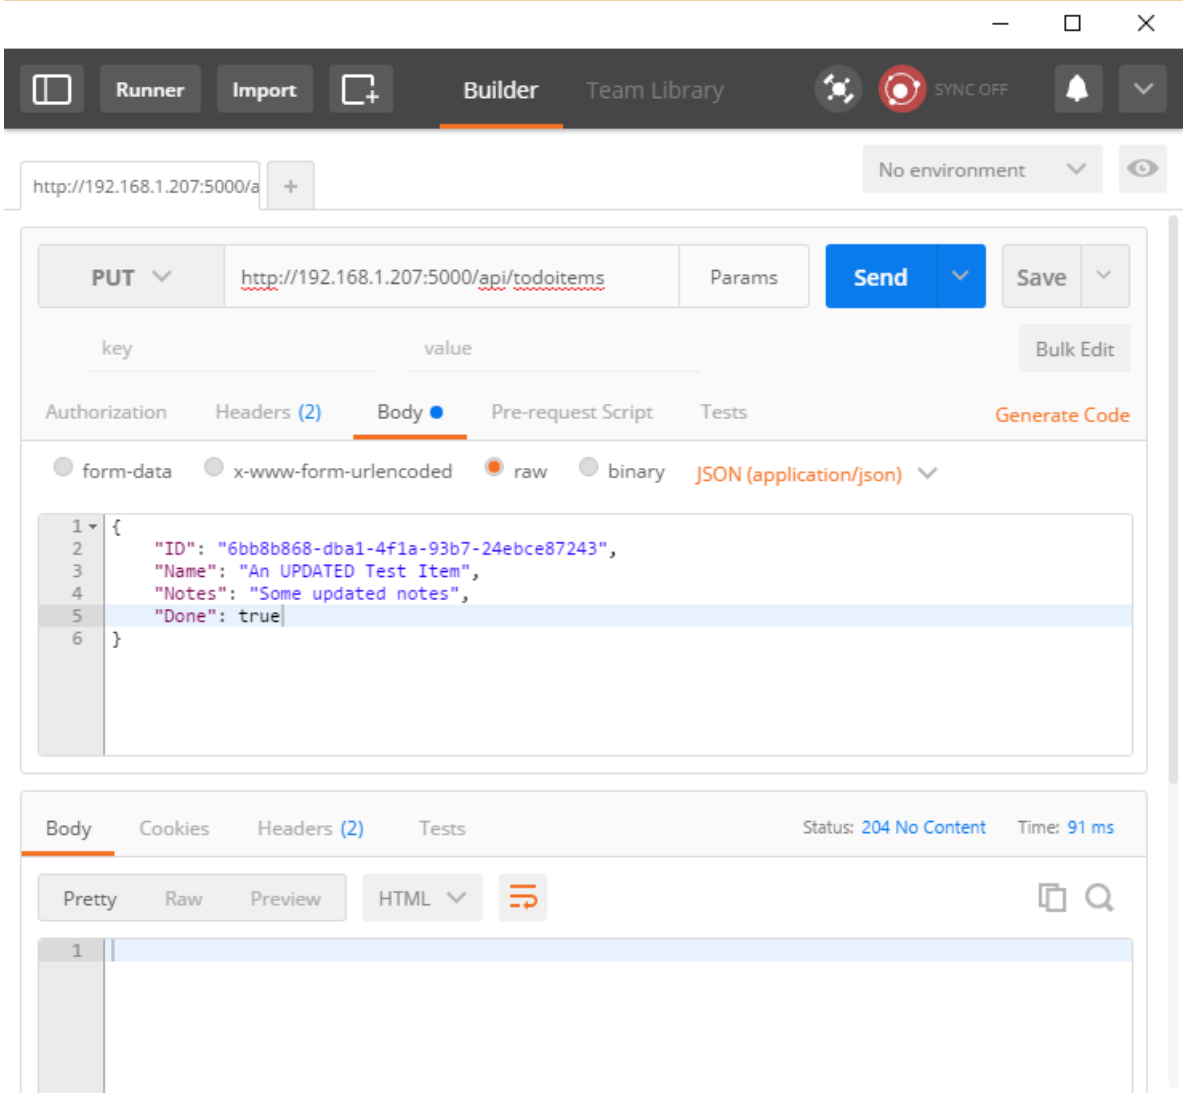
The method returns the newly created item in the response.

Updating Items

Modifying records is done using HTTP PUT requests. Other than this change, the `Edit` method is almost identical to `Create`. Note that if the record isn't found, the `Edit` action will return a `NotFound` (404) response.

```
[HttpPut]
public IActionResult Edit([FromBody] ToDoItem item)
{
    try
    {
        if (item == null || !ModelState.IsValid)
        {
            return BadRequest(ErrorCode.TodoItemNameAndNotesRequired.ToString());
        }
        var existingItem = _toDoRepository.Find(item.ID);
        if (existingItem == null)
        {
            return NotFound(ErrorCode.RecordNotFound.ToString());
        }
        _toDoRepository.Update(item);
    }
    catch (Exception)
    {
        return BadRequest(ErrorCode.CouldNotUpdateItem.ToString());
    }
    return NoContent();
}
```

To test with Postman, change the verb to PUT. Specify the updated object data in the Body of the request.



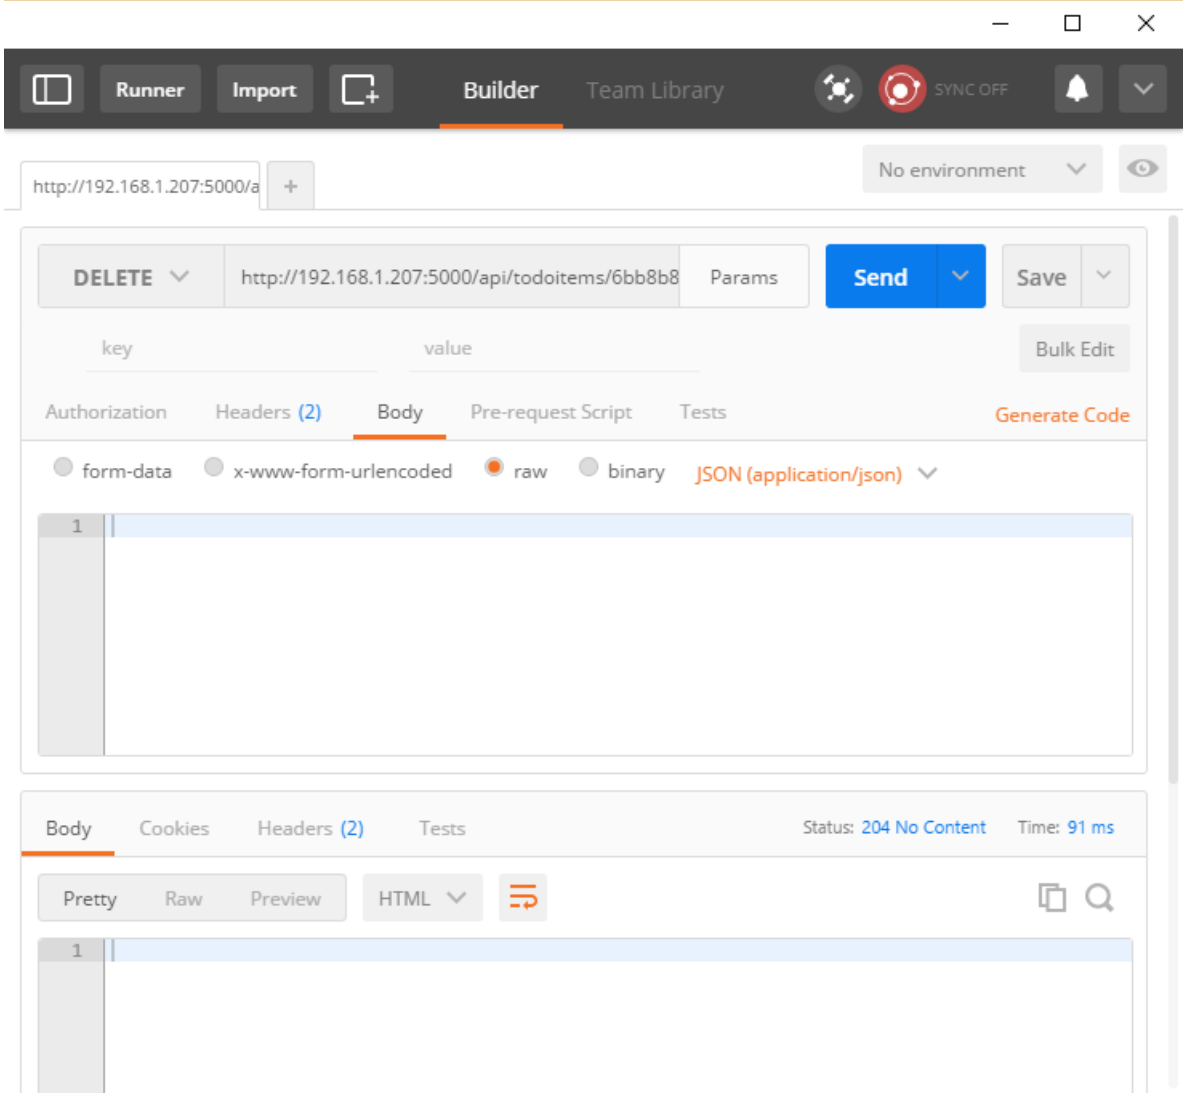
This method returns a `NoContent` (204) response when successful, for consistency with the pre-existing API.

Deleting Items

Deleting records is accomplished by making DELETE requests to the service, and passing the ID of the item to be deleted. As with updates, requests for items that don't exist will receive `NotFound` responses. Otherwise, a successful request will get a `NoContent` (204) response.

```
[HttpDelete("{id}")]
public IActionResult Delete(string id)
{
    try
    {
        var item = _toDoRepository.Find(id);
        if (item == null)
        {
            return NotFound(ErrorCode.RecordNotFound.ToString());
        }
        _toDoRepository.Delete(id);
    }
    catch (Exception)
    {
        return BadRequest(ErrorCode.CouldNotDeleteItem.ToString());
    }
    return NoContent();
}
```

Note that when testing the delete functionality, nothing is required in the Body of the request.



Common Web API Conventions

As you develop the backend services for your app, you will want to come up with a consistent set of conventions or policies for handling cross-cutting concerns. For example, in the service shown above, requests for specific records that weren't found received a `NotFound` response, rather than a `BadRequest` response. Similarly, commands made to this service that passed in model bound types always checked `ModelState.IsValid` and returned a `BadRequest` for invalid model types.

Once you've identified a common policy for your APIs, you can usually encapsulate it in a filter. Learn more about how to encapsulate common API policies in ASP.NET Core MVC applications.

Publish an ASP.NET Core web API to Azure API Management with Visual Studio

9/22/2020 • 4 minutes to read • Edit Online

By Matt Soucoup

Set up

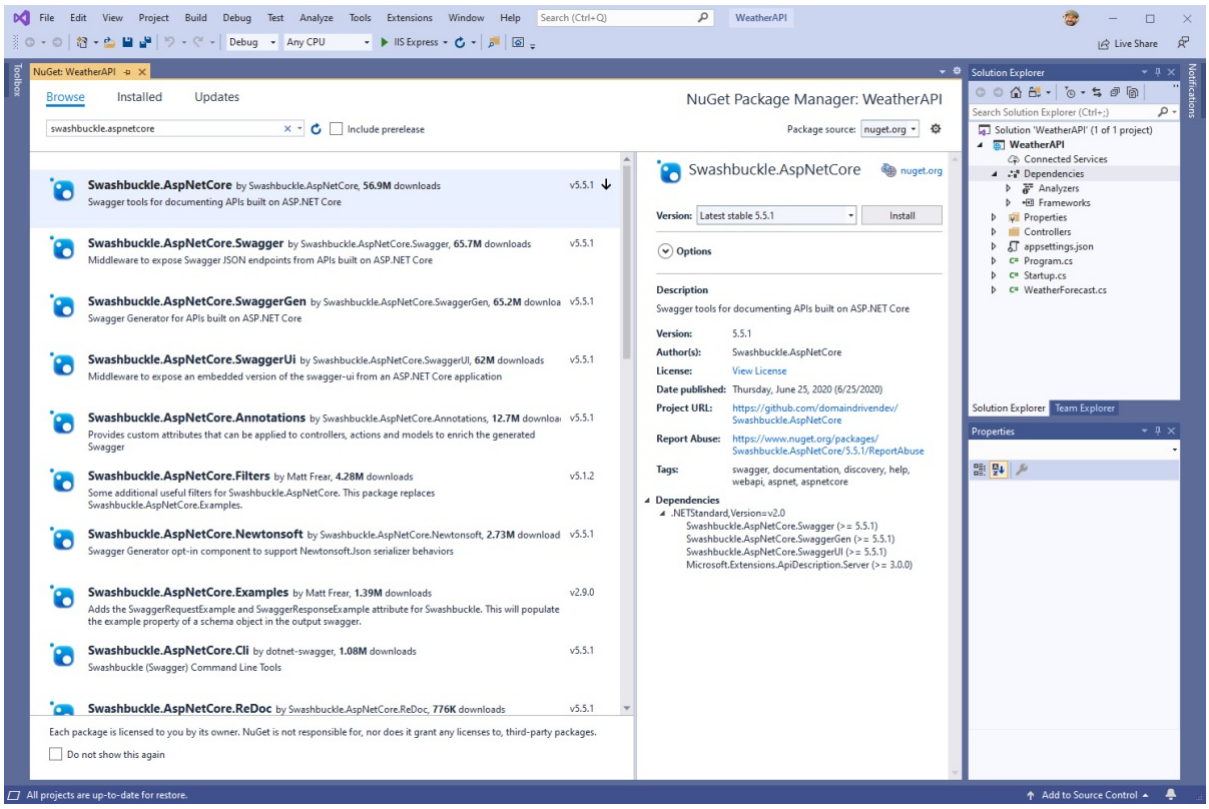
- Open a free Azure account if you don't have one.
- Create a new Azure API Management instance if you haven't already.
- Create a web API app project.

Configure the app

Adding Swagger definitions to the ASP.NET Core web API allows Azure API Management to read the app's API definitions. Complete the following steps.

Add Swagger

1. Add the Swashbuckle.AspNetCore NuGet package to the ASP.NET Core web API project:



2. Add the following line to the `Startup.ConfigureServices` method:

```
services.AddSwaggerGen();
```

3. Add the following line to the `Startup.Configure` method:

```
app.UseSwagger();
```

Change the API routing

Next, you'll change the URL structure needed to access the `Get` action of the `WeatherForecastController`. Complete the following steps:

1. Open the *WeatherForecastController.cs* file.
2. Delete the `[Route("[controller]")]` class-level attribute. The class definition will look like the following:

```
[ApiController]
public class WeatherForecastController : ControllerBase
```

3. Add a `[Route("/")]` attribute to the `Get()` action. The function definition will look like the following:

```
[HttpGet]
[Route("/")]
public IEnumerable<WeatherForecast> Get()
```

Publish the web API to Azure App Service

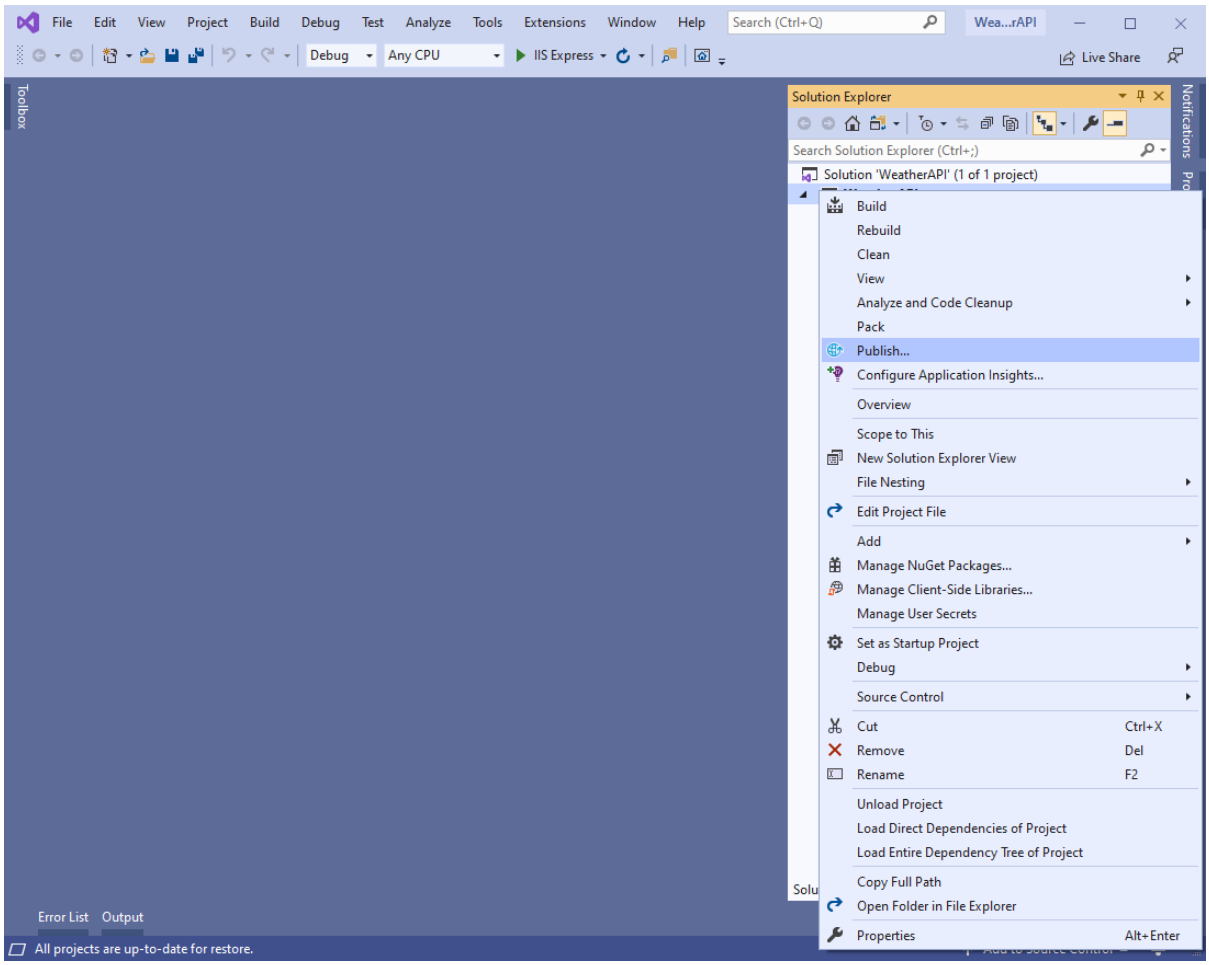
Complete the following steps to publish the ASP.NET Core web API to Azure API Management:

1. Publish the API app to Azure App Service.
2. Add a blank API to the Azure API Management service instance.
3. Publish the ASP.NET Core web API app to the Azure API Management service instance.

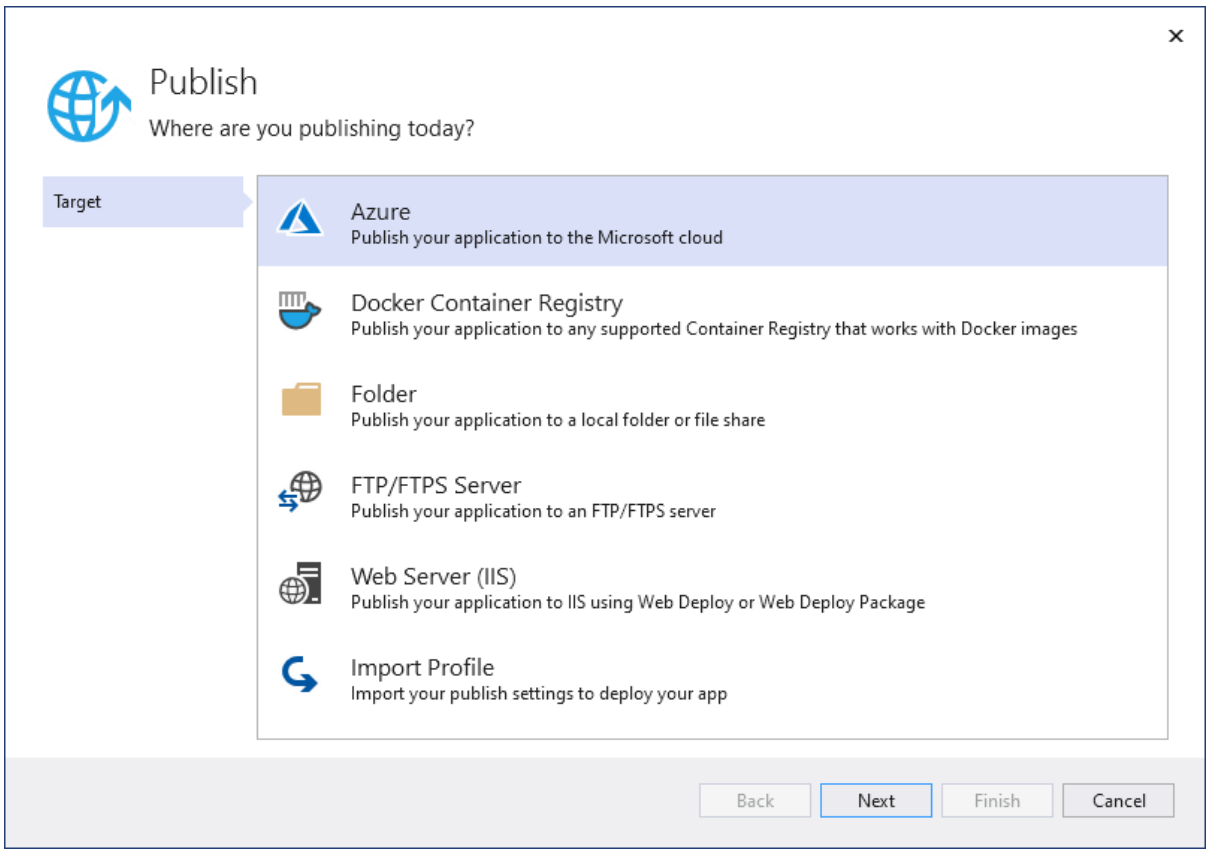
Publish the API app to Azure App Service

Complete the following steps to publish the ASP.NET Core web API to Azure API Management:

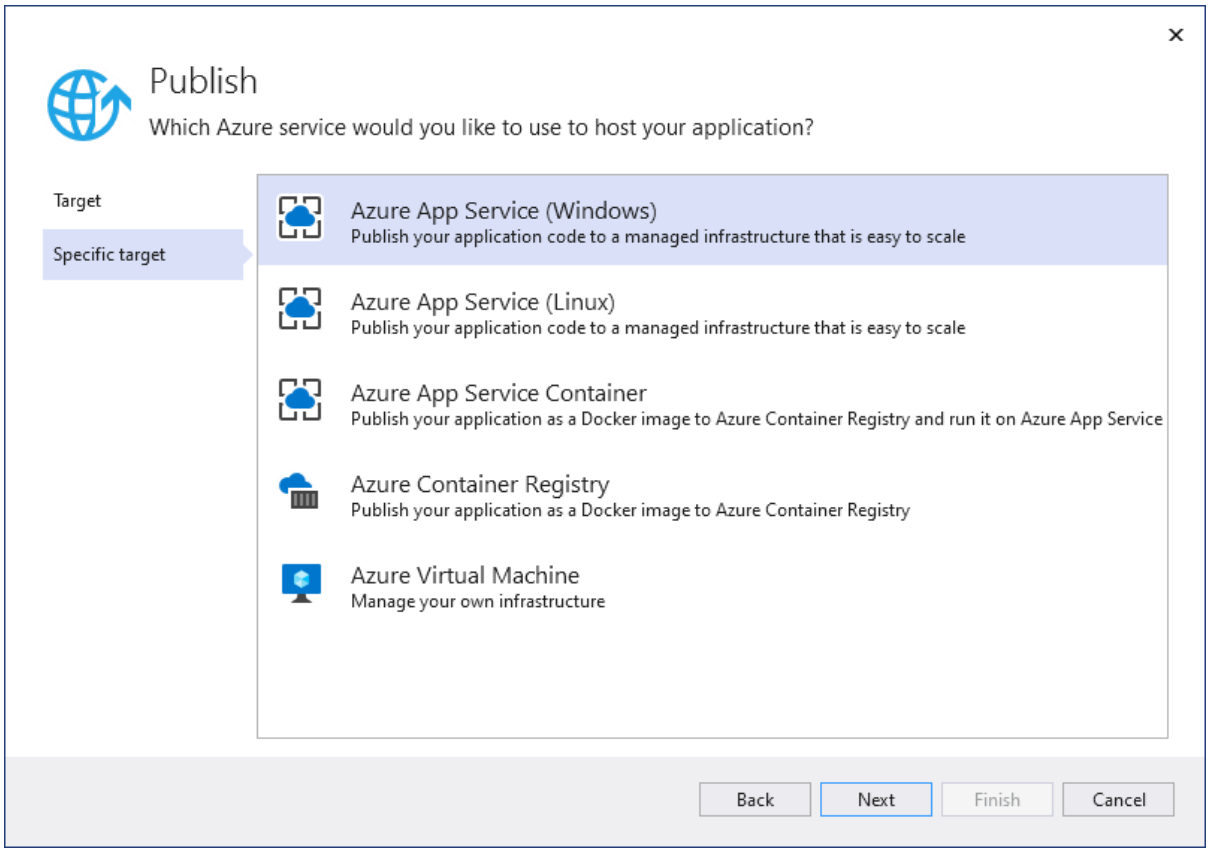
1. In **Solution Explorer**, right-click the project and select **Publish**:



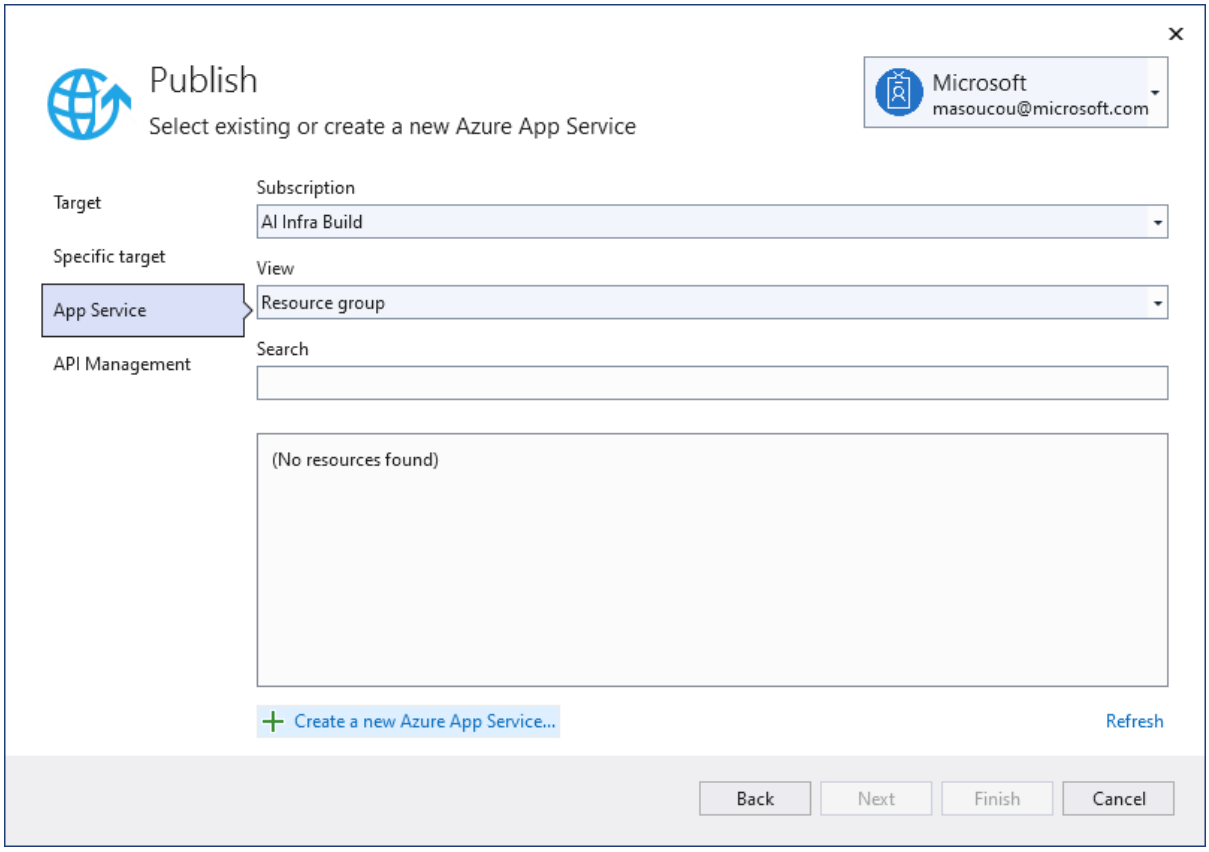
2. In the **Publish** dialog, select **Azure** and select the **Next** button:



3. Select **Azure App Service (Windows)** and select the **Next** button:

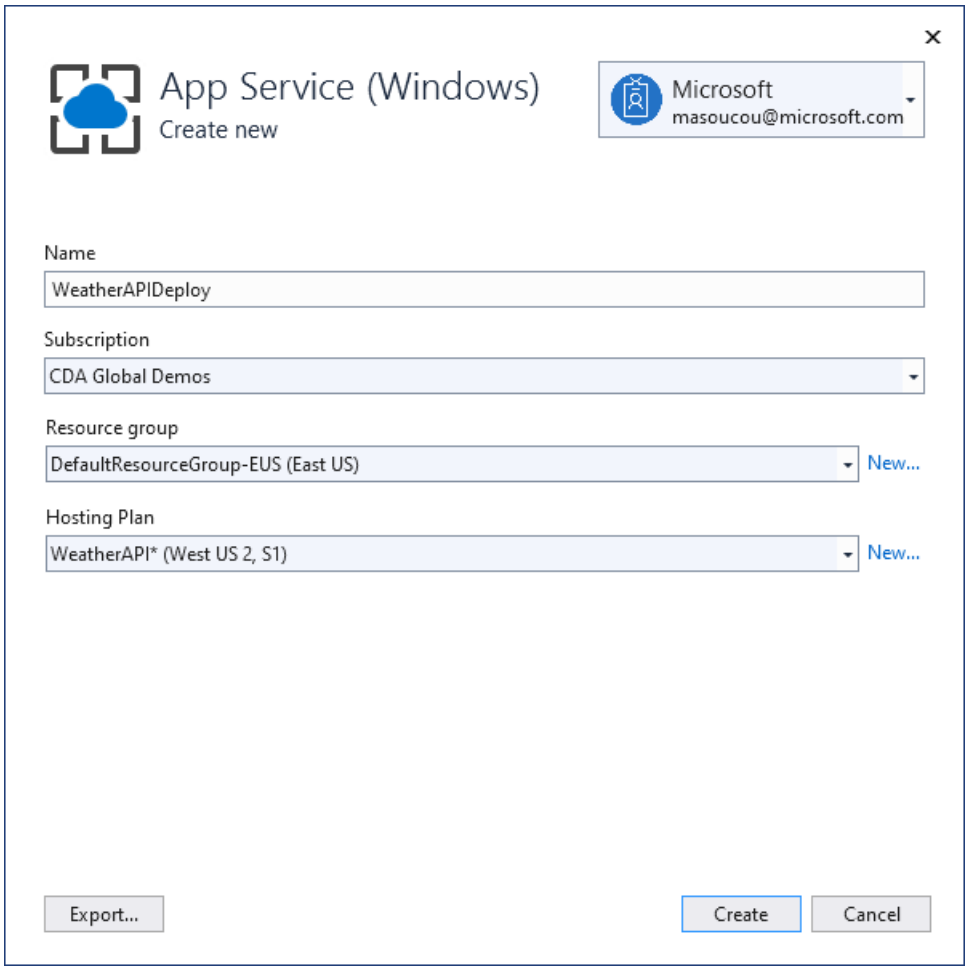


4. Select **Create a new Azure App Service**.

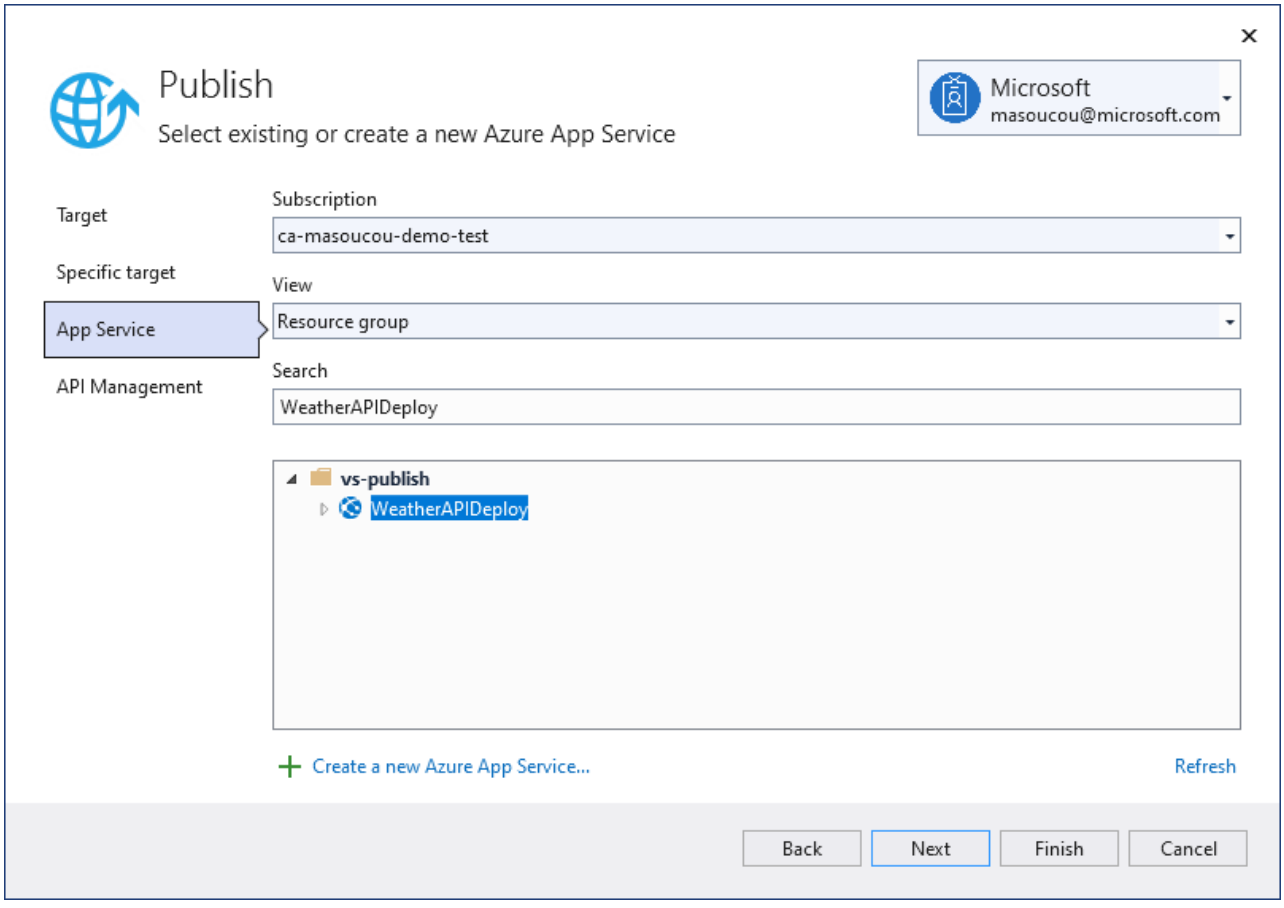


The **Create App Service** dialog appears. The **App Name**, **Resource Group**, and **App Service Plan** entry fields are populated. You can keep these names or change them.

5. Select the **Create** button.



After creation is completed, the dialog is automatically closed and the **Publish** dialog gets focus again. The instance that was created is automatically selected.

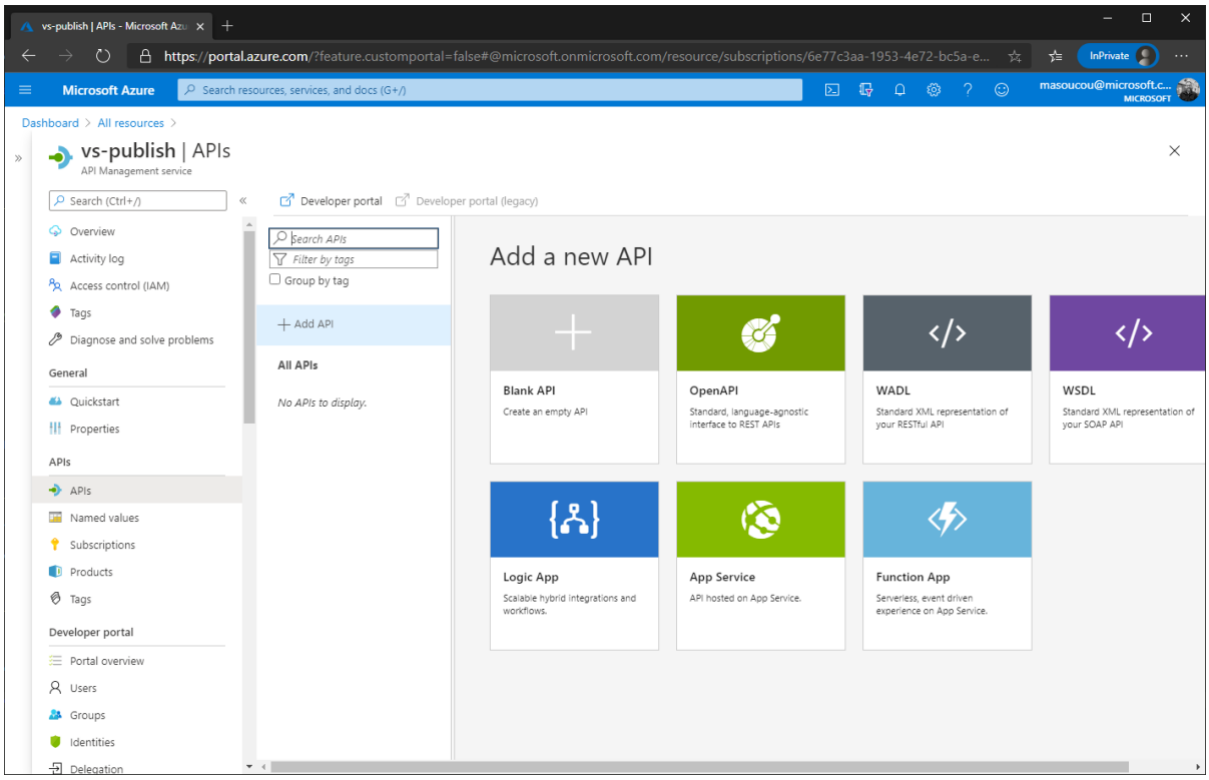


At this point, you need to add an API to the Azure API Management service. Leave Visual Studio open while you

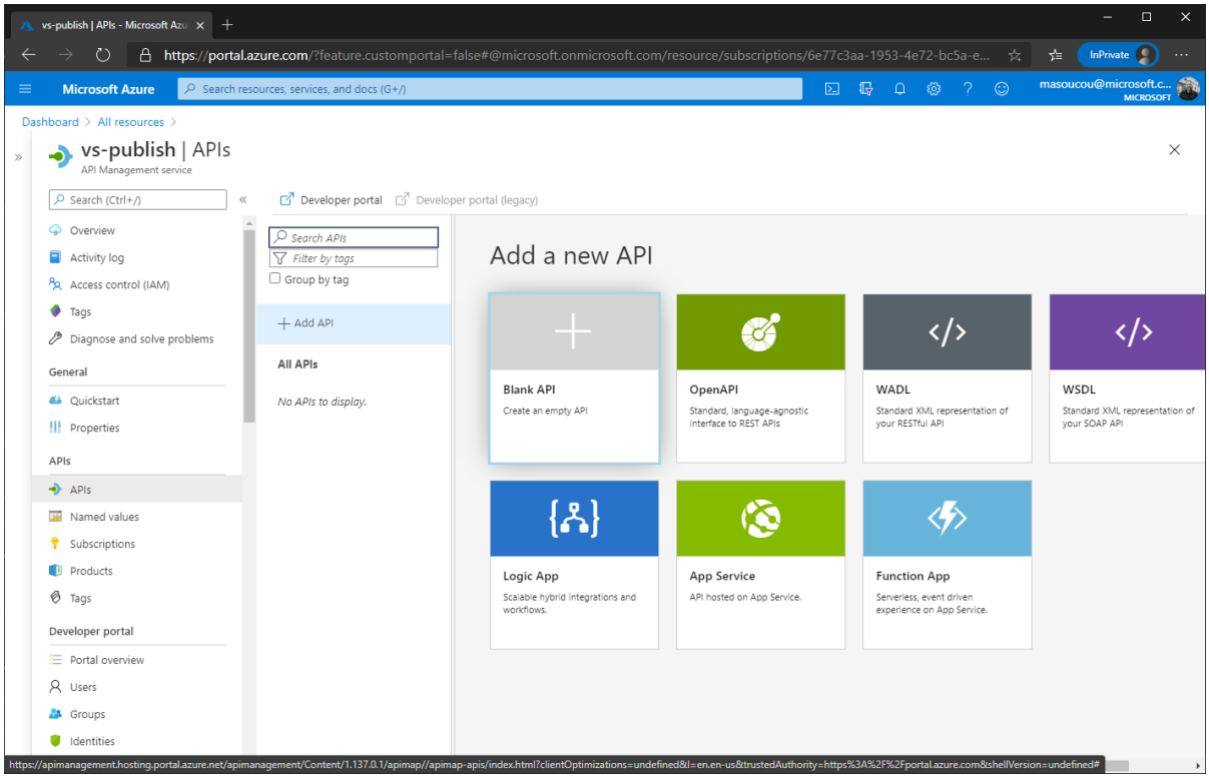
complete the following tasks.

Add an API to Azure API Management

1. Open the API Management Service instance created previously in the Azure portal. Select the **APIs** blade:



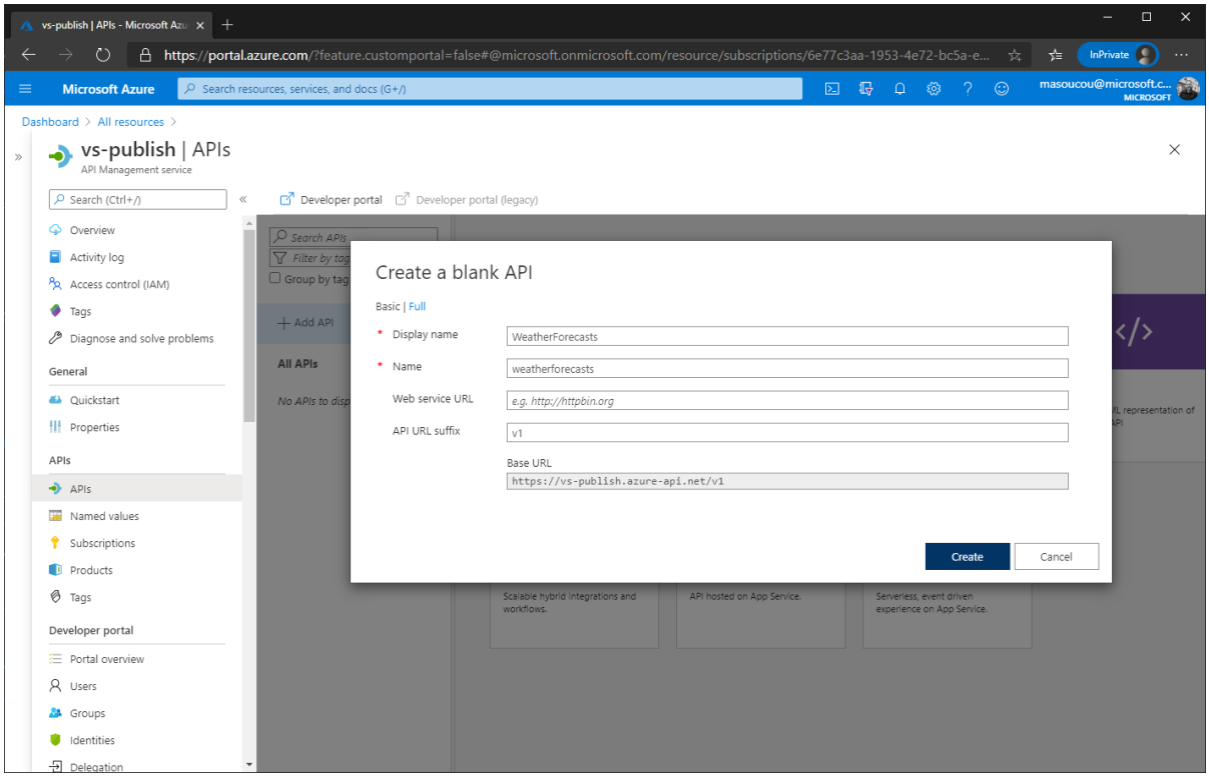
2. From the **Add a new API** panel, select the **Blank API** tile:



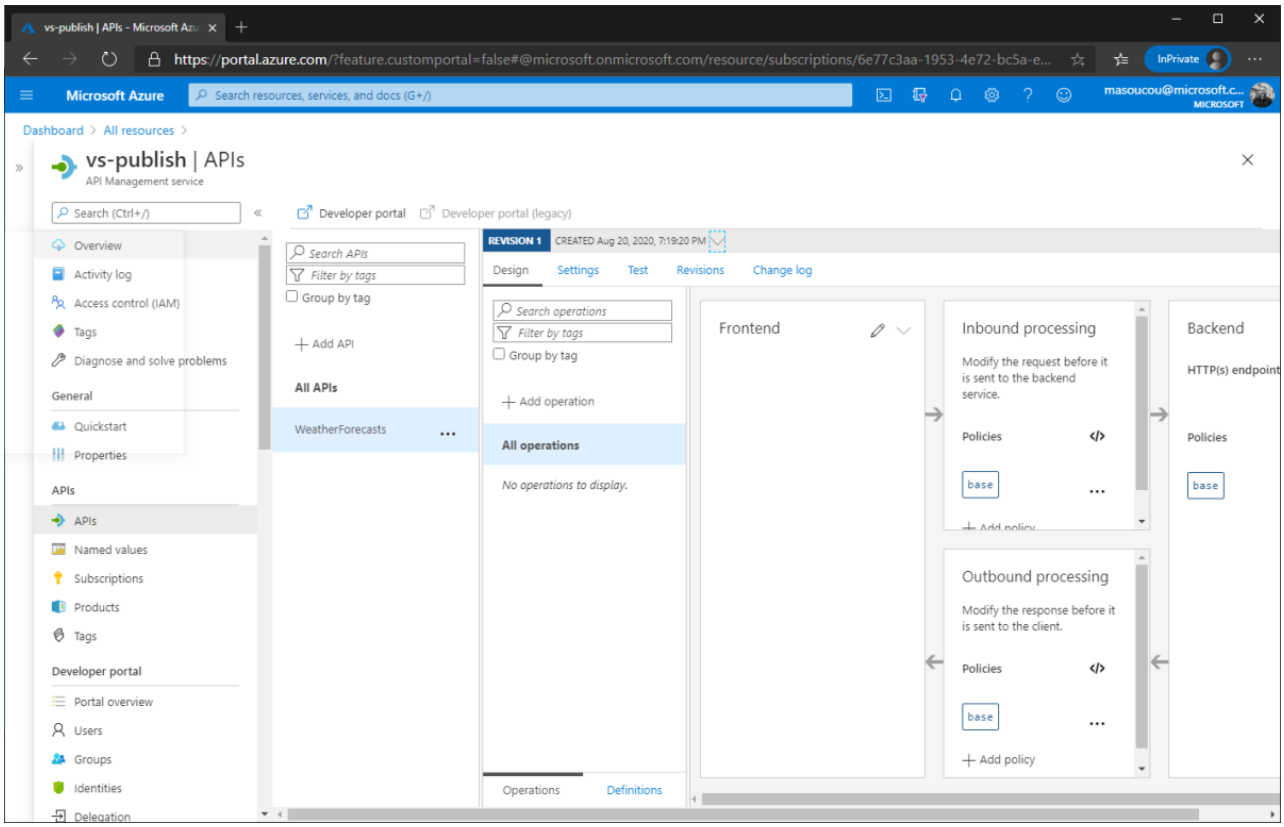
3. Enter the following values in the **Create a blank API** dialog that appears:

   - **Display Name**: *WeatherForecasts*
   - **Name**: *weatherforecasts*
   - **API Url suffix**: *v1*
   - Leave the **Web service URL** field empty.

4. Select the **Create** button.

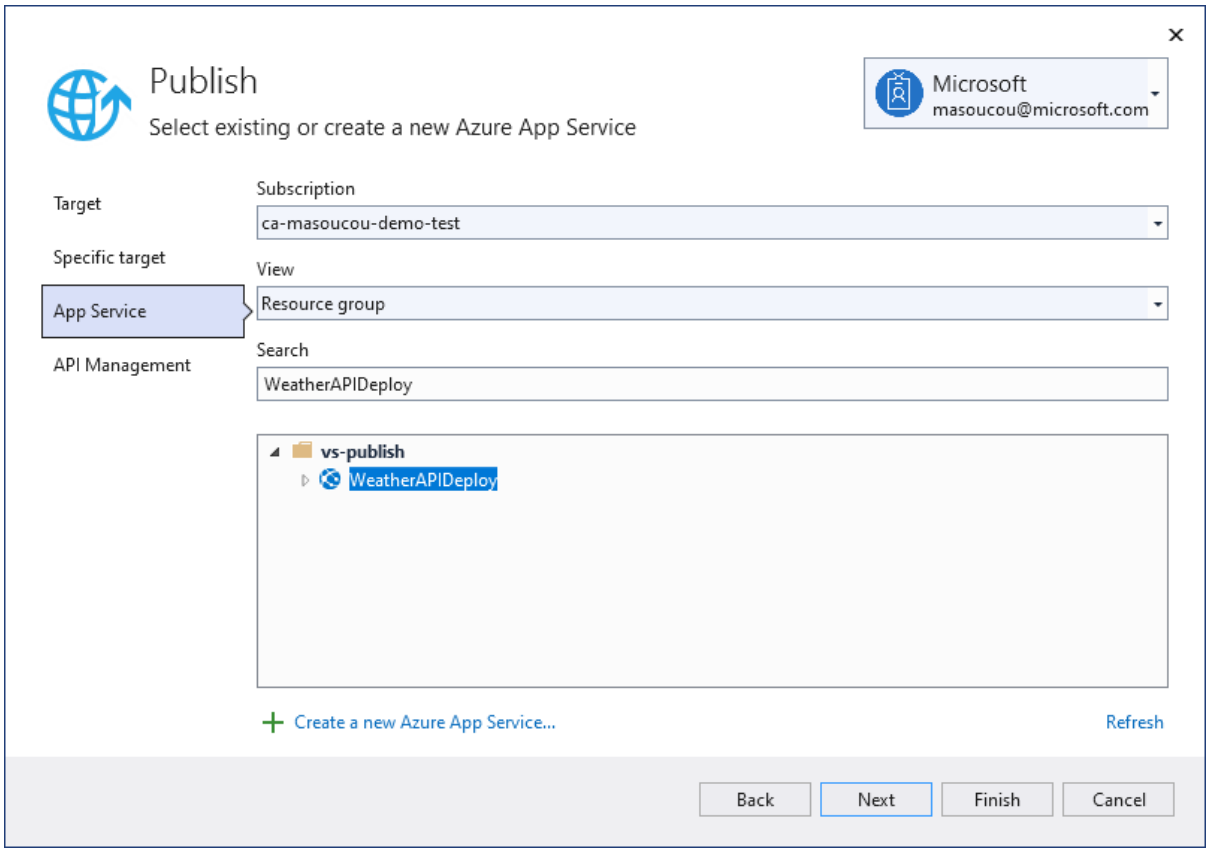


The blank API is created.



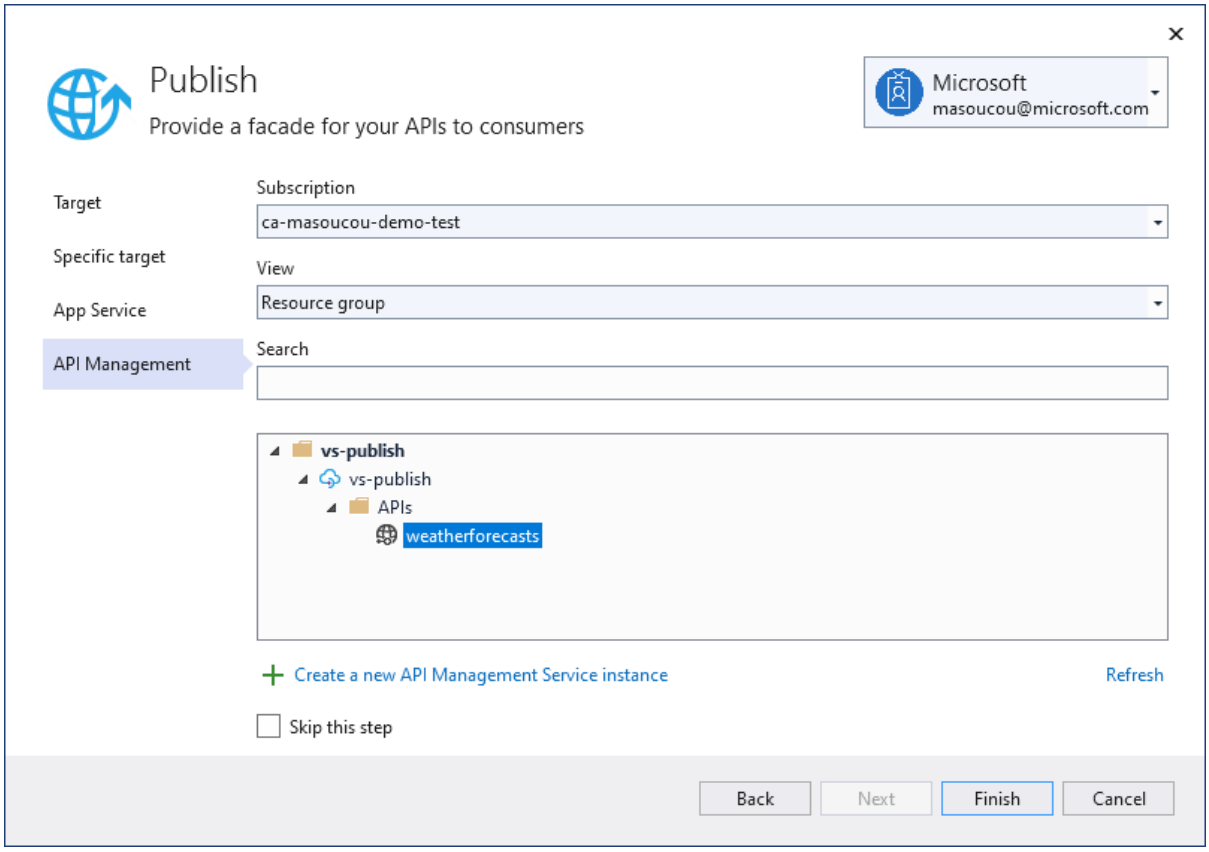
Publish the ASP.NET Core web API to Azure API Management

1. Switch back to Visual Studio. The **Publish** dialog should still be open where you left off before.
2. Select the newly published Azure App Service so it's highlighted.
3. Select the **Next** button.

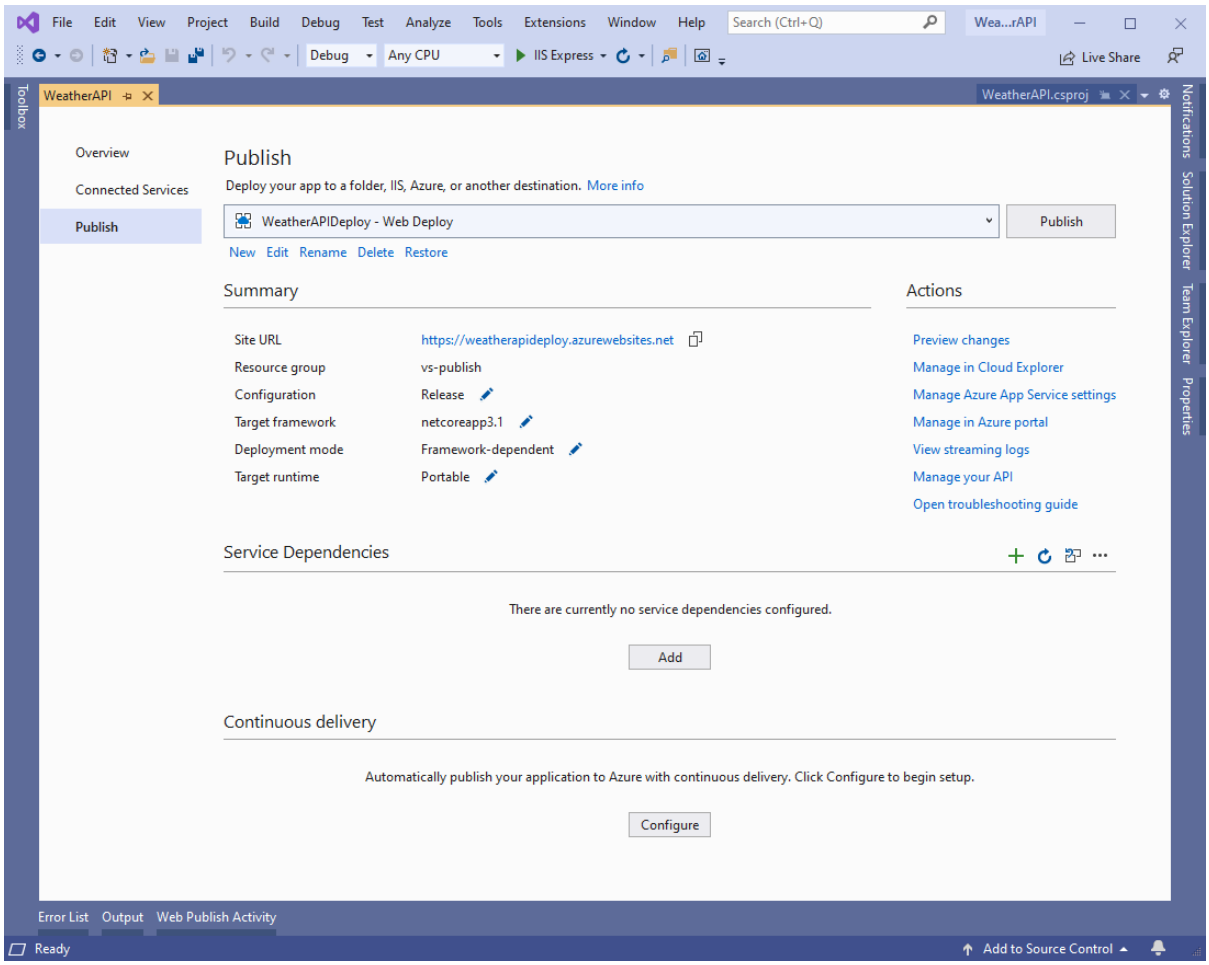


4. The dialog now shows the Azure API Management service created before. Expand it and the *APIs* folder to see the blank API you created.

5. Select the blank API's name and select the **Finish** button.



6. The dialog closes and a summary screen appears with information about the publish. Select the **Publish** button.

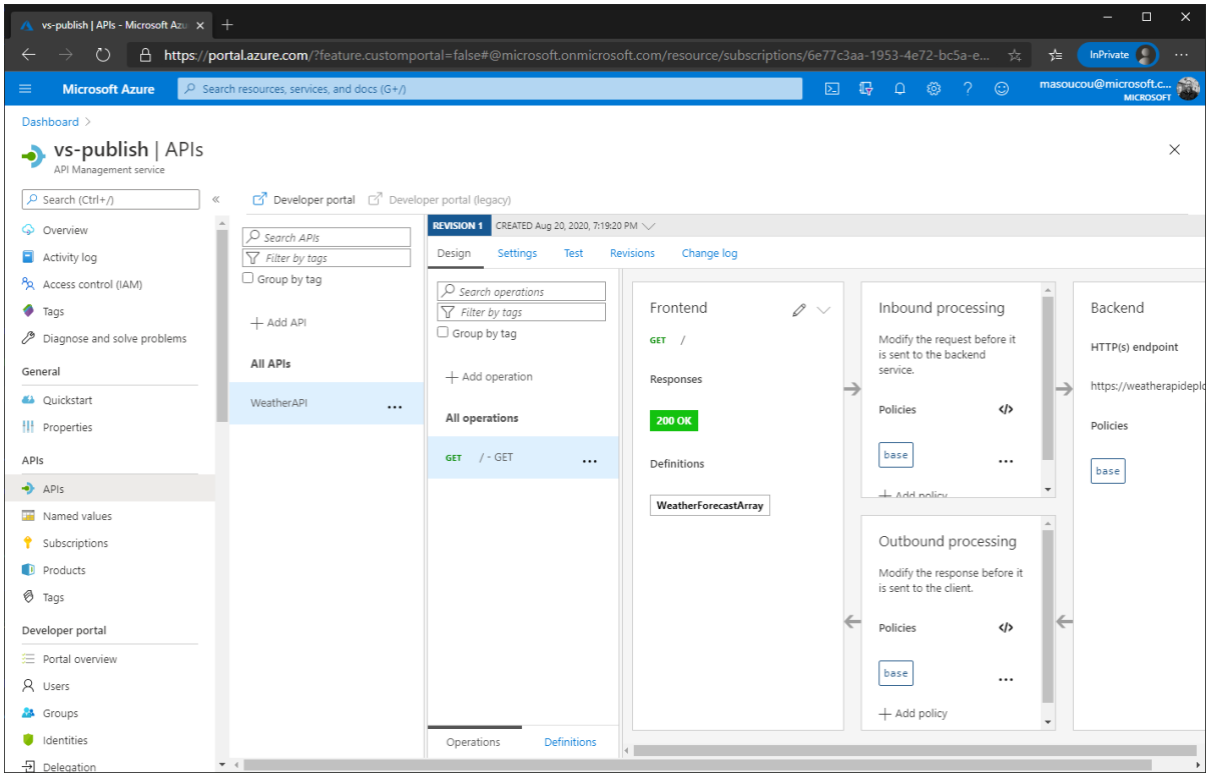


The web API will publish to both Azure App Service and Azure API Management. A new browser window will appear and show the API running in Azure App Service. You can close that window.

7. Switch back to the Azure API Management instance in the Azure portal.

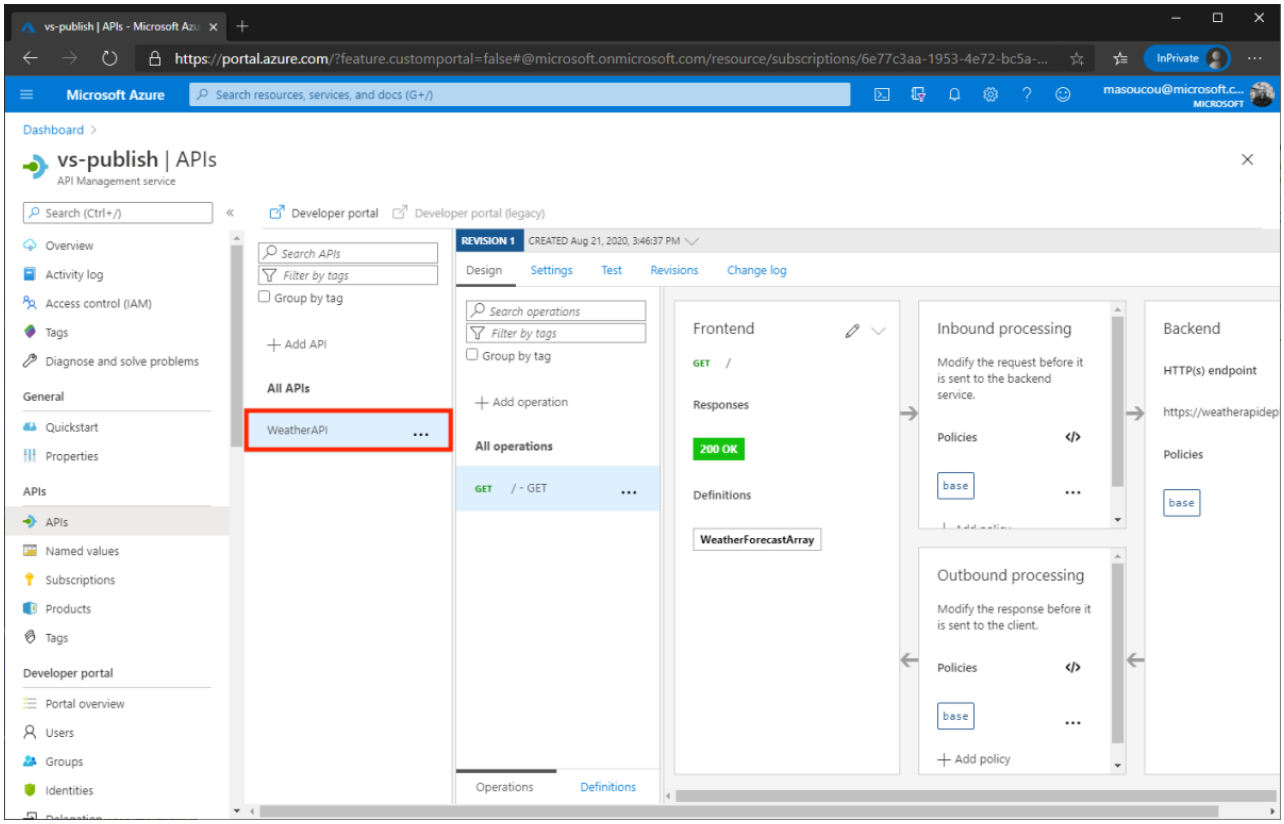
8. Refresh the browser window.

9. Select the blank API you created in the preceding steps. It's now populated and you can explore around.



Configure the published API name

Notice the name of the API is different than what you named it. The published API is named *WeatherAPI*, however, you named it *WeatherForecasts* when you created it. Complete the following steps to fix the name:



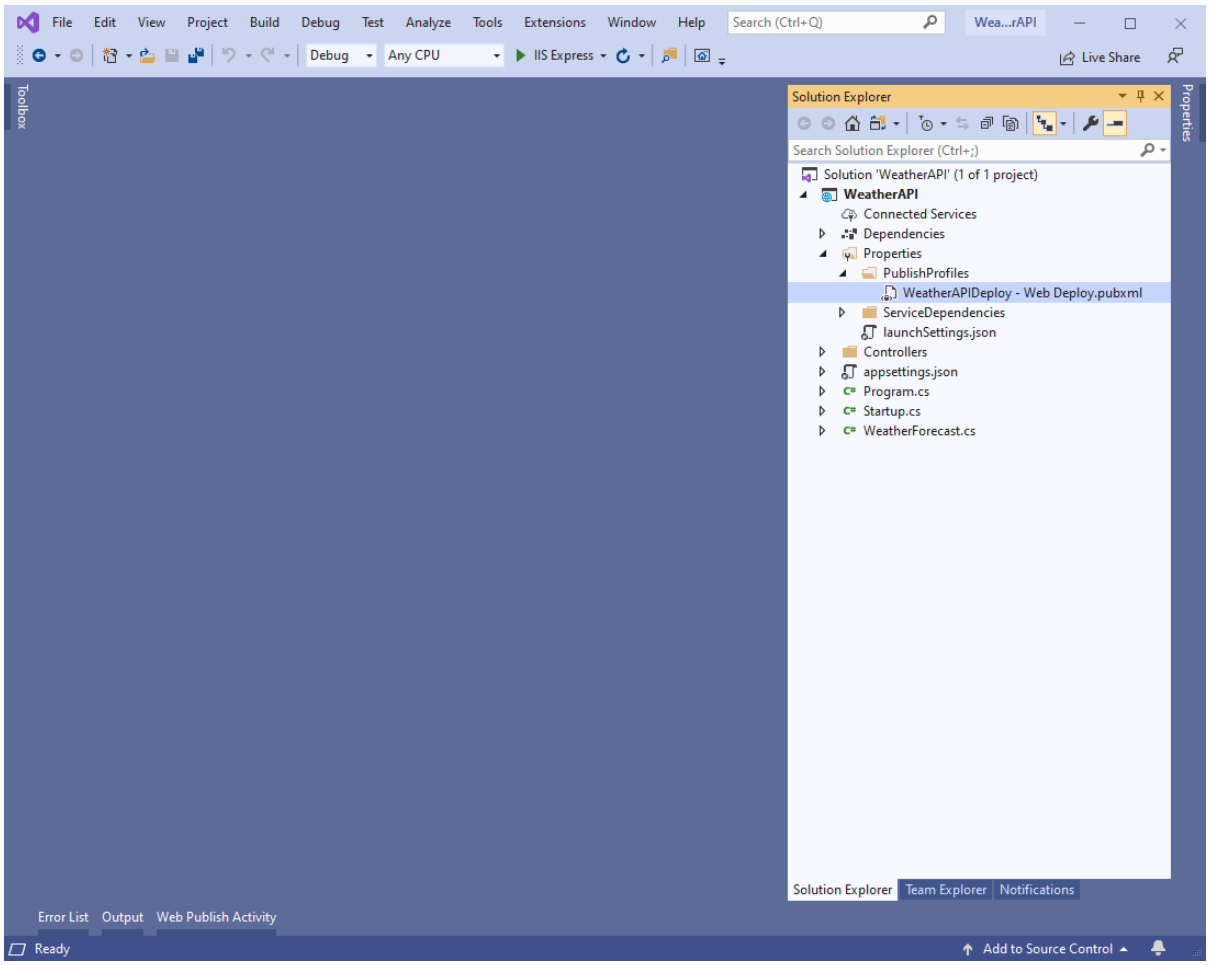
1. Delete the following line from the `Startup.ConfigureServices` method:

```
services.AddSwaggerGen();
```

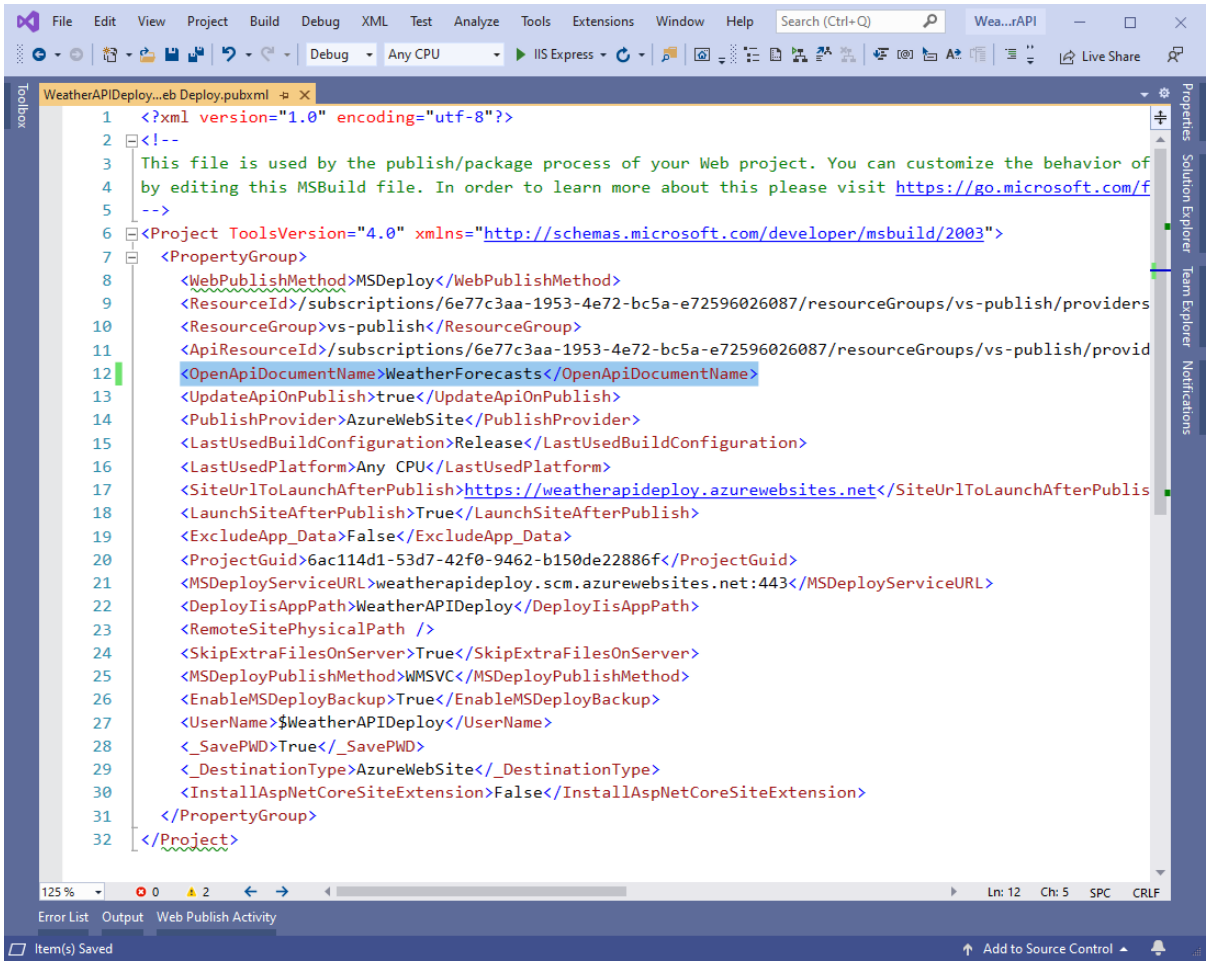
2. Add the following code to the `Startup.ConfigureServices` method:

```
services.AddSwaggerGen(config =>
{
    config.SwaggerDoc("WeatherForecasts", new Microsoft.OpenApi.Models.OpenApiInfo
    {
        Title = "Weather Forecasts",
        Version = "v1"
    });
});
```

3. Open the newly created publish profile. It can be found from **Solution Explorer** in the *Properties/PublishProfiles* folder.

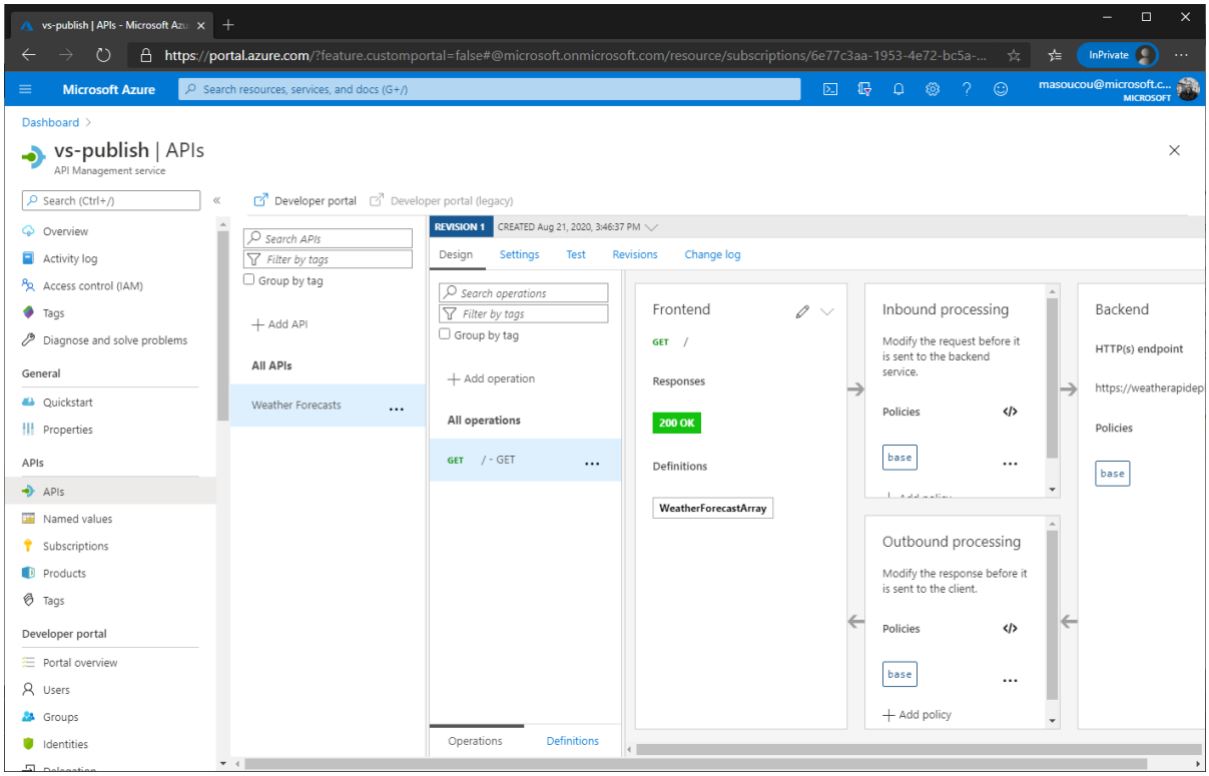


4. Change the `<OpenAPIDocumentName>` element's value from `v1` to `WeatherForecasts`.



5. Republish the ASP.NET Core web API and open the Azure API Management instance in the Azure portal.

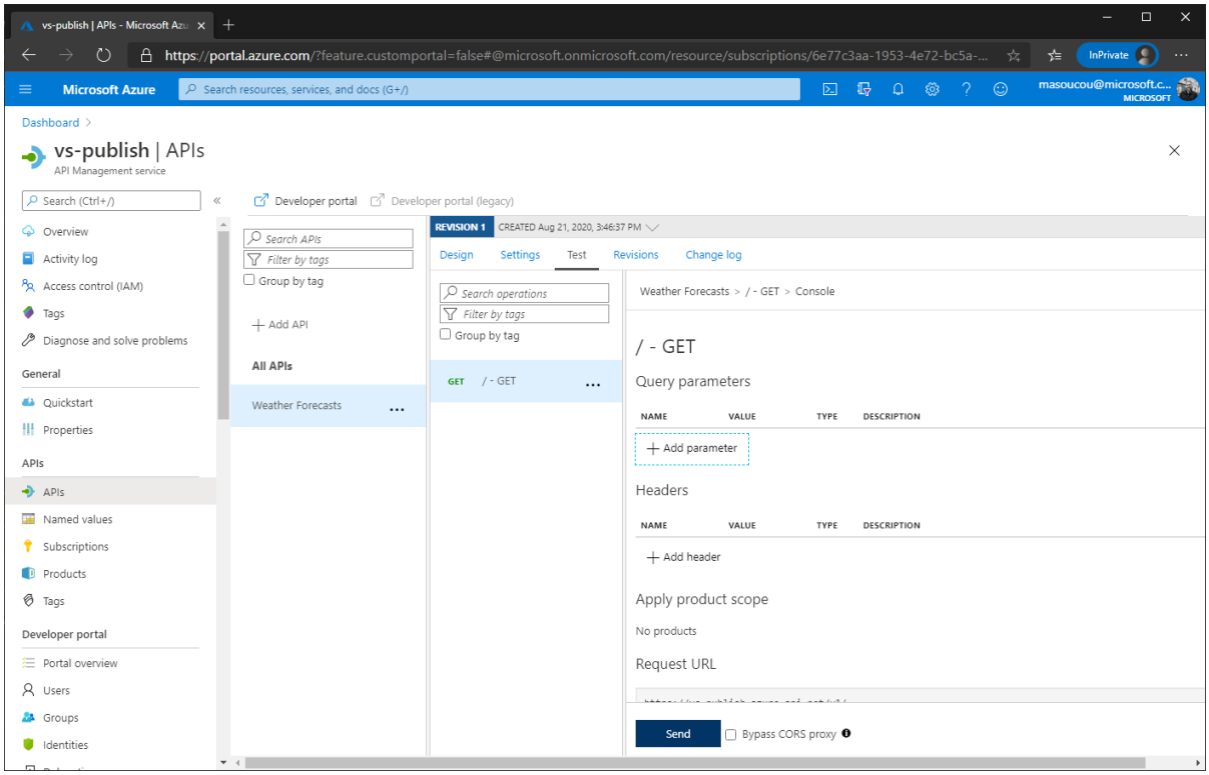
6. Refresh the page in your browser. You'll see the name of the API is now correct.



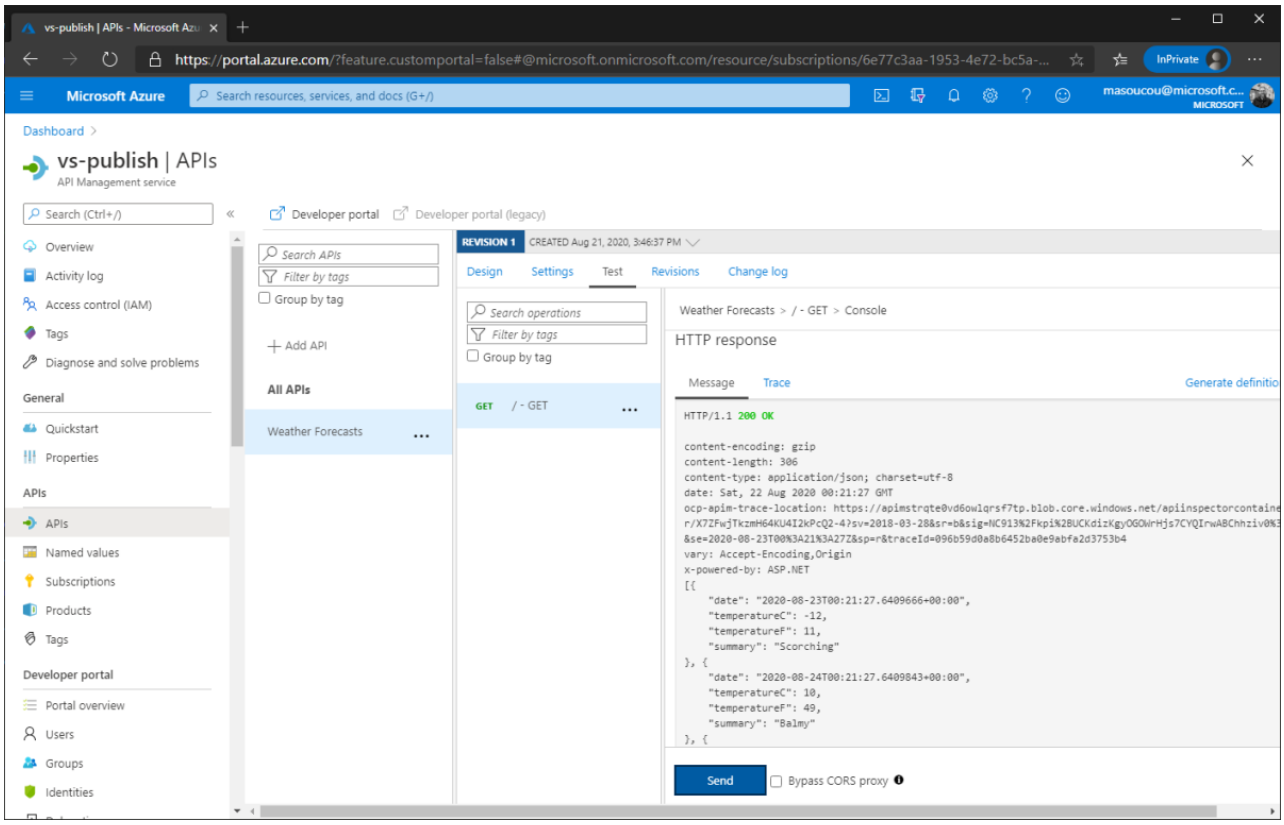
Verify the web API is working

You can test the deployed ASP.NET Core web API in Azure API Management from the Azure portal with the following steps:

1. Open the **Test** tab.
2. Select **/** or the **Get** operation.
3. Select **Send**.



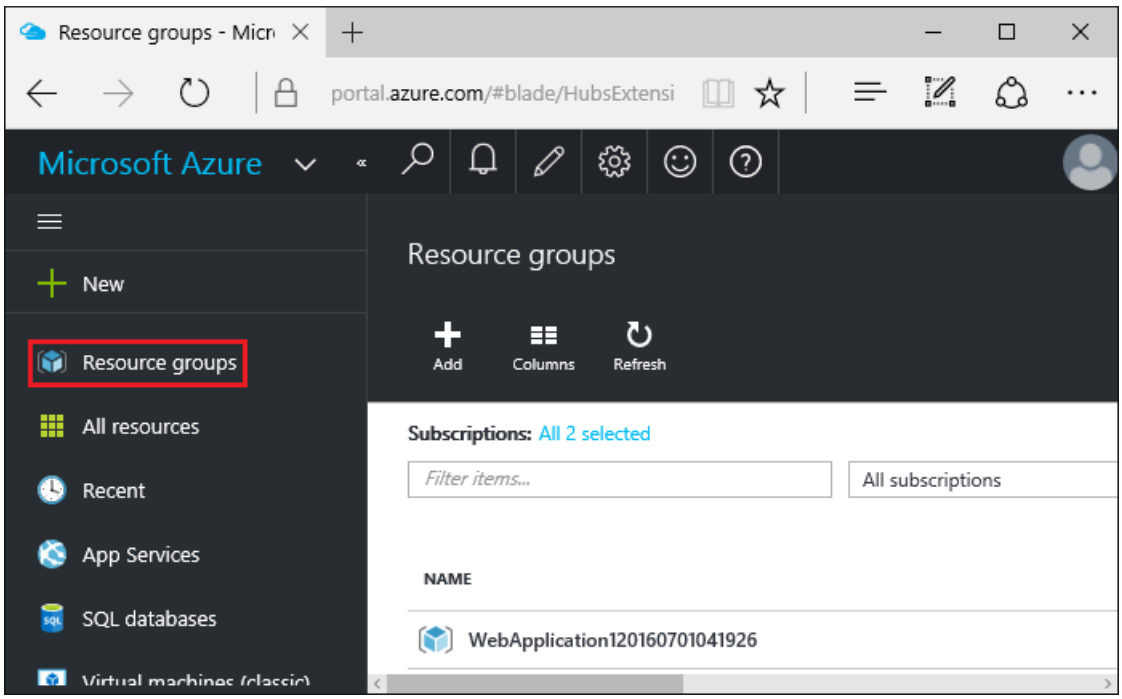
A successful response will look like the following:



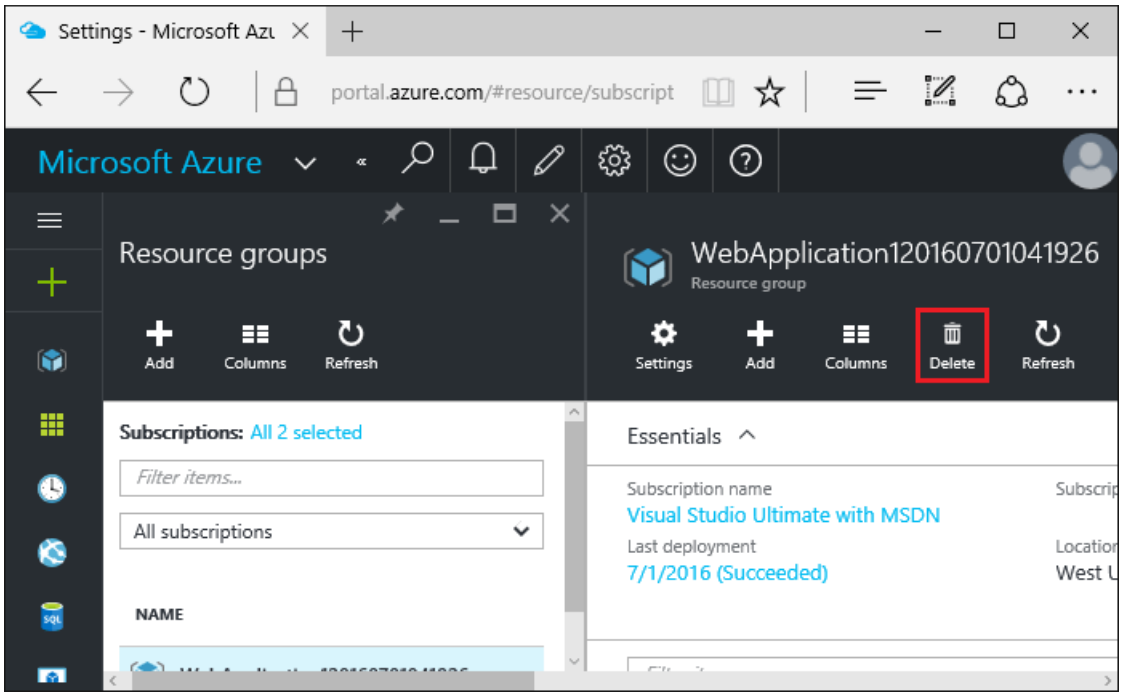
Clean up

When you've finished testing the app, go to the Azure portal and delete the app.

1. Select **Resource groups**, then select the resource group you created.



2. In the **Resource groups** page, select **Delete**.



3. Enter the name of the resource group and select **Delete**. Your app and all other resources created in this tutorial are now deleted from Azure.

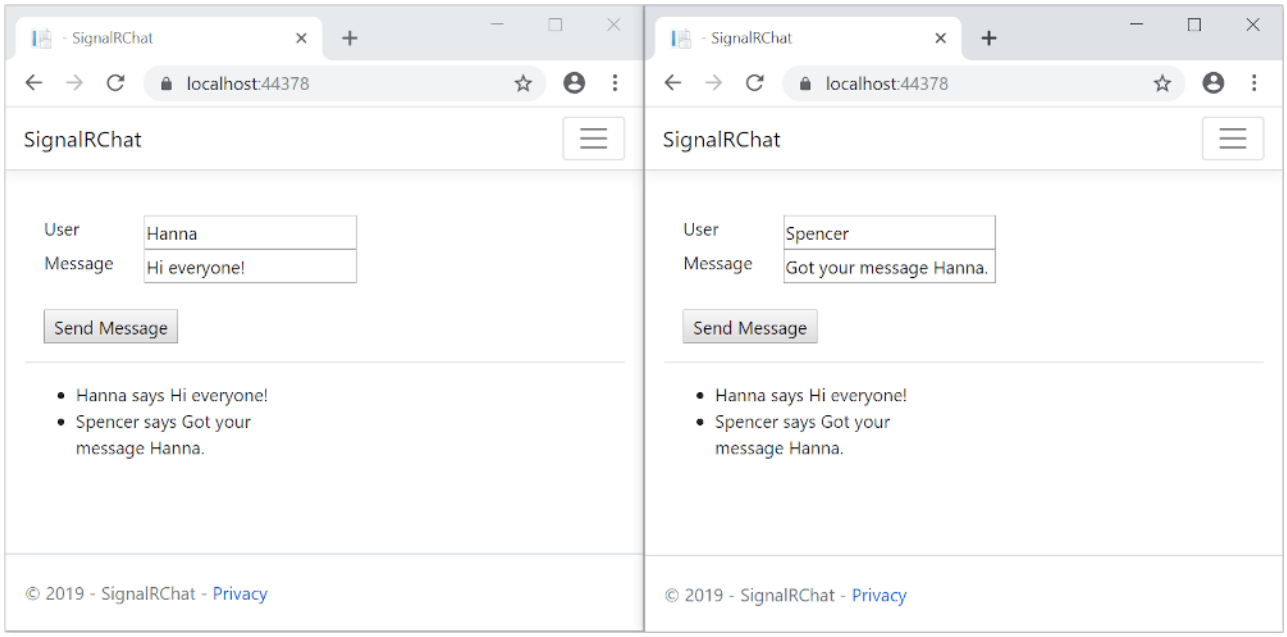
Tutorial: Get started with ASP.NET Core SignalR

9/22/2020 • 13 minutes to read • Edit Online

This tutorial teaches the basics of building a real-time app using SignalR. You learn how to:

- Create a web project.
- Add the SignalR client library.
- Create a SignalR hub.
- Configure the project to use SignalR.
- Add code that sends messages from any client to all connected clients.

At the end, you'll have a working chat app:



Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

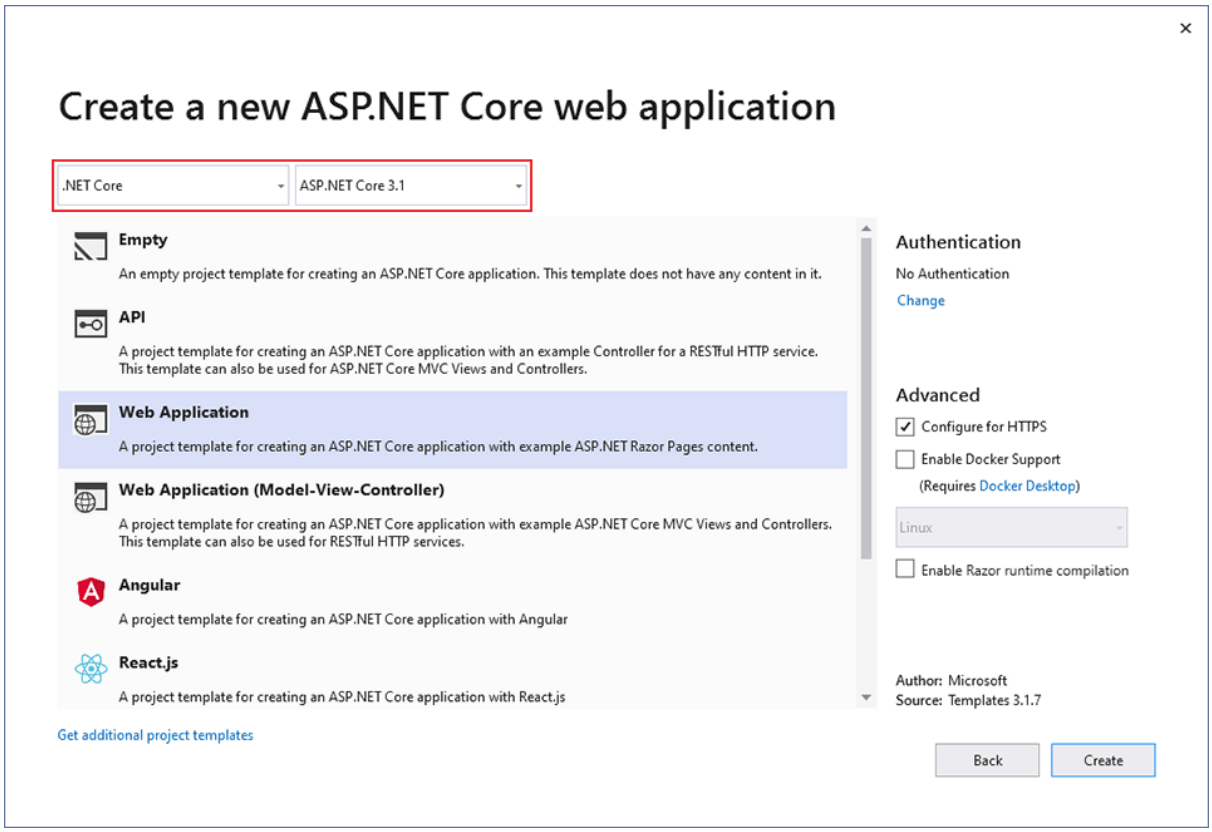
- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Create a web app project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the menu, select **File > New Project**.
- In the **Create a new project** dialog, select **ASP.NET Core Web Application**, and then select **Next**.
- In the **Configure your new project** dialog, name the project *SignalRChat*, and then select **Create**.

- In the **Create a new ASP.NET Core web Application** dialog, select **.NET Core** and **ASP.NET Core 3.1**.
- Select **Web Application** to create a project that uses Razor Pages, and then select **Create**.

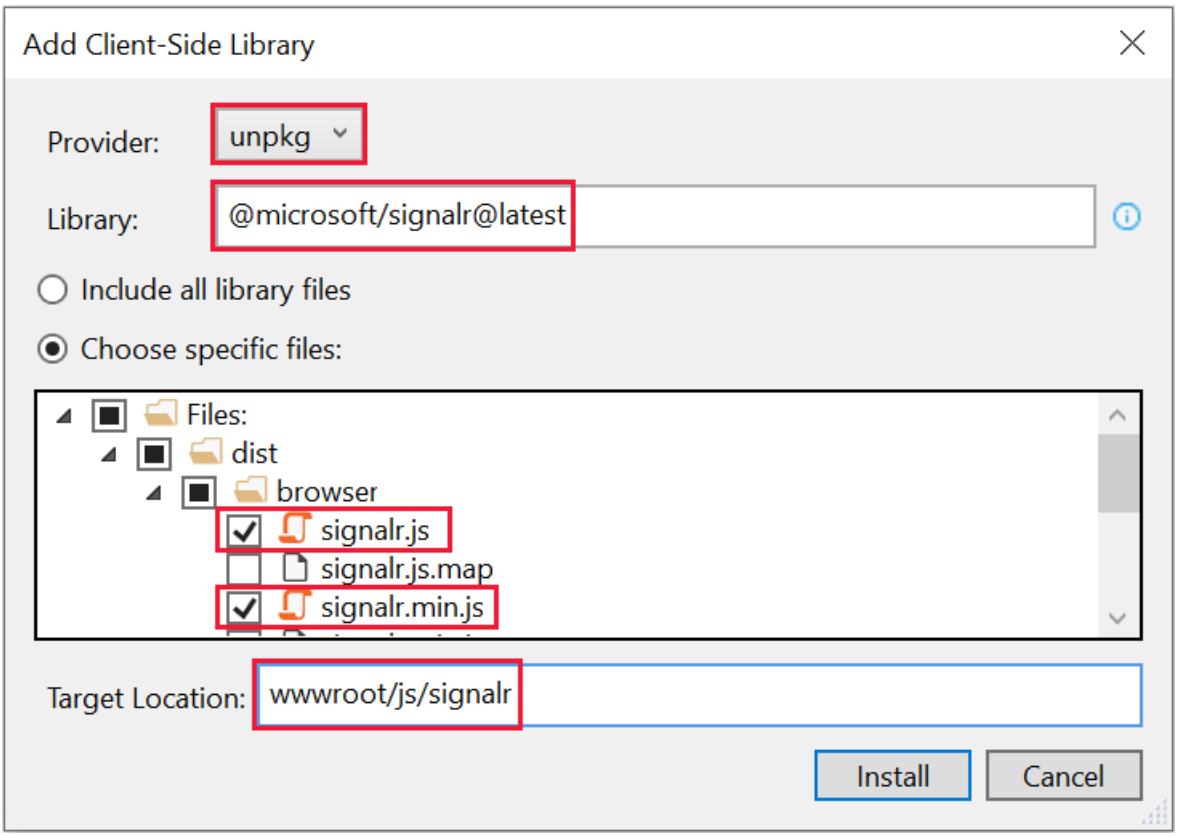


Add the SignalR client library

The SignalR server library is included in the ASP.NET Core 3.1 shared framework. The JavaScript client library isn't automatically included in the project. For this tutorial, you use Library Manager (LibMan) to get the client library from *unpkg*. unpkg is a content delivery network (CDN) that can deliver anything found in npm, the Node.js package manager.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project, and select **Add** > **Client-Side Library**.
- In the **Add Client-Side Library** dialog, for **Provider** select **unpkg**.
- For **Library**, enter `@microsoft/signalr@latest`.
- Select **Choose specific files**, expand the *dist/browser* folder, and select *signalr.js* and *signalr.min.js*.
- Set **Target Location** to *wwwroot/js/signalr/*, and select **Install**.



LibMan creates a *wwwroot/js/signalr* folder and copies the selected files to it.

Create a SignalR hub

A *hub* is a class that serves as a high-level pipeline that handles client-server communication.

- In the SignalRChat project folder, create a *Hubs* folder.
- In the *Hubs* folder, create a *ChatHub.cs* file with the following code:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRChat.Hubs
{
    public class ChatHub : Hub
    {
        public async Task SendMessage(string user, string message)
        {
            await Clients.All.SendAsync("ReceiveMessage", user, message);
        }
    }
}
```

The `ChatHub` class inherits from the SignalR `Hub` class. The `Hub` class manages connections, groups, and messaging.

The `SendMessage` method can be called by a connected client to send a message to all clients. JavaScript client code that calls the method is shown later in the tutorial. SignalR code is asynchronous to provide maximum scalability.

Configure SignalR

The SignalR server must be configured to pass SignalR requests to SignalR.

- Add the following highlighted code to the *Startup.cs* file.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.HttpsPolicy;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using SignalRChat.Hubs;

namespace SignalRChat
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        // This method gets called by the runtime. Use this method to add services to the container.
        public void ConfigureServices(IServiceCollection services)
        {
            services.AddRazorPages();
            services.AddSignalR();
        }

        // This method gets called by the runtime. Use this method to configure the HTTP request
pipeline.
        public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
                // The default HSTS value is 30 days. You may want to change this for production
scenarios, see https://aka.ms/aspnetcore-hsts.
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseStaticFiles();

            app.UseRouting();

            app.UseAuthorization();

            app.UseEndpoints(endpoints =>
            {
                endpoints.MapRazorPages();
                endpoints.MapHub<ChatHub>("/chathub");
            });
        }
    }
}
```

These changes add SignalR to the ASP.NET Core dependency injection and routing systems.

Add SignalR client code

- Replace the content in *Pages\Index.cshtml* with the following code:

```
@page
    <div class="container">
        <div class="row"> </div>
        <div class="row">
            <div class="col-2">User</div>
            <div class="col-4"><input type="text" id="userInput" /></div>
        </div>
        <div class="row">
            <div class="col-2">Message</div>
            <div class="col-4"><input type="text" id="messageInput" /></div>
        </div>
        <div class="row"> </div>
        <div class="row">
            <div class="col-6">
                <input type="button" id="sendButton" value="Send Message" />
            </div>
        </div>
    </div>
    <div class="row">
        <div class="col-12">
            <hr />
        </div>
    </div>
    <div class="row">
        <div class="col-6">
            <ul id="messagesList"></ul>
        </div>
    </div>
<script src="~/js/signalr/dist/browser/signalr.js"></script>
<script src="~/js/chat.js"></script>
```

  The preceding code:

  - Creates text boxes for name and message text, and a submit button.
  - Creates a list with `id="messagesList"` for displaying messages that are received from the SignalR hub.
  - Includes script references to SignalR and the *chat.js* application code that you create in the next step.
- In the *wwwroot/js* folder, create a *chat.js* file with the following code:

```
"use strict";

var connection = new signalR.HubConnectionBuilder().withUrl("/chatHub").build();

//Disable send button until connection is established
document.getElementById("sendButton").disabled = true;

connection.on("ReceiveMessage", function (user, message) {
    var msg = message.replace(/&/g, "&amp;").replace(/</g, "&lt;").replace(/>/g, "&gt;");
    var encodedMsg = user + " says " + msg;
    var li = document.createElement("li");
    li.textContent = encodedMsg;
    document.getElementById("messagesList").appendChild(li);
});

connection.start().then(function () {
    document.getElementById("sendButton").disabled = false;
}).catch(function (err) {
    return console.error(err.toString());
});

document.getElementById("sendButton").addEventListener("click", function (event) {
    var user = document.getElementById("userInput").value;
    var message = document.getElementById("messageInput").value;
    connection.invoke("SendMessage", user, message).catch(function (err) {
        return console.error(err.toString());
    });
    event.preventDefault();
});
```

The preceding code:

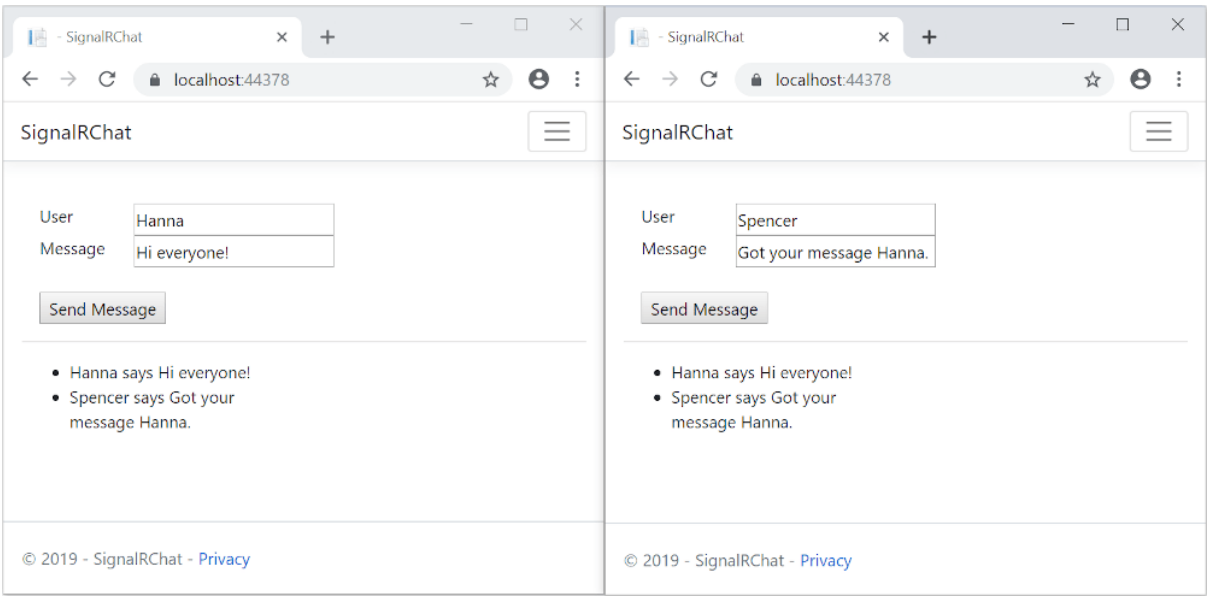
- Creates and starts a connection.
- Adds to the submit button a handler that sends messages to the hub.
- Adds to the connection object a handler that receives messages from the hub and adds them to the list.

Run the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

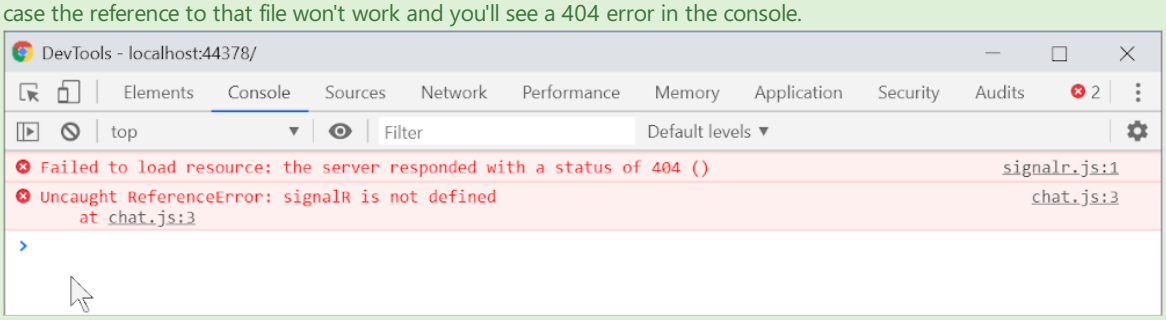
- Press **CTRL+F5** to run the app without debugging.
- Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.
- Choose either browser, enter a name and message, and select the **Send Message** button.

  The name and message are displayed on both pages instantly.



TIP

- If the app doesn't work, open your browser developer tools (F12) and go to the console. You might see errors related to your HTML and JavaScript code. For example, suppose you put *signalr.js* in a different folder than directed. In that case the reference to that file won't work and you'll see a 404 error in the console.

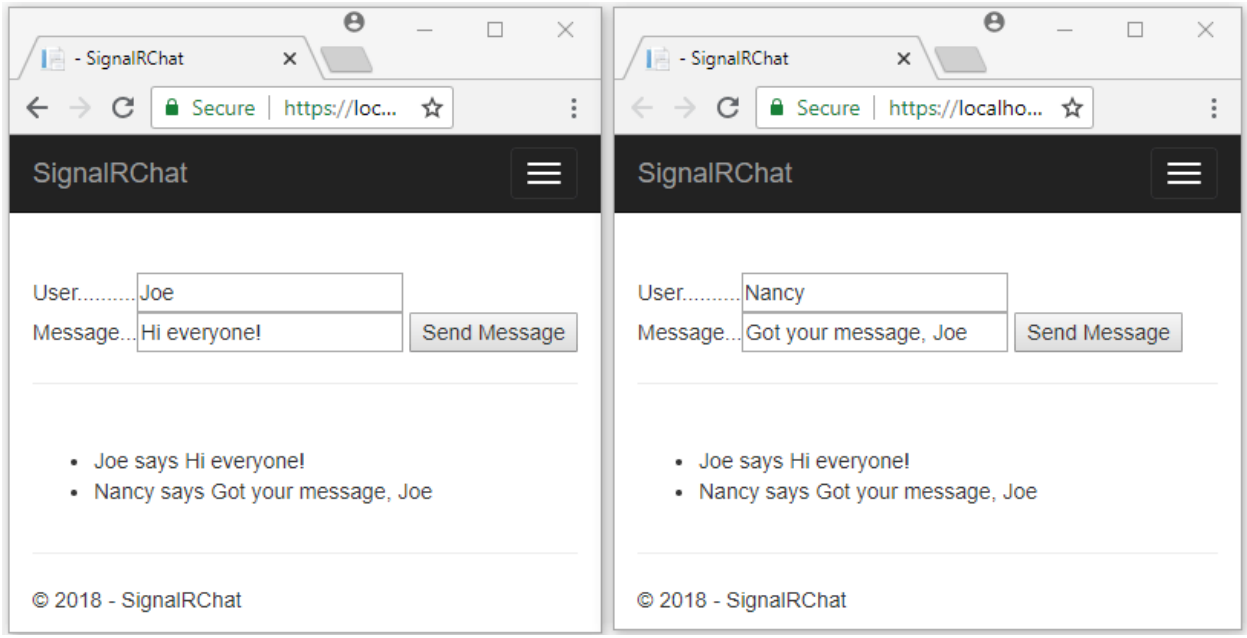


- If you get the error ERR_SPDY_INADEQUATE_TRANSPORT_SECURITY in Chrome, run these commands to update your development certificate:

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

This tutorial teaches the basics of building a real-time app using SignalR. You learn how to:

- Create a web project.
- Add the SignalR client library.
- Create a SignalR hub.
- Configure the project to use SignalR.
- Add code that sends messages from any client to all connected clients. At the end, you'll have a working chat app:



Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

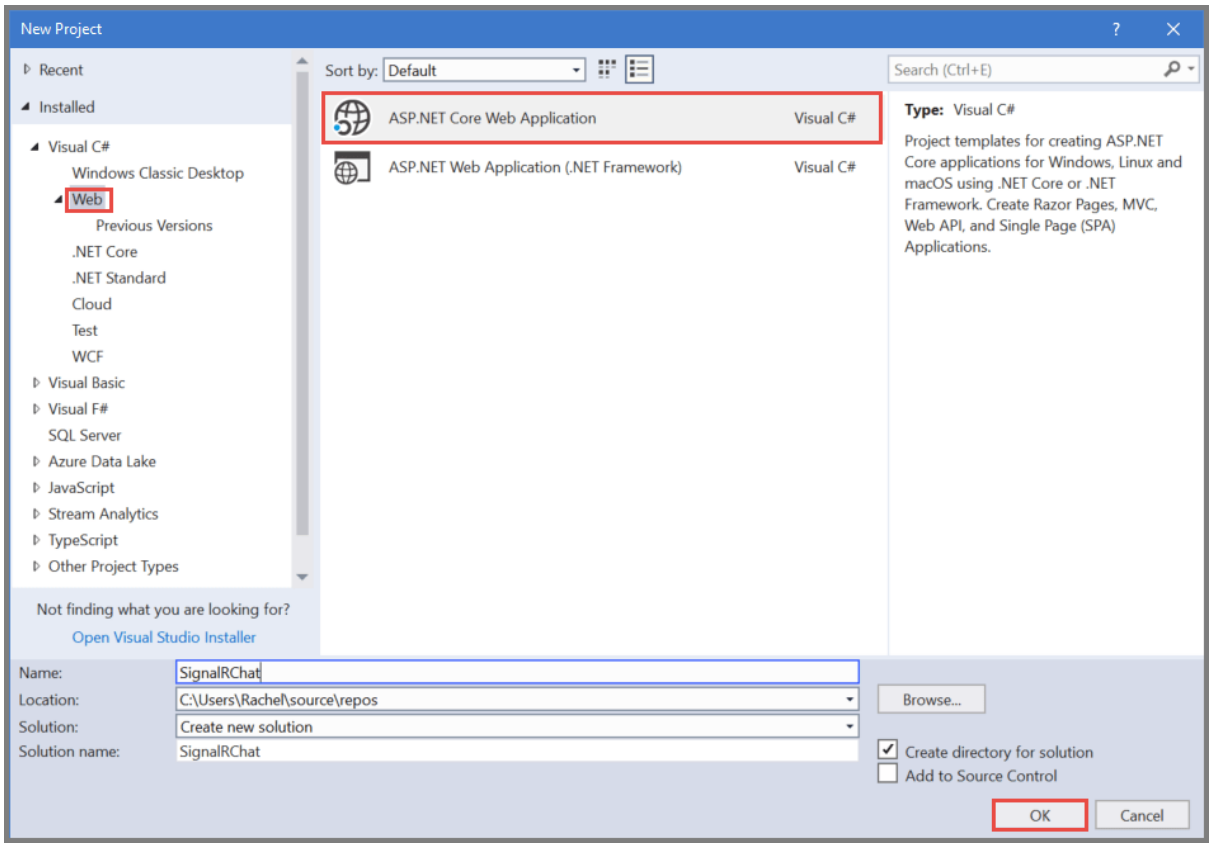
- Visual Studio 2017 version 15.9 or later with the **ASP.NET and web development** workload. You can use Visual Studio 2019, but some project creation steps differ from what's shown in the tutorial.
- .NET Core SDK 2.2 or later

> **WARNING**
> If you use Visual Studio 2017, see dotnet/sdk issue #3124 for information about .NET Core SDK versions that don't work with Visual Studio.

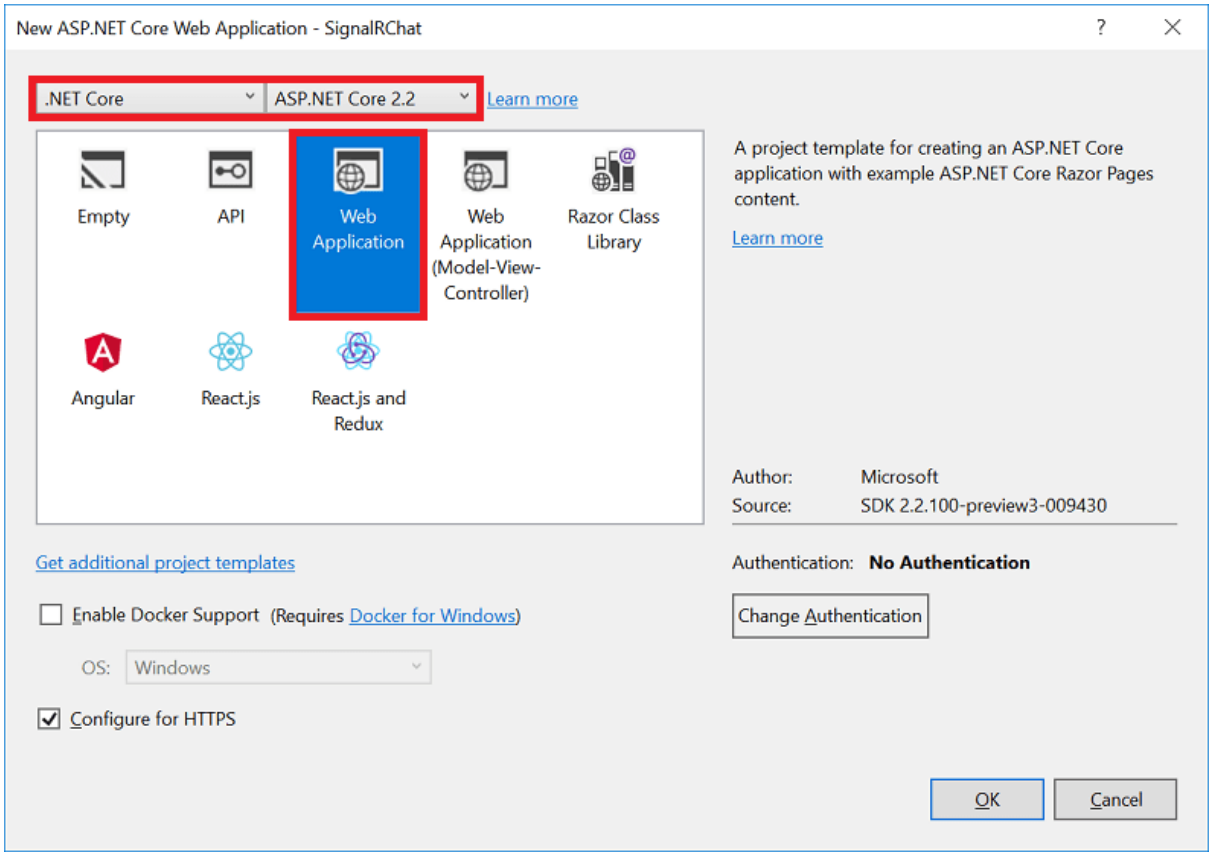
Create a web project

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- From the menu, select **File > New Project**.
- In the **New Project** dialog, select **Installed > Visual C# > Web > ASP.NET Core Web Application**. Name the project *SignalRChat*.



- Select **Web Application** to create a project that uses Razor Pages.
- Select a target framework of **.NET Core**, select **ASP.NET Core 2.2**, and click **OK**.



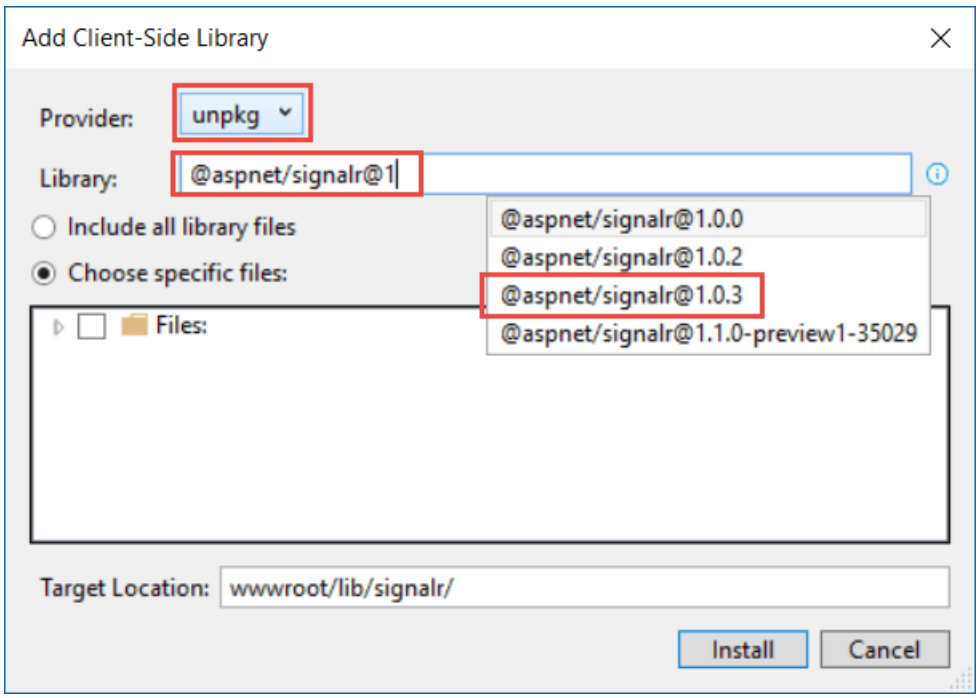
Add the SignalR client library

The SignalR server library is included in the `Microsoft.AspNetCore.App` metapackage. The JavaScript client library isn't automatically included in the project. For this tutorial, you use Library Manager (LibMan) to get the client library from *unpkg*. unpkg is a content delivery network (CDN) that can deliver anything found in npm, the Node.js

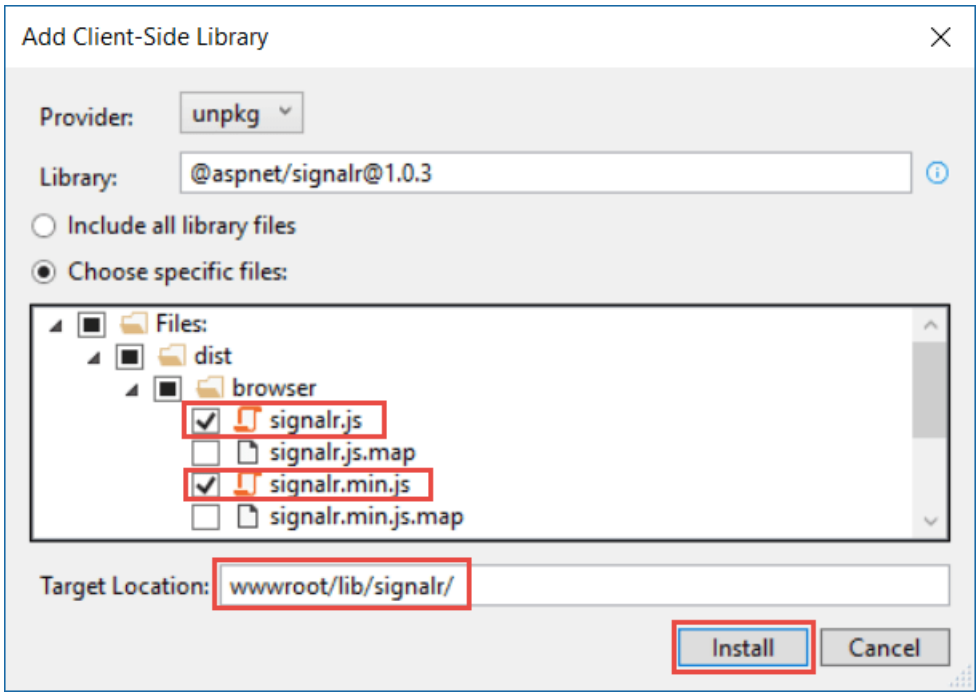
package manager.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- In **Solution Explorer**, right-click the project, and select **Add** > **Client-Side Library**.
- In the **Add Client-Side Library** dialog, for **Provider** select **unpkg**.
- For **Library**, enter `@microsoft/signalr@3`, and select the latest version that isn't preview.



- Select **Choose specific files**, expand the *dist/browser* folder, and select *signalr.js* and *signalr.min.js*.
- Set **Target Location** to *wwwroot/lib/signalr/*, and select **Install**.



LibMan creates a *wwwroot/lib/signalr* folder and copies the selected files to it.

Create a SignalR hub

A *hub* is a class that serves as a high-level pipeline that handles client-server communication.

- In the SignalRChat project folder, create a *Hubs* folder.
- In the *Hubs* folder, create a *ChatHub.cs* file with the following code:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRChat.Hubs
{
    public class ChatHub : Hub
    {
        public async Task SendMessage(string user, string message)
        {
            await Clients.All.SendAsync("ReceiveMessage", user, message);
        }
    }
}
```

  The `ChatHub` class inherits from the SignalR `Hub` class. The `Hub` class manages connections, groups, and messaging.

  The `SendMessage` method can be called by a connected client to send a message to all clients. JavaScript client code that calls the method is shown later in the tutorial. SignalR code is asynchronous to provide maximum scalability.

Configure SignalR

The SignalR server must be configured to pass SignalR requests to SignalR.

- Add the following highlighted code to the *Startup.cs* file.

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using SignalRChat.Hubs;

namespace SignalRChat
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        // This method gets called by the runtime. Use this method to add services to the container.
        public void ConfigureServices(IServiceCollection services)
        {
            services.Configure<CookiePolicyOptions>(options =>
            {
                // This lambda determines whether user consent for non-essential cookies is needed for a
given request.
                options.CheckConsentNeeded = context => true;
                options.MinimumSameSitePolicy = SameSiteMode.None;
            });

            services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

            services.AddSignalR();
        }

        // This method gets called by the runtime. Use this method to configure the HTTP request
pipeline.
        public void Configure(IApplicationBuilder app, IHostingEnvironment env)
        {
            if (env.IsDevelopment())
            {
                app.UseDeveloperExceptionPage();
            }
            else
            {
                app.UseExceptionHandler("/Error");
                app.UseHsts();
            }

            app.UseHttpsRedirection();
            app.UseStaticFiles();
            app.UseCookiePolicy();
            app.UseSignalR(routes =>
            {
                routes.MapHub<ChatHub>("/chathub");
            });
            app.UseMvc();
        }
    }
}
```

These changes add SignalR to the ASP.NET Core dependency injection system and the middleware pipeline.

Add SignalR client code

- Replace the content in *Pages\Index.cshtml* with the following code:

```
@page
<div class="container">
    <div class="row"> </div>
    <div class="row">
        <div class="col-6"> </div>
        <div class="col-6">
            User.........<input type="text" id="userInput" />
            <br />
            Message...<input type="text" id="messageInput" />
            <input type="button" id="sendButton" value="Send Message" />
        </div>
    </div>
    <div class="row">
        <div class="col-12">
            <hr />
        </div>
    </div>
    <div class="row">
        <div class="col-6"> </div>
        <div class="col-6">
            <ul id="messagesList"></ul>
        </div>
    </div>
</div>
<script src="~/lib/signalr/dist/browser/signalr.js"></script>
<script src="~/js/chat.js"></script>
```

  The preceding code:

  - Creates text boxes for name and message text, and a submit button.
  - Creates a list with `id="messagesList"` for displaying messages that are received from the SignalR hub.
  - Includes script references to SignalR and the *chat.js* application code that you create in the next step.
- In the *wwwroot/js* folder, create a *chat.js* file with the following code:

```
"use strict";

var connection = new signalR.HubConnectionBuilder().withUrl("/chatHub").build();

//Disable send button until connection is established
document.getElementById("sendButton").disabled = true;

connection.on("ReceiveMessage", function (user, message) {
    var msg = message.replace(/&/g, "&amp;").replace(/</g, "&lt;").replace(/>/g, "&gt;");
    var encodedMsg = user + " says " + msg;
    var li = document.createElement("li");
    li.textContent = encodedMsg;
    document.getElementById("messagesList").appendChild(li);
});

connection.start().then(function(){
    document.getElementById("sendButton").disabled = false;
}).catch(function (err) {
    return console.error(err.toString());
});

document.getElementById("sendButton").addEventListener("click", function (event) {
    var user = document.getElementById("userInput").value;
    var message = document.getElementById("messageInput").value;
    connection.invoke("SendMessage", user, message).catch(function (err) {
        return console.error(err.toString());
    });
    event.preventDefault();
});
```

The preceding code:

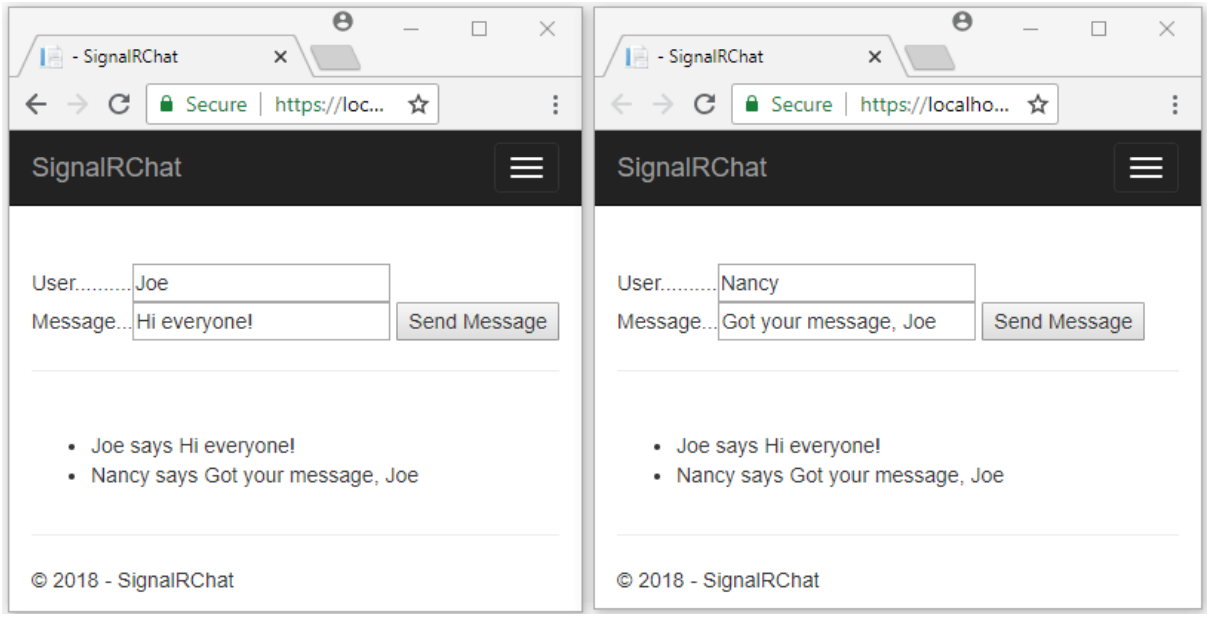
- Creates and starts a connection.
- Adds to the submit button a handler that sends messages to the hub.
- Adds to the connection object a handler that receives messages from the hub and adds them to the list.

Run the app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Press **CTRL+F5** to run the app without debugging.
- Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.
- Choose either browser, enter a name and message, and select the **Send Message** button.

  The name and message are displayed on both pages instantly.



TIP

If the app doesn't work, open your browser developer tools (F12) and go to the console. You might see errors related to your HTML and JavaScript code. For example, suppose you put *signalr.js* in a different folder than directed. In that case the reference to that file won't work and you'll see a 404 error in the console.

Use ASP.NET Core SignalR with TypeScript and Webpack

9/22/2020 • 21 minutes to read • Edit Online

By Sébastien Sougnez and Scott Addie

Webpack enables developers to bundle and build the client-side resources of a web app. This tutorial demonstrates using Webpack in an ASP.NET Core SignalR web app whose client is written in TypeScript.

In this tutorial, you learn how to:

- Scaffold a starter ASP.NET Core SignalR app
- Configure the SignalR TypeScript client
- Configure a build pipeline using Webpack
- Configure the SignalR server
- Enable communication between client and server

View or download sample code (how to download)

Prerequisites

- Visual Studio
- Visual Studio Code

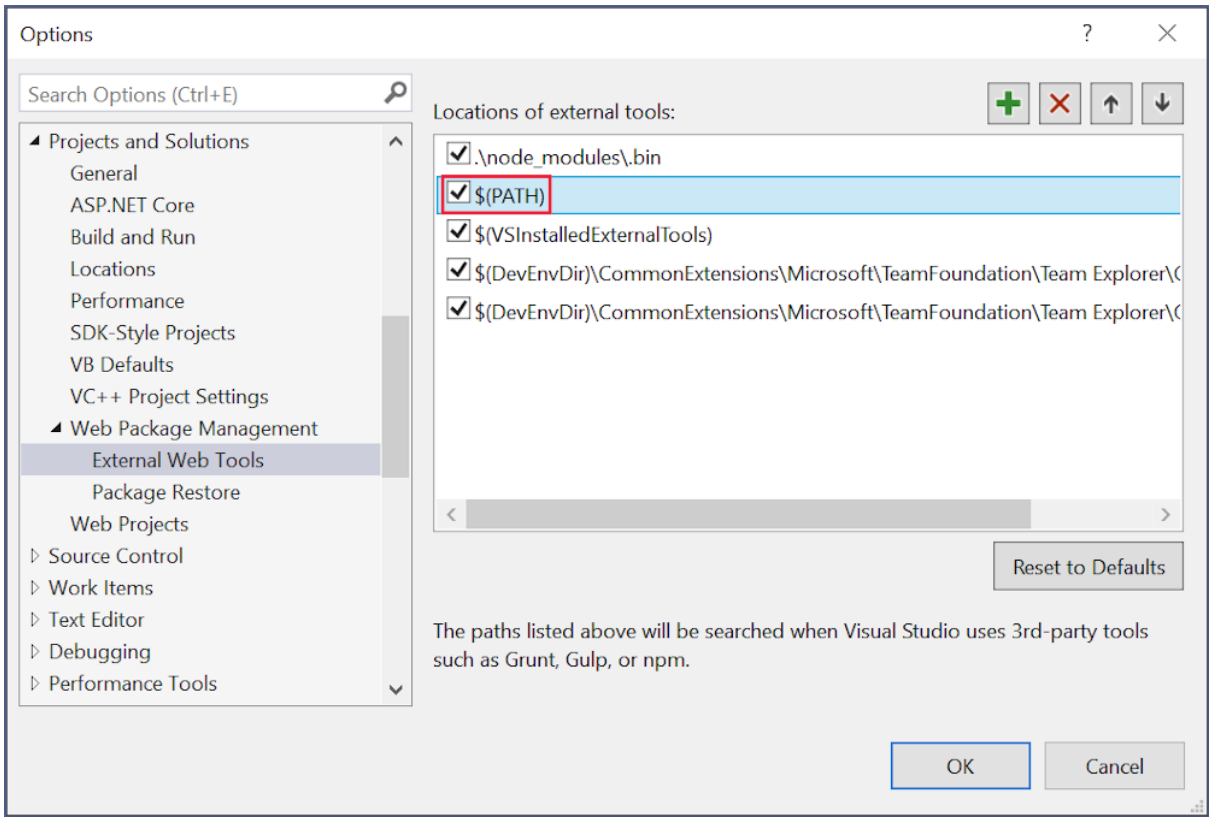
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 3.0 or later
- Node.js with npm

Create the ASP.NET Core web app

- Visual Studio
- Visual Studio Code

Configure Visual Studio to look for npm in the *PATH* environment variable. By default, Visual Studio uses the version of npm found in its installation directory. Follow these instructions in Visual Studio:

1. Launch Visual Studio. At the start window, select **Continue without code**.
2. Navigate to **Tools** > **Options** > **Projects and Solutions** > **Web Package Management** > **External Web Tools**.
3. Select the *$(PATH)* entry from the list. Click the up arrow to move the entry to the second position in the list, and select **OK**.



Visual Studio configuration is complete.

1. Use the **File** > **New** > **Project** menu option and choose the **ASP.NET Core Web Application** template. Select **Next**.
2. Name the project *SignalRWebPack*, and select **Create**.
3. Select *.NET Core* from the target framework drop-down, and select *ASP.NET Core 3.1* from the framework selector drop-down. Select the **Empty** template, and select **Create**.

Add the `Microsoft.TypeScript.MSBuild` package to the project:

1. In **Solution Explorer** (right pane), right-click the project node and select **Manage NuGet Packages**. In the **Browse** tab, search for `Microsoft.TypeScript.MSBuild`, and then click **Install** on the right to install the package.

Visual Studio adds the NuGet package under the **Dependencies** node in **Solution Explorer**, enabling TypeScript compilation in the project.

Configure Webpack and TypeScript

The following steps configure the conversion of TypeScript to JavaScript and the bundling of client-side resources.

1. Run the following command in the project root to create a *package.json* file:

```
npm init -y
```

2. Add the highlighted property to the *package.json* file and save the file changes:

```
{
  "name": "SignalRWebPack",
  "version": "1.0.0",
  "private": true,
  "description": "",
  "main": "index.js",
  "scripts": {
    "test": "echo \"Error: no test specified\" && exit 1"
  },
  "keywords": [],
  "author": "",
  "license": "ISC"
}
```

Setting the `private` property to `true` prevents package installation warnings in the next step.

3. Install the required npm packages. Run the following command from the project root:

```
npm i -D -E clean-webpack-plugin@3.0.0 css-loader@3.4.2 html-webpack-plugin@3.2.0 mini-css-extract-plugin@0.9.0 ts-loader@6.2.1 typescript@3.7.5 webpack@4.41.5 webpack-cli@3.3.10
```

Some command details to note:

- A version number follows the `@` sign for each package name. npm installs those specific package versions.
- The `-E` option disables npm's default behavior of writing semantic versioning range operators to *package.json*. For example, `"webpack": "4.41.5"` is used instead of `"webpack": "^4.41.5"`. This option prevents unintended upgrades to newer package versions.

See the npm-install docs for more detail.

4. Replace the `scripts` property of the *package.json* file with the following code:

```
"scripts": {
  "build": "webpack --mode=development --watch",
  "release": "webpack --mode=production",
  "publish": "npm run release && dotnet publish -c Release"
},
```

Some explanation of the scripts:

- `build`: Bundles the client-side resources in development mode and watches for file changes. The file watcher causes the bundle to regenerate each time a project file changes. The `mode` option disables production optimizations, such as tree shaking and minification. Only use `build` in development.
- `release`: Bundles the client-side resources in production mode.
- `publish`: Runs the `release` script to bundle the client-side resources in production mode. It calls the .NET Core CLI's publish command to publish the app.

5. Create a file named *webpack.config.js*, in the project root, with the following code:

```
const path = require("path");
const HtmlWebpackPlugin = require("html-webpack-plugin");
const { CleanWebpackPlugin } = require("clean-webpack-plugin");
const MiniCssExtractPlugin = require("mini-css-extract-plugin");
module.exports = {
    entry: "./src/index.ts",
    output: {
        path: path.resolve(__dirname, "wwwroot"),
        filename: "[name].[chunkhash].js",
        publicPath: "/"
    },
    resolve: {
        extensions: [".js", ".ts"]
    },
    module: {
        rules: [
            {
                test: /\.ts$/,
                use: "ts-loader"
            },
            {
                test: /\.css$/,
                use: [MiniCssExtractPlugin.loader, "css-loader"]
            }
        ]
    },
    plugins: [
        new CleanWebpackPlugin(),
        new HtmlWebpackPlugin({
            template: "./src/index.html"
        }),
        new MiniCssExtractPlugin({
            filename: "css/[name].[chunkhash].css"
        })
    ]
};
```

The preceding file configures the Webpack compilation. Some configuration details to note:

- The `output` property overrides the default value of *dist*. The bundle is instead emitted in the *wwwroot* directory.
- The `resolve.extensions` array includes *.js* to import the SignalR client JavaScript.

6. Create a new *src* directory in the project root to store the project's client-side assets.

7. Create *src/index.html* with the following markup.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>ASP.NET Core SignalR</title>
</head>
<body>
    <div id="divMessages" class="messages">
    </div>
    <div class="input-zone">
        <label id="lblMessage" for="tbMessage">Message:</label>
        <input id="tbMessage" class="input-zone-input" type="text" />
        <button id="btnSend">Send</button>
    </div>
</body>
</html>
```

The preceding HTML defines the homepage's boilerplate markup.

8. Create a new *src/css* directory. Its purpose is to store the project's *.css* files.

9. Create *src/css/main.css* with the following CSS:

```
*, *::before, *::after {
    box-sizing: border-box;
}

html, body {
    margin: 0;
    padding: 0;
}

.input-zone {
    align-items: center;
    display: flex;
    flex-direction: row;
    margin: 10px;
}

.input-zone-input {
    flex: 1;
    margin-right: 10px;
}

.message-author {
    font-weight: bold;
}

.messages {
    border: 1px solid #000;
    margin: 10px;
    max-height: 300px;
    min-height: 300px;
    overflow-y: auto;
    padding: 5px;
}
```

The preceding *main.css* file styles the app.

10. Create *src/tsconfig.json* with the following JSON:

```
{
  "compilerOptions": {
    "target": "es5"
  }
}
```

The preceding code configures the TypeScript compiler to produce ECMAScript 5-compatible JavaScript.

11. Create *src/index.ts* with the following code:

```
import "./css/main.css";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.key === "Enter") {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
}
```

The preceding TypeScript retrieves references to DOM elements and attaches two event handlers:

- `keyup`: This event fires when the user types in the `tbMessage` textbox. The `send` function is called when the user presses the **Enter** key.
- `click`: This event fires when the user clicks the **Send** button. The `send` function is called.

Configure the app

1. In `Startup.Configure`, add calls to UseDefaultFiles and UseStaticFiles.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.UseRouting();
    app.UseDefaultFiles();
    app.UseStaticFiles();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapHub<ChatHub>("/hub");
    });

}
```

The preceding code allows the server to locate and serve the *index.html* file. The file is served whether the user enters its full URL or the root URL of the web app.

2. At the end of `Startup.Configure`, map a */hub* route to the `ChatHub` hub. Replace the code that displays *Hello World!* with the following line:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapHub<ChatHub>("/hub");
});
```

3. In `Startup.ConfigureServices`, call AddSignalR.

```
services.AddSignalR();
```

4. Create a new directory named *Hubs* in the project root *SignalRWebPack/* to store the SignalR hub.

5. Create hub *Hubs/ChatHub.cs* with the following code:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRWebPack.Hubs
{
    public class ChatHub : Hub
    {
    }
}
```

6. Add the following `using` statement at the top of the *Startup.cs* file to resolve the `ChatHub` reference:

```
using SignalRWebPack.Hubs;
```

Enable client and server communication

The app currently displays a basic form to send messages, but is not yet functional. The server is listening to a specific route but does nothing with sent messages.

1. Run the following command at the project root:

```
npm i @microsoft/signalr @types/node
```

   The preceding command installs:

   - The SignalR TypeScript client, which allows the client to send messages to the server.
   - The TypeScript type definitions for Node.js, which enables compile-time checking of Node.js types.

2. Add the highlighted code to the *src/index.ts* file:

```
import "./css/main.css";
import * as signalR from "@microsoft/signalr";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message: string) => {
    let m = document.createElement("div");

    m.innerHTML =
        `<div class="message-author">${username}</div><div>${message}</div>`;

    divMessages.appendChild(m);
    divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch(err => document.write(err));

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.key === "Enter") {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
}
```

The preceding code supports receiving messages from the server. The `HubConnectionBuilder` class creates a new builder for configuring the server connection. The `withUrl` function configures the hub URL.

SignalR enables the exchange of messages between a client and a server. Each message has a specific name. For example, messages with the name `messageReceived` can run the logic responsible for displaying the new message in the messages zone. Listening to a specific message can be done via the `on` function. Any number of message names can be listened to. It's also possible to pass parameters to the message, such as the author's name and the content of the message received. Once the client receives a message, a new `div` element is created with the author's name and the message content in its `innerHTML` attribute. It's added to the main `div` element displaying the messages.

3. Now that the client can receive a message, configure it to send messages. Add the highlighted code to the *src/index.ts* file:

```
import "./css/main.css";
import * as signalR from "@microsoft/signalr";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message: string) => {
    let messages = document.createElement("div");

    messages.innerHTML =
        `<div class="message-author">${username}</div><div>${message}</div>`;

    divMessages.appendChild(messages);
    divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch(err => document.write(err));

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.key === "Enter") {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
    connection.send("newMessage", username, tbMessage.value)
        .then(() => tbMessage.value = "");
}
```

Sending a message through the WebSockets connection requires calling the `send` method. The method's first parameter is the message name. The message data inhabits the other parameters. In this example, a message identified as `newMessage` is sent to the server. The message consists of the username and the user input from a text box. If the send works, the text box value is cleared.

4. Add the `NewMessage` method to the `ChatHub` class:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRWebPack.Hubs
{
    public class ChatHub : Hub
    {
        public async Task NewMessage(long username, string message)
        {
            await Clients.All.SendAsync("messageReceived", username, message);
        }
    }
}
```

The preceding code broadcasts received messages to all connected users once the server receives them. It's unnecessary to have a generic `on` method to receive all the messages. A method named after the message name suffices.

In this example, the TypeScript client sends a message identified as `newMessage`. The C# `NewMessage` method

expects the data sent by the client. A call is made to SendAsync on Clients.All. The received messages are sent to all clients connected to the hub.

Test the app

Confirm that the app works with the following steps.

- Visual Studio
- Visual Studio Code

1. Run Webpack in *release* mode. Using the **Package Manager Console** window, run the following command in the project root. If you are not in the project root, enter `cd SignalRWebPack` before entering the command.

   ```
   npm run release
   ```

   This command generates the client-side assets to be served when running the app. The assets are placed in the *wwwroot* folder.

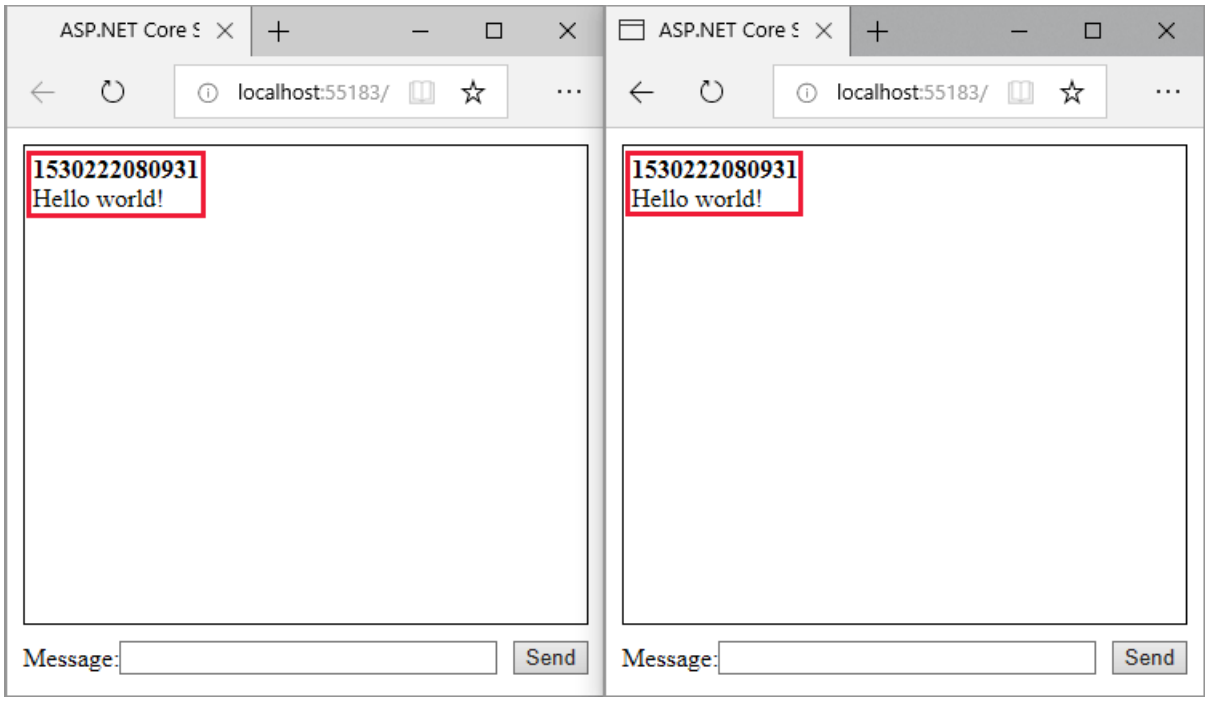
   Webpack completed the following tasks:

   - Purged the contents of the *wwwroot* directory.
   - Converted the TypeScript to JavaScript in a process known as *transpilation*.
   - Mangled the generated JavaScript to reduce file size in a process known as *minification*.
   - Copied the processed JavaScript, CSS, and HTML files from *src* to the *wwwroot* directory.
   - Injected the following elements into the *wwwroot/index.html* file:
     - A `<link>` tag, referencing the *wwwroot/main.<hash>.css* file. This tag is placed immediately before the closing `</head>` tag.
     - A `<script>` tag, referencing the minified *wwwroot/main.<hash>.js* file. This tag is placed immediately before the closing `</body>` tag.
2. Select **Debug** > **Start without debugging** to launch the app in a browser without attaching the debugger. The *wwwroot/index.html* file is served at `http://localhost:<port_number>`.

   If you get compile errors, try closing and reopening the solution.

3. Open another browser instance (any browser). Paste the URL in the address bar.

4. Choose either browser, type something in the **Message** text box, and click the **Send** button. The unique user name and message are displayed on both pages instantly.



Prerequisites

- Visual Studio
- Visual Studio Code

- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core SDK 2.2 or later
- Node.js with npm

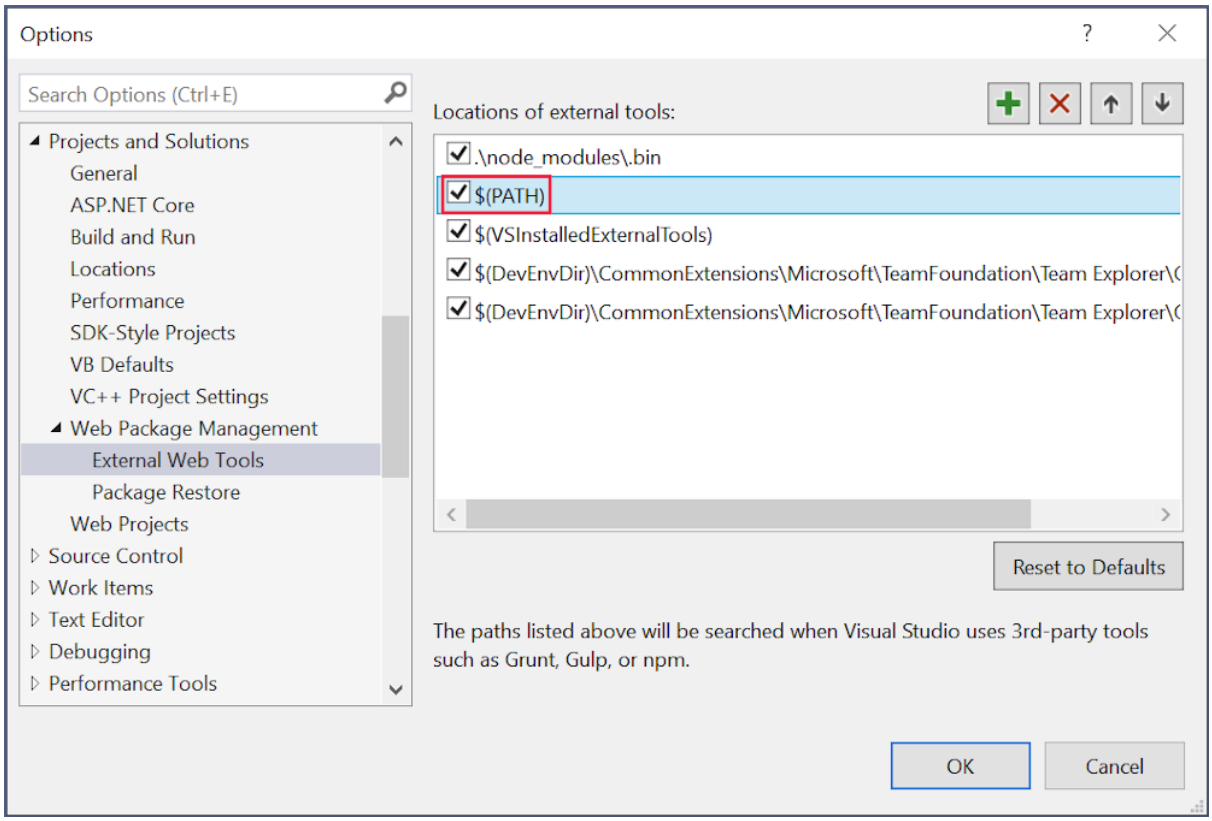
Create the ASP.NET Core web app

- Visual Studio
- Visual Studio Code

Configure Visual Studio to look for npm in the *PATH* environment variable. By default, Visual Studio uses the version of npm found in its installation directory. Follow these instructions in Visual Studio:

1. Navigate to **Tools** > **Options** > **Projects and Solutions** > **Web Package Management** > **External Web Tools**.

2. Select the *$(PATH)* entry from the list. Click the up arrow to move the entry to the second position in the list.



Visual Studio configuration is completed. It's time to create the project.

1. Use the **File** > **New** > **Project** menu option and choose the **ASP.NET Core Web Application** template.
2. Name the project *SignalRWebPack*, and select **Create**.
3. Select *.NET Core* from the target framework drop-down, and select *ASP.NET Core 2.2* from the framework selector drop-down. Select the **Empty** template, and select **Create**.

Configure Webpack and TypeScript

The following steps configure the conversion of TypeScript to JavaScript and the bundling of client-side resources.

1. Run the following command in the project root to create a *package.json* file:

```
npm init -y
```

2. Add the highlighted property to the *package.json* file:

```
{
  "name": "SignalRWebPack",
  "version": "1.0.0",
  "private": true,
  "description": "",
  "main": "index.js",
  "scripts": {
    "test": "echo \"Error: no test specified\" && exit 1"
  },
  "keywords": [],
  "author": "",
  "license": "ISC"
}
```

   Setting the `private` property to `true` prevents package installation warnings in the next step.

3. Install the required npm packages. Run the following command from the project root:

```
npm install -D -E clean-webpack-plugin@1.0.1 css-loader@2.1.0 html-webpack-plugin@4.0.0-beta.5 mini-css-extract-plugin@0.5.0 ts-loader@5.3.3 typescript@3.3.3 webpack@4.29.3 webpack-cli@3.2.3
```

Some command details to note:

- A version number follows the `@` sign for each package name. npm installs those specific package versions.
- The `-E` option disables npm's default behavior of writing semantic versioning range operators to *package.json*. For example, `"webpack": "4.29.3"` is used instead of `"webpack": "^4.29.3"`. This option prevents unintended upgrades to newer package versions.

See the npm-install docs for more detail.

4. Replace the `scripts` property of the *package.json* file with the following code:

```
"scripts": {
  "build": "webpack --mode=development --watch",
  "release": "webpack --mode=production",
  "publish": "npm run release && dotnet publish -c Release"
},
```

Some explanation of the scripts:

- `build`: Bundles the client-side resources in development mode and watches for file changes. The file watcher causes the bundle to regenerate each time a project file changes. The `mode` option disables production optimizations, such as tree shaking and minification. Only use `build` in development.
- `release`: Bundles the client-side resources in production mode.
- `publish`: Runs the `release` script to bundle the client-side resources in production mode. It calls the .NET Core CLI's publish command to publish the app.

5. Create a file named *webpack.config.js* in the project root, with the following code:

```
const path = require("path");
const HtmlWebpackPlugin = require("html-webpack-plugin");
const CleanWebpackPlugin = require("clean-webpack-plugin");
const MiniCssExtractPlugin = require("mini-css-extract-plugin");

module.exports = {
    entry: "./src/index.ts",
    output: {
        path: path.resolve(__dirname, "wwwroot"),
        filename: "[name].[chunkhash].js",
        publicPath: "/"
    },
    resolve: {
        extensions: [".js", ".ts"]
    },
    module: {
        rules: [
            {
                test: /\.ts$/,
                use: "ts-loader"
            },
            {
                test: /\.css$/,
                use: [MiniCssExtractPlugin.loader, "css-loader"]
            }
        ]
    },
    plugins: [
        new CleanWebpackPlugin(["wwwroot/*"]),
        new HtmlWebpackPlugin({
            template: "./src/index.html"
        }),
        new MiniCssExtractPlugin({
            filename: "css/[name].[chunkhash].css"
        })
    ]
};
```

The preceding file configures the Webpack compilation. Some configuration details to note:

- The `output` property overrides the default value of *dist*. The bundle is instead emitted in the *wwwroot* directory.
- The `resolve.extensions` array includes *.js* to import the SignalR client JavaScript.

6. Create a new *src* directory in the project root to store the project's client-side assets.

7. Create *src/index.html* with the following markup.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>ASP.NET Core SignalR</title>
</head>
<body>
    <div id="divMessages" class="messages">
    </div>
    <div class="input-zone">
        <label id="lblMessage" for="tbMessage">Message:</label>
        <input id="tbMessage" class="input-zone-input" type="text" />
        <button id="btnSend">Send</button>
    </div>
</body>
</html>
```

The preceding HTML defines the homepage's boilerplate markup.

8. Create a new *src/css* directory. Its purpose is to store the project's *.css* files.

9. Create *src/css/main.css* with the following markup:

```
*, *::before, *::after {
    box-sizing: border-box;
}

html, body {
    margin: 0;
    padding: 0;
}

.input-zone {
    align-items: center;
    display: flex;
    flex-direction: row;
    margin: 10px;
}

.input-zone-input {
    flex: 1;
    margin-right: 10px;
}

.message-author {
    font-weight: bold;
}

.messages {
    border: 1px solid #000;
    margin: 10px;
    max-height: 300px;
    min-height: 300px;
    overflow-y: auto;
    padding: 5px;
}
```

The preceding *main.css* file styles the app.

10. Create *src/tsconfig.json* with the following JSON:

```
{
  "compilerOptions": {
    "target": "es5"
  }
}
```

The preceding code configures the TypeScript compiler to produce ECMAScript 5-compatible JavaScript.

11. Create *src/index.ts* with the following code:

```
import "./css/main.css";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.keyCode === 13) {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
}
```

The preceding TypeScript retrieves references to DOM elements and attaches two event handlers:

- `keyup`: This event fires when the user types in the `tbMessage` textbox. The `send` function is called when the user presses the **Enter** key.
- `click`: This event fires when the user clicks the **Send** button. The `send` function is called.

Configure the ASP.NET Core app

1. The code provided in the `Startup.Configure` method displays *Hello World!*. Replace the `app.Run` method call with calls to UseDefaultFiles and UseStaticFiles.

   ```
   app.UseDefaultFiles();
   app.UseStaticFiles();
   ```

   The preceding code allows the server to locate and serve the *index.html* file, whether the user enters its full URL or the root URL of the web app.

2. Call AddSignalR in `Startup.ConfigureServices`. It adds the SignalR services to the project.

   ```
   services.AddSignalR();
   ```

3. Map a */hub* route to the `ChatHub` hub. Add the following lines at the end of `Startup.Configure`:

   ```
   app.UseSignalR(options =>
   {
       options.MapHub<ChatHub>("/hub");
   });
   ```

4. Create a new directory, called *Hubs*, in the project root. Its purpose is to store the SignalR hub, which is created in the next step.

5. Create hub *Hubs/ChatHub.cs* with the following code:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRWebPack.Hubs
{
    public class ChatHub : Hub
    {
    }
}
```

6. Add the following code at the top of the *Startup.cs* file to resolve the `ChatHub` reference:

```
using SignalRWebPack.Hubs;
```

Enable client and server communication

The app currently displays a simple form to send messages. Nothing happens when you try to do so. The server is listening to a specific route but does nothing with sent messages.

1. Run the following command at the project root:

```
npm install @aspnet/signalr
```

   The preceding command installs the SignalR TypeScript client, which allows the client to send messages to the server.

2. Add the highlighted code to the *src/index.ts* file:

```
import "./css/main.css";
import * as signalR from "@aspnet/signalr";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message: string) => {
    let m = document.createElement("div");

    m.innerHTML =
        `<div class="message-author">${username}</div><div>${message}</div>`;

    divMessages.appendChild(m);
    divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch(err => document.write(err));

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.keyCode === 13) {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
}
```

The preceding code supports receiving messages from the server. The `HubConnectionBuilder` class creates a new builder for configuring the server connection. The `withUrl` function configures the hub URL.

SignalR enables the exchange of messages between a client and a server. Each message has a specific name. For example, messages with the name `messageReceived` can run the logic responsible for displaying the new message in the messages zone. Listening to a specific message can be done via the `on` function. You can listen to any number of message names. It's also possible to pass parameters to the message, such as the author's name and the content of the message received. Once the client receives a message, a new `div` element is created with the author's name and the message content in its `innerHTML` attribute. The new message is added to the main `div` element displaying the messages.

3. Now that the client can receive a message, configure it to send messages. Add the highlighted code to the *src/index.ts* file:

```
import "./css/main.css";
import * as signalR from "@aspnet/signalr";

const divMessages: HTMLDivElement = document.querySelector("#divMessages");
const tbMessage: HTMLInputElement = document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement = document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message: string) => {
    let messageContainer = document.createElement("div");

    messageContainer.innerHTML =
        `<div class="message-author">${username}</div><div>${message}</div>`;

    divMessages.appendChild(messageContainer);
    divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch(err => document.write(err));

tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
    if (e.keyCode === 13) {
        send();
    }
});

btnSend.addEventListener("click", send);

function send() {
    connection.send("newMessage", username, tbMessage.value)
              .then(() => tbMessage.value = "");
}
```

Sending a message through the WebSockets connection requires calling the `send` method. The method's first parameter is the message name. The message data inhabits the other parameters. In this example, a message identified as `newMessage` is sent to the server. The message consists of the username and the user input from a text box. If the send works, the text box value is cleared.

4. Add the `NewMessage` method to the `ChatHub` class:

```
using Microsoft.AspNetCore.SignalR;
using System.Threading.Tasks;

namespace SignalRWebPack.Hubs
{
    public class ChatHub : Hub
    {
        public async Task NewMessage(long username, string message)
        {
            await Clients.All.SendAsync("messageReceived", username, message);
        }
    }
}
```

The preceding code broadcasts received messages to all connected users once the server receives them. It's unnecessary to have a generic `on` method to receive all the messages. A method named after the message name suffices.

In this example, the TypeScript client sends a message identified as `newMessage`. The C# `NewMessage` method

expects the data sent by the client. A call is made to SendAsync on Clients.All. The received messages are sent to all clients connected to the hub.

Test the app

Confirm that the app works with the following steps.

- Visual Studio
- Visual Studio Code

1. Run Webpack in *release* mode. Using the **Package Manager Console** window, run the following command in the project root. If you are not in the project root, enter `cd SignalRWebPack` before entering the command.

   ```
   npm run release
   ```

   This command generates the client-side assets to be served when running the app. The assets are placed in the *wwwroot* folder.

   Webpack completed the following tasks:

   - Purged the contents of the *wwwroot* directory.
   - Converted the TypeScript to JavaScript in a process known as *transpilation*.
   - Mangled the generated JavaScript to reduce file size in a process known as *minification*.
   - Copied the processed JavaScript, CSS, and HTML files from *src* to the *wwwroot* directory.
   - Injected the following elements into the *wwwroot/index.html* file:
     - A `<link>` tag, referencing the *wwwroot/main.<hash>.css* file. This tag is placed immediately before the closing `</head>` tag.
     - A `<script>` tag, referencing the minified *wwwroot/main.<hash>.js* file. This tag is placed immediately before the closing `</body>` tag.
2. Select **Debug** > **Start without debugging** to launch the app in a browser without attaching the debugger. The *wwwroot/index.html* file is served at `http://localhost:<port_number>`.
3. Open another browser instance (any browser). Paste the URL in the address bar.
4. Choose either browser, type something in the **Message** text box, and click the **Send** button. The unique user name and message are displayed on both pages instantly.

Use ASP.NET Core SignalR with Blazor WebAssembly

9/22/2020 • 7 minutes to read • Edit Online

By Daniel Roth and Luke Latham

This tutorial teaches the basics of building a real-time app using SignalR with Blazor WebAssembly. You learn how to:

- Create a Blazor WebAssembly Hosted app project
- Add the SignalR client library
- Add a SignalR hub
- Add SignalR services and an endpoint for the SignalR hub
- Add Razor component code for chat

At the end of this tutorial, you'll have a working chat app.

View or download sample code (how to download)

Prerequisites

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

- Visual Studio 2019 16.6 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Create a hosted Blazor WebAssembly app project

Follow the guidance for your choice of tooling:

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

> **NOTE**
> Visual Studio 16.6 or later and .NET Core SDK 3.1.300 or later are required.

1. Create a new project.
2. Select **Blazor App** and select **Next**.
3. Type `BlazorSignalRApp` in the **Project name** field. Confirm the **Location** entry is correct or provide a location for the project. Select **Create**.
4. Choose the **Blazor WebAssembly App** template.
5. Under **Advanced**, select the **ASP.NET Core hosted** check box.

6. Select **Create**.

Add the SignalR client library

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

1. In **Solution Explorer**, right-click the `BlazorSignalRApp.Client` project and select **Manage NuGet Packages**.
2. In the **Manage NuGet Packages** dialog, confirm that the **Package source** is set to `nuget.org`.
3. With **Browse** selected, type `Microsoft.AspNetCore.SignalR.Client` in the search box.
4. In the search results, select the `Microsoft.AspNetCore.SignalR.Client` package and select **Install**.
5. If the **Preview Changes** dialog appears, select **OK**.
6. If the **License Acceptance** dialog appears, select **I Accept** if you agree with the license terms.

Add a SignalR hub

In the `BlazorSignalRApp.Server` project, create a `Hubs` (plural) folder and add the following `ChatHub` class (`Hubs/ChatHub.cs`):

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.SignalR;

namespace BlazorSignalRApp.Server.Hubs
{
    public class ChatHub : Hub
    {
        public async Task SendMessage(string user, string message)
        {
            await Clients.All.SendAsync("ReceiveMessage", user, message);
        }
    }
}
```

Add services and an endpoint for the SignalR hub

1. In the `BlazorSignalRApp.Server` project, open the `Startup.cs` file.
2. Add the namespace for the `ChatHub` class to the top of the file:

   ```
   using BlazorSignalRApp.Server.Hubs;
   ```

3. Add SignalR and Response Compression Middleware services to `Startup.ConfigureServices`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR();
    services.AddControllersWithViews();
    services.AddResponseCompression(opts =>
    {
        opts.MimeTypes = ResponseCompressionDefaults.MimeTypes.Concat(
            new[] { "application/octet-stream" });
    });
}
```

4. In `Startup.Configure`:

   - Use Response Compression Middleware at the top of the processing pipeline's configuration.
   - Between the endpoints for controllers and the client-side fallback, add an endpoint for the hub.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    app.UseResponseCompression();

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseWebAssemblyDebugging();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseBlazorFrameworkFiles();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
        endpoints.MapHub<ChatHub>("/chathub");
        endpoints.MapFallbackToFile("index.html");
    });
}
```

Add Razor component code for chat

1. In the `BlazorSignalRApp.Client` project, open the `Pages/Index.razor` file.

2. Replace the markup with the following code:

```
@page "/"
@using Microsoft.AspNetCore.SignalR.Client
@inject NavigationManager NavigationManager
@implements IDisposable

<div class="form-group">
    <label>
        User:
        <input @bind="userInput" />
    </label>
</div>
<div class="form-group">
    <label>
        Message:
        <input @bind="messageInput" size="50" />
    </label>
</div>
<button @onclick="Send" disabled="@(!IsConnected)">Send</button>

<hr>

<ul id="messagesList">
    @foreach (var message in messages)
    {
        <li>@message</li>
    }
</ul>

@code {
    private HubConnection hubConnection;
    private List<string> messages = new List<string>();
    private string userInput;
    private string messageInput;

    protected override async Task OnInitializedAsync()
    {
        hubConnection = new HubConnectionBuilder()
            .WithUrl(NavigationManager.ToAbsoluteUri("/chathub"))
            .Build();

        hubConnection.On<string, string>("ReceiveMessage", (user, message) =>
        {
            var encodedMsg = $"{user}: {message}";
            messages.Add(encodedMsg);
            StateHasChanged();
        });

        await hubConnection.StartAsync();
    }

    Task Send() =>
        hubConnection.SendAsync("SendMessage", userInput, messageInput);

    public bool IsConnected =>
        hubConnection.State == HubConnectionState.Connected;

    public void Dispose()
    {
        _ = hubConnection.DisposeAsync();
    }
}
```

Run the app

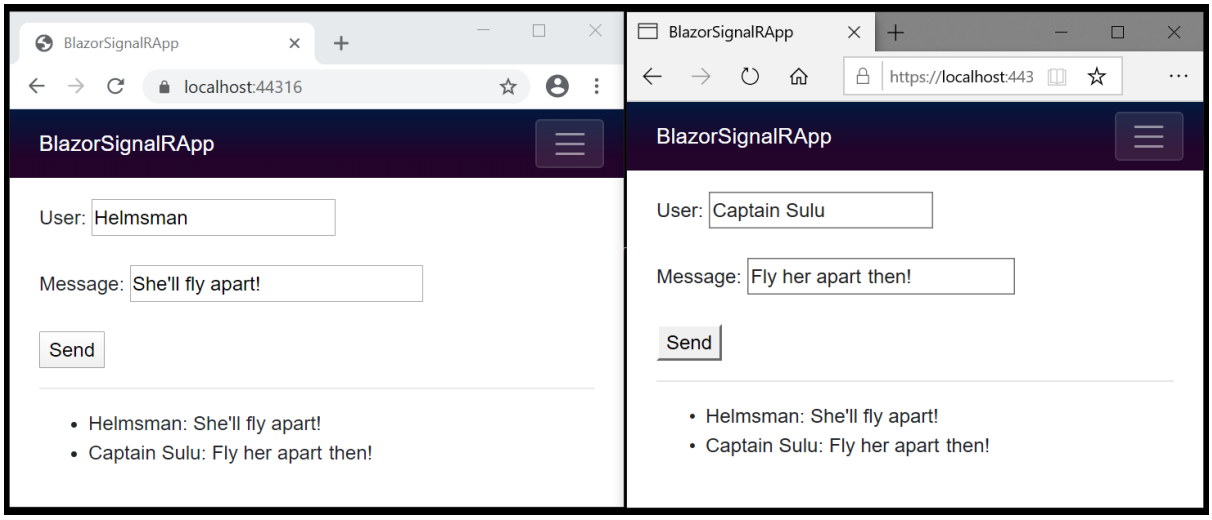
1. Follow the guidance for your tooling:

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac
- .NET Core CLI

1. In **Solution Explorer**, select the `BlazorSignalRApp.Server` project. Press `F5` to run the app with debugging or `Ctrl+F5` to run the app without debugging.

2. Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.

3. Choose either browser, enter a name and message, and select the button to send the message. The name and message are displayed on both pages instantly:



Quotes: *Star Trek VI: The Undiscovered Country* © 1991 Paramount

Next steps

In this tutorial, you learned how to:

- Create a Blazor WebAssembly Hosted app project
- Add the SignalR client library
- Add a SignalR hub
- Add SignalR services and an endpoint for the SignalR hub
- Add Razor component code for chat

To learn more about building Blazor apps, see the Blazor documentation:

Introduction to ASP.NET Core Blazor

Tutorial: Create a gRPC client and server in ASP.NET Core

9/22/2020 • 9 minutes to read • Edit Online

By John Luo

This tutorial shows how to create a .NET Core gRPC client and an ASP.NET Core gRPC Server.

At the end, you'll have a gRPC client that communicates with the gRPC Greeter service.

View or download sample code (how to download).

In this tutorial, you:

- Create a gRPC Server.
- Create a gRPC client.
- Test the gRPC client service with the gRPC Greeter service.

Prerequisites

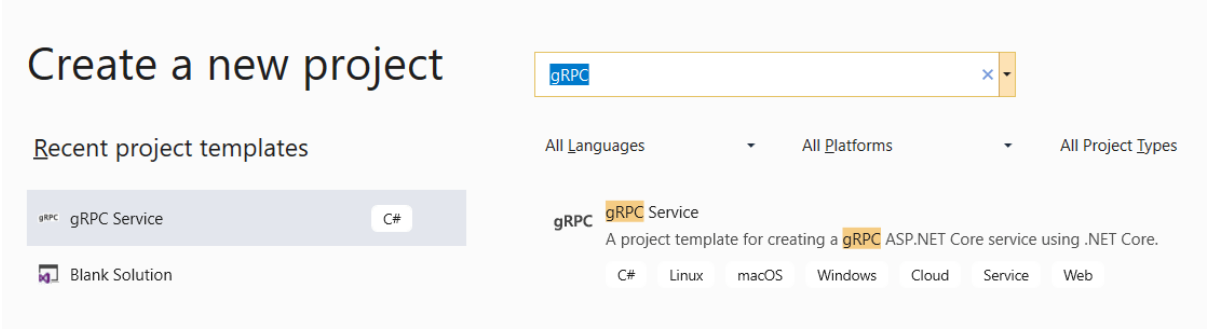
- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Visual Studio 2019 16.4 or later with the **ASP.NET and web development** workload
- .NET Core 3.1 SDK or later

Create a gRPC service

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Start Visual Studio and select **Create a new project**. Alternatively, from the Visual Studio **File** menu, select **New** > **Project**.
- In the **Create a new project** dialog, select **gRPC Service** and select **Next**:



- Name the project **GrpcGreeter**. It's important to name the project *GrpcGreeter* so the namespaces will match when you copy and paste code.
- Select **Create**.

- In the **Create a new gRPC service** dialog:
  - The **gRPC Service** template is selected.
  - Select **Create**.

Run the service

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Press Ctrl+F5 to run without the debugger.

  Visual Studio displays the following dialog:

  Select **Yes** if you trust the IIS Express SSL certificate.

  The following dialog is displayed:

  Select **Yes** if you agree to trust the development certificate.

  Visual Studio starts IIS Express and runs the app. The address bar shows `localhost:port#` and not something like `example.com`. That's because `localhost` is the standard hostname for the local computer. Localhost only serves web requests from the local computer. When Visual Studio creates a web project, a random port is used for the web server.

The logs show the service listening on `https://localhost:5001`.

```
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:5001
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
```

> **NOTE**
>
> The gRPC template is configured to use Transport Layer Security (TLS). gRPC clients need to use HTTPS to call the server.
>
> macOS doesn't support ASP.NET Core gRPC with TLS. Additional configuration is required to successfully run gRPC services on macOS. For more information, see Unable to start ASP.NET Core gRPC app on macOS.

Examine the project files

GrpcGreeter project files:

- *greet.proto*: The *Protos/greet.proto* file defines the `Greeter` gRPC and is used to generate the gRPC server assets. For more information, see Introduction to gRPC.
- *Services* folder: Contains the implementation of the `Greeter` service.
- *appSettings.json*: Contains configuration data, such as protocol used by Kestrel. For more information, see Configuration in ASP.NET Core.
- *Program.cs*: Contains the entry point for the gRPC service. For more information, see .NET Generic Host.
- *Startup.cs*: Contains code that configures app behavior. For more information, see App startup.

Create the gRPC client in a .NET console app

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

- Open a second instance of Visual Studio and select **Create a new project**.
- In the **Create a new project** dialog, select **Console App (.NET Core)** and select **Next**.
- In the **Project name** text box, enter **GrpcGreeterClient** and select **Create**.

Add required packages

The gRPC client project requires the following packages:

- Grpc.Net.Client, which contains the .NET Core client.
- Google.Protobuf, which contains protobuf message APIs for C#.
- Grpc.Tools, which contains C# tooling support for protobuf files. The tooling package isn't required at runtime, so the dependency is marked with `PrivateAssets="All"`.

- Visual Studio
- Visual Studio Code
- Visual Studio for Mac

Install the packages using either the Package Manager Console (PMC) or Manage NuGet Packages.

PMC option to install packages

- From Visual Studio, select **Tools** > **NuGet Package Manager** > **Package Manager Console**
- From the **Package Manager Console** window, run `cd GrpcGreeterClient` to change directories to the folder containing the *GrpcGreeterClient.csproj* files.

- Run the following commands:

```
Install-Package Grpc.Net.Client
Install-Package Google.Protobuf
Install-Package Grpc.Tools
```

Manage NuGet Packages option to install packages

- Right-click the project in **Solution Explorer** > **Manage NuGet Packages**
- Select the **Browse** tab.
- Enter **Grpc.Net.Client** in the search box.
- Select the **Grpc.Net.Client** package from the **Browse** tab and select **Install**.
- Repeat for `Google.Protobuf` and `Grpc.Tools`.

Add greet.proto

- Create a *Protos* folder in the gRPC client project.
- Copy the *Protos\greet.proto* file from the gRPC Greeter service to the gRPC client project.
- Edit the *GrpcGreeterClient.csproj* project file:
  - Visual Studio
  - Visual Studio Code
  - Visual Studio for Mac

  Right-click the project and select **Edit Project File**.

- Add an item group with a `<Protobuf>` element that refers to the *greet.proto* file:

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Client" />
</ItemGroup>
```

Create the Greeter client

Build the project to create the types in the `GrpcGreeter` namespace. The `GrpcGreeter` types are generated automatically by the build process.

Update the gRPC client *Program.cs* file with the following code:

```
using System;
using System.Net.Http;
using System.Threading.Tasks;
using GrpcGreeter;
using Grpc.Net.Client;

namespace GrpcGreeterClient
{
    class Program
    {
        static async Task Main(string[] args)
        {
            // The port number(5001) must match the port of the gRPC server.
            using var channel = GrpcChannel.ForAddress("https://localhost:5001");
            var client =  new Greeter.GreeterClient(channel);
            var reply = await client.SayHelloAsync(
                              new HelloRequest { Name = "GreeterClient" });
            Console.WriteLine("Greeting: " + reply.Message);
            Console.WriteLine("Press any key to exit...");
            Console.ReadKey();
        }
    }
}
```

Program.cs contains the entry point and logic for the gRPC client.

The Greeter client is created by:

- Instantiating a `GrpcChannel` containing the information for creating the connection to the gRPC service.
- Using the `GrpcChannel` to construct the Greeter client:

```
static async Task Main(string[] args)
{
    // The port number(5001) must match the port of the gRPC server.
    using var channel = GrpcChannel.ForAddress("https://localhost:5001");
    var client =  new Greeter.GreeterClient(channel);
    var reply = await client.SayHelloAsync(
                      new HelloRequest { Name = "GreeterClient" });
    Console.WriteLine("Greeting: " + reply.Message);
    Console.WriteLine("Press any key to exit...");
    Console.ReadKey();
}
```

The Greeter client calls the asynchronous `SayHello` method. The result of the `SayHello` call is displayed:

```
static async Task Main(string[] args)
{
    // The port number(5001) must match the port of the gRPC server.
    using var channel = GrpcChannel.ForAddress("https://localhost:5001");
    var client =  new Greeter.GreeterClient(channel);
    var reply = await client.SayHelloAsync(
                      new HelloRequest { Name = "GreeterClient" });
    Console.WriteLine("Greeting: " + reply.Message);
    Console.WriteLine("Press any key to exit...");
    Console.ReadKey();
}
```

Test the gRPC client with the gRPC Greeter service

- Visual Studio

- Visual Studio Code
- Visual Studio for Mac

- In the Greeter service, press `Ctrl+F5` to start the server without the debugger.
- In the `GrpcGreeterClient` project, press `Ctrl+F5` to start the client without the debugger.

The client sends a greeting to the service with a message containing its name, *GreeterClient*. The service sends the message "Hello GreeterClient" as a response. The "Hello GreeterClient" response is displayed in the command prompt:

```
Greeting: Hello GreeterClient
Press any key to exit...
```

The gRPC service records the details of the successful call in the logs written to the command prompt:

```
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:5001
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: C:\GH\aspnet\docs\4\Docs\aspnetcore\tutorials\grpc\grpc-start\sample\GrpcGreeter
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/2 POST https://localhost:5001/Greet.Greeter/SayHello application/grpc
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 78.32260000000001ms 200 application/grpc
```

> **NOTE**
>
> The code in this article requires the ASP.NET Core HTTPS development certificate to secure the gRPC service. If the .NET gRPC client fails with the message `The remote certificate is invalid according to the validation procedure.` or `The SSL connection could not be established.`, the development certificate isn't trusted. To fix this issue, see Call a gRPC service with an untrusted/invalid certificate.

> **WARNING**
>
> ASP.NET Core gRPC is not currently supported on Azure App Service or IIS. The HTTP/2 implementation of Http.Sys does not support HTTP response trailing headers which gRPC relies on. For more information, see this GitHub issue.

Razor Pages with Entity Framework Core in ASP.NET Core - Tutorial 1 of 8

9/22/2020 • 50 minutes to read • Edit Online

By Tom Dykstra and Rick Anderson

This is the first in a series of tutorials that show how to use Entity Framework (EF) Core in an ASP.NET Core Razor Pages app. The tutorials build a web site for a fictional Contoso University. The site includes functionality such as student admission, course creation, and instructor assignments. The tutorial uses the code first approach. For information on following this tutorial using the database first approach, see this Github issue.

Download or view the completed app. Download instructions.

Prerequisites

- If you're new to Razor Pages, go through the Get started with Razor Pages tutorial series before starting this one.
- Visual Studio
- Visual Studio Code
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core 3.0 SDK or later

Database engines

The Visual Studio instructions use SQL Server LocalDB, a version of SQL Server Express that runs only on Windows.

The Visual Studio Code instructions use SQLite, a cross-platform database engine.

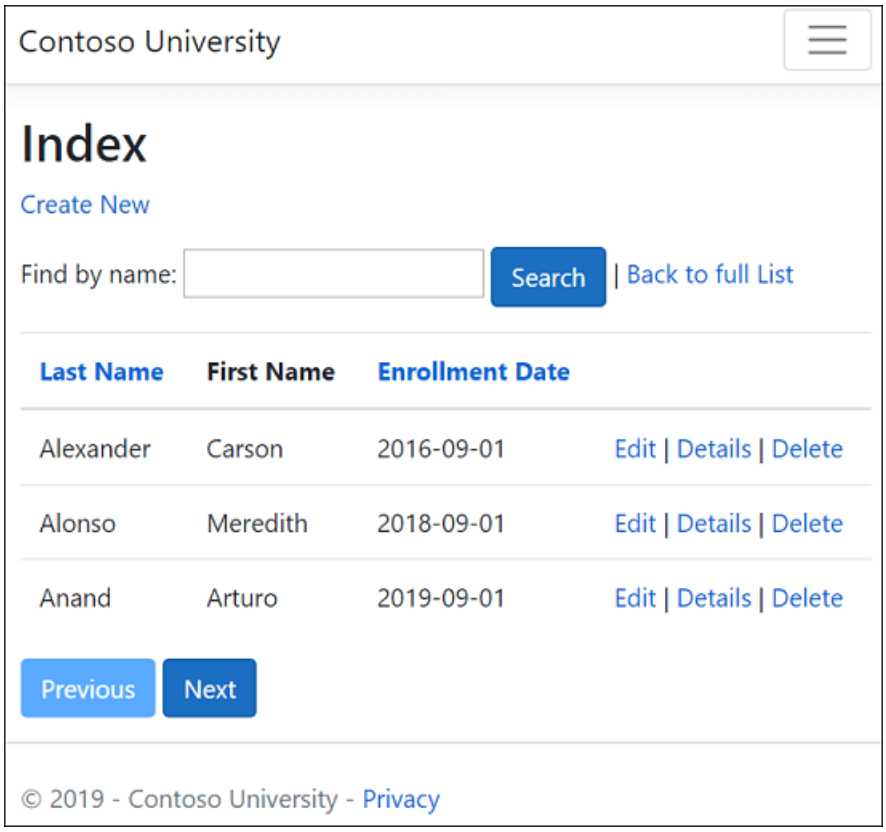
If you choose to use SQLite, download and install a third-party tool for managing and viewing a SQLite database, such as DB Browser for SQLite.

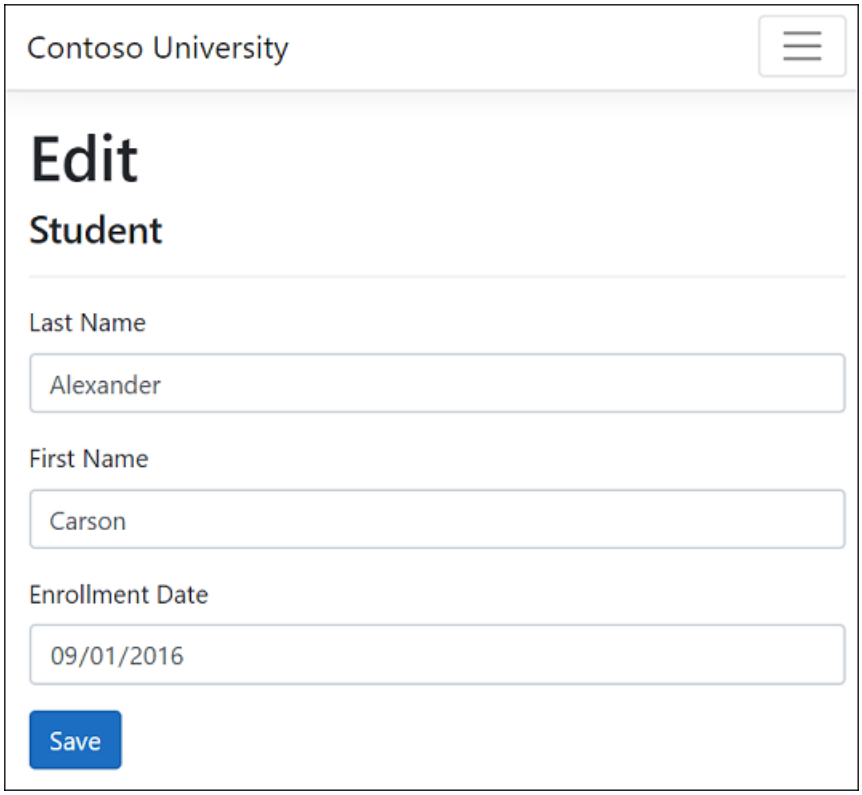
Troubleshooting

If you run into a problem you can't resolve, compare your code to the completed project. A good way to get help is by posting a question to StackOverflow.com, using the ASP.NET Core tag or the EF Core tag.

The sample app

The app built in these tutorials is a basic university web site. Users can view and update student, course, and instructor information. Here are a few of the screens created in the tutorial.





The UI style of this site is based on the built-in project templates. The tutorial's focus is on how to use EF Core, not how to customize the UI.

Follow the link at the top of the page to get the source code for the completed project. The *cu30* folder has the code for the ASP.NET Core 3.0 version of the tutorial. Files that reflect the state of the code for tutorials 1-7 can be found in the *cu30snapshots* folder.

- Visual Studio
- Visual Studio Code

To run the app after downloading the completed project:

- Build the project.
- In Package Manager Console (PMC) run the following command:

```
Update-Database
```

- Run the project to seed the database.

Create the web app project

- Visual Studio
- Visual Studio Code

- From the Visual Studio **File** menu, select **New** > **Project**.
- Select **ASP.NET Core Web Application**.
- Name the project *ContosoUniversity*. It's important to use this exact name including capitalization, so the namespaces match when code is copied and pasted.
- Select **.NET Core** and **ASP.NET Core 3.0** in the dropdowns, and then select **Web Application**.

Set up the site style

Set up the site header, footer, and menu by updating *Pages/Shared/_Layout.cshtml*:

- Change each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- Delete the **Home** and **Privacy** menu entries, and add entries for **About**, **Students**, **Courses**, **Instructors**, and **Departments**.

The changes are highlighted.

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Contoso University</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom box-shadow
mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-page="/Index">Contoso University</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-target=".navbar-
collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/About">About</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/Students/Index">Students</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/Courses/Index">Courses</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Instructors/Index">Instructors</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Departments/Index">Departments</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2019 - Contoso University - <a asp-area="" asp-page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

In *Pages/Index.cshtml*, replace the contents of the file with the following code to replace the text about ASP.NET Core with text about this app:

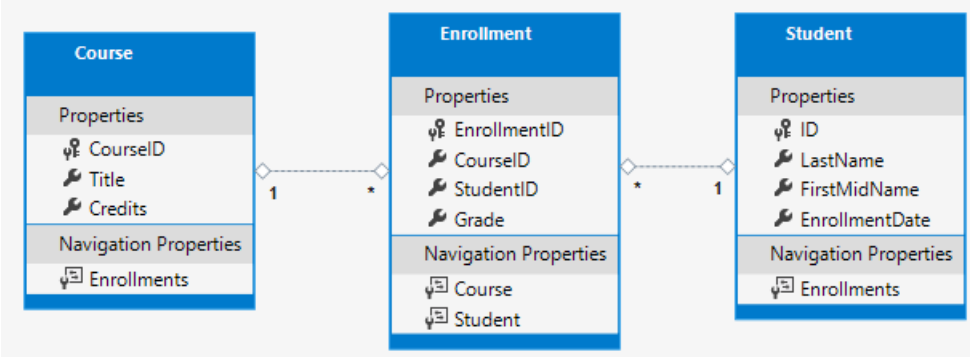
```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="row mb-auto">
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 mb-4 ">
                <p class="card-text">
                    Contoso University is a sample application that
                    demonstrates how to use Entity Framework Core in an
                    ASP.NET Core Razor Pages web app.
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column position-static">
                <p class="card-text mb-auto">
                    You can build the application by following the steps in a series of tutorials.
                </p>
                <p>
                    <a href="https://docs.microsoft.com/aspnet/core/data/ef-rp/intro" class="stretched-
link">See the tutorial</a>
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column">
                <p class="card-text mb-auto">
                    You can download the completed project from GitHub.
                </p>
                <p>
                    <a href="https://github.com/dotnet/AspNetCore.Docs/tree/master/aspnetcore/data/ef-
rp/intro/samples" class="stretched-link">See project source code</a>
                </p>
            </div>
        </div>
    </div>
</div>
```

Run the app to verify that the home page appears.

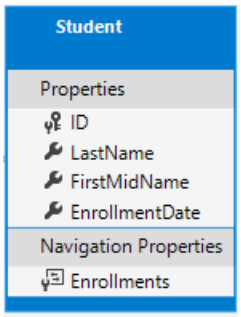
The data model

The following sections create a data model:



A student can enroll in any number of courses, and a course can have any number of students enrolled in it.

The Student entity



- Create a *Models* folder in the project folder.
- Create *Models/Student.cs* with the following code:

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

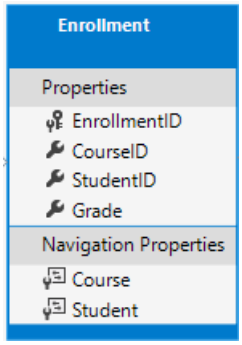
The `ID` property becomes the primary key column of the database table that corresponds to this class. By default, EF Core interprets a property that's named `ID` or `classnameID` as the primary key. So the alternative automatically recognized name for the `Student` class primary key is `StudentID`. For more information, see EF Core - Keys.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student` entity holds all of the `Enrollment` entities that are related to that Student. For example, if a Student row in the database has two related Enrollment rows, the `Enrollments` navigation property contains those two Enrollment entities.

In the database, an Enrollment row is related to a Student row if its StudentID column contains the student's ID value. For example, suppose a Student row has ID=1. Related Enrollment rows will have StudentID = 1. StudentID is a *foreign key* in the Enrollment table.

The `Enrollments` property is defined as `ICollection<Enrollment>` because there may be multiple related Enrollment entities. You can use other collection types, such as `List<Enrollment>` or `HashSet<Enrollment>`. When `ICollection<Enrollment>` is used, EF Core creates a `HashSet<Enrollment>` collection by default.

The Enrollment entity



Create *Models/Enrollment.cs* with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the primary key; this entity uses the `classnameID` pattern instead of `ID` by itself. For a production data model, choose one pattern and use it consistently. This tutorial uses both just to illustrate that both work. Using `ID` without `classname` makes it easier to implement some kinds of data model changes.

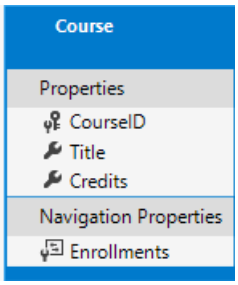
The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade—null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property contains a single `Student` entity.

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

EF Core interprets a property as a foreign key if it's named `<navigation property name><primary key property name>`. For example, `StudentID` is the foreign key for the `Student` navigation property, since the `Student` entity's primary key is `ID`. Foreign key properties can also be named `<primary key property name>`. For example, `CourseID` since the `Course` entity's primary key is `CourseID`.

The Course entity



Create *Models/Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The `DatabaseGenerated` attribute allows the app to specify the primary key rather than having the database generate it.

Build the project to validate that there are no compiler errors.

Scaffold Student pages

In this section, you use the ASP.NET Core scaffolding tool to generate:

- An EF Core *context* class. The context is the main class that coordinates Entity Framework functionality for a given data model. It derives from the `Microsoft.EntityFrameworkCore.DbContext` class.
- Razor pages that handle Create, Read, Update, and Delete (CRUD) operations for the `Student` entity.

- Visual Studio
- Visual Studio Code

- Create a *Students* folder in the *Pages* folder.
- In **Solution Explorer**, right-click the *Pages/Students* folder and select **Add** > **New Scaffolded Item**.
- In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **ADD**.
- In the **Add Razor Pages using Entity Framework (CRUD)** dialog:
  - In the **Model class** drop-down, select **Student (ContosoUniversity.Models)**.
  - In the **Data context class** row, select the **+** (plus) sign.
  - Change the data context name from *ContosoUniversity.Models.ContosoUniversityContext* to *ContosoUniversity.Data.SchoolContext*.
  - Select **Add**.

The following packages are automatically installed:

- `Microsoft.VisualStudio.Web.CodeGeneration.Design`
- `Microsoft.EntityFrameworkCore.SqlServer`
- `Microsoft.Extensions.Logging.Debug`
- `Microsoft.EntityFrameworkCore.Tools`

If you have a problem with the preceding step, build the project and retry the scaffold step.

The scaffolding process:

- Creates Razor pages in the *Pages/Students* folder:
  - *Create.cshtml* and *Create.cshtml.cs*
  - *Delete.cshtml* and *Delete.cshtml.cs*
  - *Details.cshtml* and *Details.cshtml.cs*
  - *Edit.cshtml* and *Edit.cshtml.cs*
  - *Index.cshtml* and *Index.cshtml.cs*
- Creates *Data/SchoolContext.cs*.
- Adds the context to dependency injection in *Startup.cs*.
- Adds a database connection string to *appsettings.json*.

Database connection string

- Visual Studio
- Visual Studio Code

The connection string specifies SQL Server LocalDB.

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "SchoolContext": "Server=
(localdb)\\mssqllocaldb;Database=SchoolContext6;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. By default, LocalDB creates *.mdf* files in the `C:/Users/<user>` directory.

Update the database context class

The main class that coordinates EF Core functionality for a given data model is the database context class. The context is derived from Microsoft.EntityFrameworkCore.DbContext. The context specifies which entities are included in the data model. In this project, the class is named `SchoolContext`.

Update *SchoolContext.cs* with the following code:

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext (DbContextOptions<SchoolContext> options)
            : base(options)
        {
        }

        public DbSet<Student> Students { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Course> Courses { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

The highlighted code creates a DbSet<TEntity> property for each entity set. In EF Core terminology:

- An entity set typically corresponds to a database table.
- An entity corresponds to a row in the table.

Since an entity set contains multiple entities, the DBSet properties should be plural names. Since the scaffolding tool created a `Student` DBSet, this step changes it to plural `Students`.

To make the Razor Pages code match the new DBSet name, make a global change across the whole project of `_context.Student` to `_context.Students`. There are 8 occurrences.

Build the project to verify there are no compiler errors.

Startup.cs

ASP.NET Core is built with dependency injection. Services (such as the EF Core database context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a database context instance is shown later in the tutorial.

The scaffolding tool automatically registered the context class with the dependency injection container.

- Visual Studio
- Visual Studio Code

- In `ConfigureServices`, the highlighted lines were added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddDbContext<SchoolContext>(options =>
            options.UseSqlServer(Configuration.GetConnectionString("SchoolContext")));
}
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Create the database

Update *Program.cs* to create the database if it doesn't exist:

```
using ContosoUniversity.Data;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using System;

namespace ContosoUniversity
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            CreateDbIfNotExists(host);

            host.Run();
        }

        private static void CreateDbIfNotExists(IHost host)
        {
            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context = services.GetRequiredService<SchoolContext>();
                    context.Database.EnsureCreated();
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred creating the DB.");
                }
            }
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

The EnsureCreated method takes no action if a database for the context exists. If no database exists, it creates the database and schema. `EnsureCreated` enables the following workflow for handling data model changes:

- Delete the database. Any existing data is lost.
- Change the data model. For example, add an `EmailAddress` field.
- Run the app.
- `EnsureCreated` creates a database with the new schema.

This workflow works well early in development when the schema is rapidly evolving, as long as you don't need to preserve data. The situation is different when data that has been entered into the database needs to be preserved. When that is the case, use migrations.

Later in the tutorial series, you delete the database that was created by `EnsureCreated` and use migrations instead. A database that is created by `EnsureCreated` can't be updated by using migrations.

Test the app

- Run the app.
- Select the **Students** link and then **Create New**.
- Test the Edit, Details, and Delete links.

Seed the database

The `EnsureCreated` method creates an empty database. This section adds code that populates the database with test data.

Create *Data/DbInitializer.cs* with the following code:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.Parse("2019-09-
01")},
                new Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Parse("2017-09-
01")},
                new Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse("2018-09-
01")},
                new Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Parse("2017-09-
01")},
                new Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2017-09-01")},
                new Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Parse("2016-09-
01")},
                new Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse("2018-09-
01")},
                new Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Parse("2019-09-
01")}
            };

            context.Students.AddRange(students);
            context.SaveChanges();

            var courses = new Course[]
            {
                new Course{CourseID=1050,Title="Chemistry",Credits=3},
                new Course{CourseID=4022,Title="Microeconomics",Credits=3},
```

```
                new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
                new Course{CourseID=1045,Title="Calculus",Credits=4},
                new Course{CourseID=3141,Title="Trigonometry",Credits=4},
                new Course{CourseID=2021,Title="Composition",Credits=3},
                new Course{CourseID=2042,Title="Literature",Credits=4}
            };

            context.Courses.AddRange(courses);
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
                new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
                new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
                new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
                new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
                new Enrollment{StudentID=3,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
                new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
                new Enrollment{StudentID=6,CourseID=1045},
                new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };

            context.Enrollments.AddRange(enrollments);
            context.SaveChanges();
        }
    }
}
```

The code checks if there are any students in the database. If there are no students, it adds test data to the database. It creates the test data in arrays rather than `List<T>` collections to optimize performance.

- In *Program.cs*, replace the `EnsureCreated` call with a `DbInitializer.Initialize` call:

```
// context.Database.EnsureCreated();
DbInitializer.Initialize(context);
```

- Visual Studio
- Visual Studio Code

Stop the app if it's running, and run the following command in the **Package Manager Console** (PMC):

```
Drop-Database
```

- Restart the app.
- Select the Students page to see the seeded data.

View the database

- Visual Studio
- Visual Studio Code

- Open **SQL Server Object Explorer** (SSOX) from the **View** menu in Visual Studio.
- In SSOX, select **(localdb)\MSSQLLocalDB > Databases > SchoolContext-{GUID}**. The database name is generated from the context name you provided earlier plus a dash and a GUID.

- Expand the **Tables** node.
- Right-click the **Student** table and click **View Data** to see the columns created and the rows inserted into the table.
- Right-click the **Student** table and click **View Code** to see how the `Student` model maps to the `Student` table schema.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server can handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time. For low traffic situations, the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the async keyword, `Task<T>` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
public async Task OnGetAsync()
{
    Students = await _context.Students.ToListAsync();
}
```

- The `async` keyword tells the compiler to:
  - Generate callbacks for parts of the method body.
  - Create the Task object that's returned.
- The `Task<T>` return type represents ongoing work.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF Core:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes `ToListAsync`, `SingleOrDefaultAsync`, `FirstOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF Core context isn't thread safe: don't try to do multiple operations in parallel.
- To take advantage of the performance benefits of async code, verify that library packages (such as for paging) use async if they call EF Core methods that send queries to the database.

For more information about asynchronous programming in .NET, see Async Overview and Asynchronous programming with async and await.

Next steps

NEXT TUTORIAL

This is the first in a series of tutorials that show how to use Entity Framework (EF) Core in an ASP.NET Core Razor Pages app. The tutorials build a web site for a fictional Contoso University. The site includes functionality such as student admission, course creation, and instructor assignments. The tutorial uses the code first approach. For information on following this tutorial using the database first approach, see this Github issue.

Download or view the completed app. Download instructions.

Prerequisites

- If you're new to Razor Pages, go through the Get started with Razor Pages tutorial series before starting this one.
- Visual Studio
- Visual Studio Code
- Visual Studio 2019 with the **ASP.NET and web development** workload
- .NET Core 3.0 SDK or later

Database engines

The Visual Studio instructions use SQL Server LocalDB, a version of SQL Server Express that runs only on Windows.

The Visual Studio Code instructions use SQLite, a cross-platform database engine.

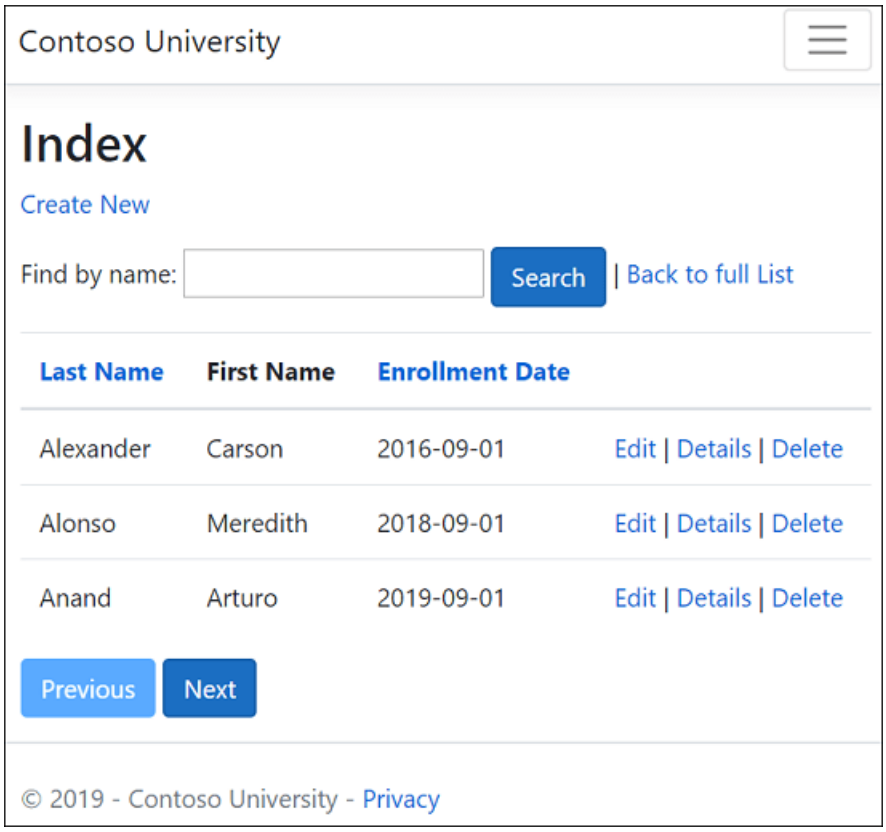
If you choose to use SQLite, download and install a third-party tool for managing and viewing a SQLite database, such as DB Browser for SQLite.

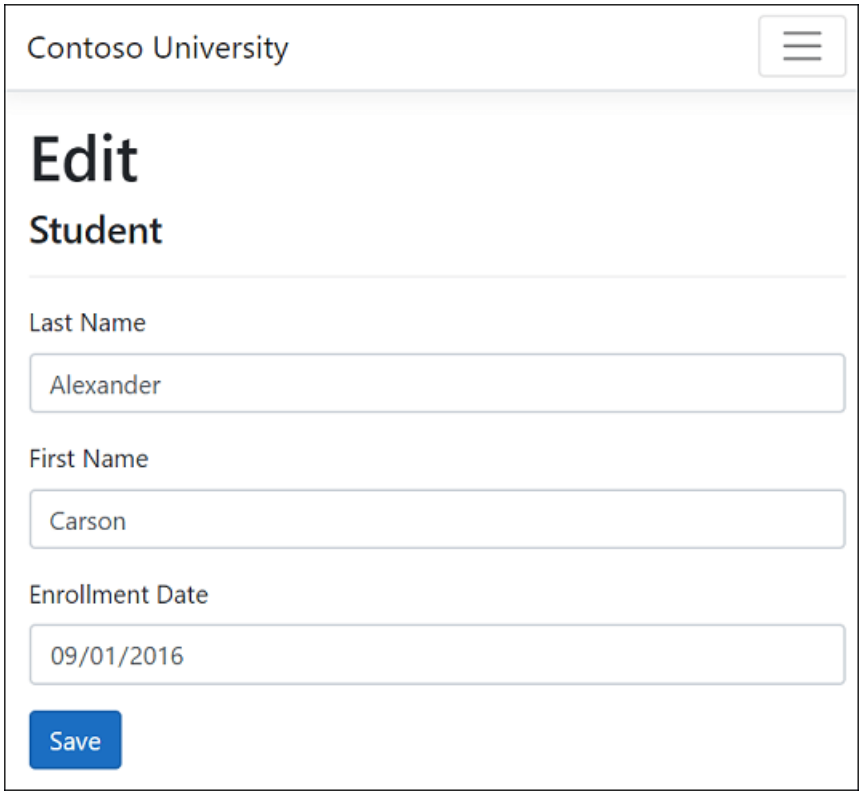
Troubleshooting

If you run into a problem you can't resolve, compare your code to the completed project. A good way to get help is by posting a question to StackOverflow.com, using the ASP.NET Core tag or the EF Core tag.

The sample app

The app built in these tutorials is a basic university web site. Users can view and update student, course, and instructor information. Here are a few of the screens created in the tutorial.





The UI style of this site is based on the built-in project templates. The tutorial's focus is on how to use EF Core, not how to customize the UI.

Follow the link at the top of the page to get the source code for the completed project. The *cu30* folder has the code for the ASP.NET Core 3.0 version of the tutorial. Files that reflect the state of the code for tutorials 1-7 can be found in the *cu30snapshots* folder.

- Visual Studio
- Visual Studio Code

To run the app after downloading the completed project:

- Build the project.
- In Package Manager Console (PMC) run the following command:

```
Update-Database
```

- Run the project to seed the database.

Create the web app project

- Visual Studio
- Visual Studio Code

- From the Visual Studio **File** menu, select **New** > **Project**.
- Select **ASP.NET Core Web Application**.
- Name the project *ContosoUniversity*. It's important to use this exact name including capitalization, so the namespaces match when code is copied and pasted.
- Select **.NET Core** and **ASP.NET Core 3.0** in the dropdowns, and then select **Web Application**.

Set up the site style

Set up the site header, footer, and menu by updating *Pages/Shared/_Layout.cshtml*:

- Change each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- Delete the **Home** and **Privacy** menu entries, and add entries for **About**, **Students**, **Courses**, **Instructors**, and **Departments**.

The changes are highlighted.

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Contoso University</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-light bg-white border-bottom box-shadow
mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-page="/Index">Contoso University</a>
                <button class="navbar-toggler" type="button" data-toggle="collapse" data-target=".navbar-
collapse" aria-controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex flex-sm-row-reverse">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/About">About</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/Students/Index">Students</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-page="/Courses/Index">Courses</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Instructors/Index">Instructors</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Departments/Index">Departments</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2019 - Contoso University - <a asp-area="" asp-page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

In *Pages/Index.cshtml*, replace the contents of the file with the following code to replace the text about ASP.NET Core with text about this app:

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="row mb-auto">
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 mb-4 ">
                <p class="card-text">
                    Contoso University is a sample application that
                    demonstrates how to use Entity Framework Core in an
                    ASP.NET Core Razor Pages web app.
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column position-static">
                <p class="card-text mb-auto">
                    You can build the application by following the steps in a series of tutorials.
                </p>
                <p>
                    <a href="https://docs.microsoft.com/aspnet/core/data/ef-rp/intro" class="stretched-
link">See the tutorial</a>
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 d-flex flex-column">
                <p class="card-text mb-auto">
                    You can download the completed project from GitHub.
                </p>
                <p>
                    <a href="https://github.com/dotnet/AspNetCore.Docs/tree/master/aspnetcore/data/ef-
rp/intro/samples" class="stretched-link">See project source code</a>
                </p>
            </div>
        </div>
    </div>
</div>
```

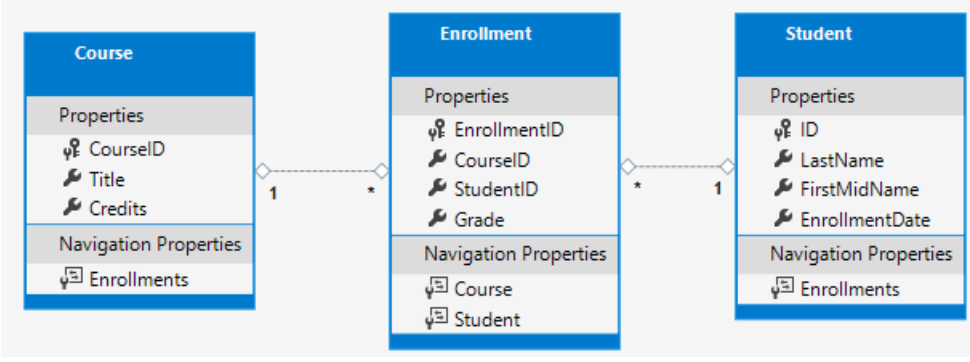
Run the app to verify that the home page appears.

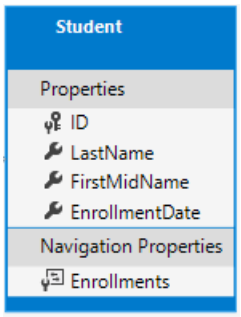
The data model

The following sections create a data model:



A student can enroll in any number of courses, and a course can have any number of students enrolled in it.

The Student entity



- Create a *Models* folder in the project folder.
- Create *Models/Student.cs* with the following code:

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

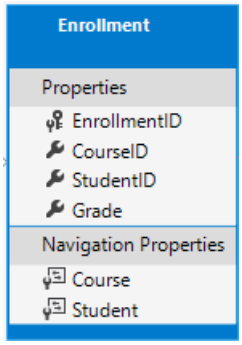
The `ID` property becomes the primary key column of the database table that corresponds to this class. By default, EF Core interprets a property that's named `ID` or `classnameID` as the primary key. So the alternative automatically recognized name for the `Student` class primary key is `StudentID`. For more information, see EF Core - Keys.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student` entity holds all of the `Enrollment` entities that are related to that Student. For example, if a Student row in the database has two related Enrollment rows, the `Enrollments` navigation property contains those two Enrollment entities.

In the database, an Enrollment row is related to a Student row if its StudentID column contains the student's ID value. For example, suppose a Student row has ID=1. Related Enrollment rows will have StudentID = 1. StudentID is a *foreign key* in the Enrollment table.

The `Enrollments` property is defined as `ICollection<Enrollment>` because there may be multiple related Enrollment entities. You can use other collection types, such as `List<Enrollment>` or `HashSet<Enrollment>`. When `ICollection<Enrollment>` is used, EF Core creates a `HashSet<Enrollment>` collection by default.

The Enrollment entity



Create *Models/Enrollment.cs* with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the primary key; this entity uses the `classnameID` pattern instead of `ID` by itself. For a production data model, choose one pattern and use it consistently. This tutorial uses both just to illustrate that both work. Using `ID` without `classname` makes it easier to implement some kinds of data model changes.

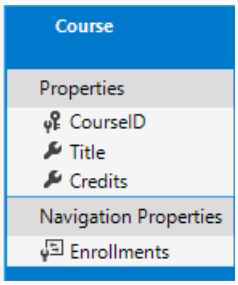
The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade—null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property contains a single `Student` entity.

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

EF Core interprets a property as a foreign key if it's named `<navigation property name><primary key property name>`. For example, `StudentID` is the foreign key for the `Student` navigation property, since the `Student` entity's primary key is `ID`. Foreign key properties can also be named `<primary key property name>`. For example, `CourseID` since the `Course` entity's primary key is `CourseID`.

The Course entity



Create *Models/Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The `DatabaseGenerated` attribute allows the app to specify the primary key rather than having the database generate it.

Build the project to validate that there are no compiler errors.

Scaffold Student pages

In this section, you use the ASP.NET Core scaffolding tool to generate:

- An EF Core *context* class. The context is the main class that coordinates Entity Framework functionality for a given data model. It derives from the `Microsoft.EntityFrameworkCore.DbContext` class.
- Razor pages that handle Create, Read, Update, and Delete (CRUD) operations for the `Student` entity.

- Visual Studio
- Visual Studio Code

- Create a *Students* folder in the *Pages* folder.
- In **Solution Explorer**, right-click the *Pages/Students* folder and select **Add** > **New Scaffolded Item**.
- In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **ADD**.
- In the **Add Razor Pages using Entity Framework (CRUD)** dialog:
  - In the **Model class** drop-down, select **Student (ContosoUniversity.Models)**.
  - In the **Data context class** row, select the **+** (plus) sign.
  - Change the data context name from *ContosoUniversity.Models.ContosoUniversityContext* to *ContosoUniversity.Data.SchoolContext*.
  - Select **Add**.

The following packages are automatically installed:

- `Microsoft.VisualStudio.Web.CodeGeneration.Design`
- `Microsoft.EntityFrameworkCore.SqlServer`
- `Microsoft.Extensions.Logging.Debug`
- `Microsoft.EntityFrameworkCore.Tools`

If you have a problem with the preceding step, build the project and retry the scaffold step.

The scaffolding process:

- Creates Razor pages in the *Pages/Students* folder:
  - *Create.cshtml* and *Create.cshtml.cs*
  - *Delete.cshtml* and *Delete.cshtml.cs*
  - *Details.cshtml* and *Details.cshtml.cs*
  - *Edit.cshtml* and *Edit.cshtml.cs*
  - *Index.cshtml* and *Index.cshtml.cs*
- Creates *Data/SchoolContext.cs*.
- Adds the context to dependency injection in *Startup.cs*.
- Adds a database connection string to *appsettings.json*.

Database connection string

- Visual Studio
- Visual Studio Code

The connection string specifies SQL Server LocalDB.

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "SchoolContext": "Server=
(localdb)\\mssqllocaldb;Database=SchoolContext6;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. By default, LocalDB creates *.mdf* files in the `C:/Users/<user>` directory.

Update the database context class

The main class that coordinates EF Core functionality for a given data model is the database context class. The context is derived from Microsoft.EntityFrameworkCore.DbContext. The context specifies which entities are included in the data model. In this project, the class is named `SchoolContext`.

Update *SchoolContext.cs* with the following code:

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext (DbContextOptions<SchoolContext> options)
            : base(options)
        {
        }

        public DbSet<Student> Students { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Course> Courses { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

The highlighted code creates a DbSet<TEntity> property for each entity set. In EF Core terminology:

- An entity set typically corresponds to a database table.
- An entity corresponds to a row in the table.

Since an entity set contains multiple entities, the DBSet properties should be plural names. Since the scaffolding tool created a `Student` DBSet, this step changes it to plural `Students`.

To make the Razor Pages code match the new DBSet name, make a global change across the whole project of `_context.Student` to `_context.Students`. There are 8 occurrences.

Build the project to verify there are no compiler errors.

Startup.cs

ASP.NET Core is built with dependency injection. Services (such as the EF Core database context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a database context instance is shown later in the tutorial.

The scaffolding tool automatically registered the context class with the dependency injection container.

- Visual Studio
- Visual Studio Code

- In `ConfigureServices`, the highlighted lines were added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddRazorPages();

    services.AddDbContext<SchoolContext>(options =>
            options.UseSqlServer(Configuration.GetConnectionString("SchoolContext")));
}
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Create the database

Update *Program.cs* to create the database if it doesn't exist:

```
using ContosoUniversity.Data;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using System;

namespace ContosoUniversity
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            CreateDbIfNotExists(host);

            host.Run();
        }

        private static void CreateDbIfNotExists(IHost host)
        {
            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context = services.GetRequiredService<SchoolContext>();
                    context.Database.EnsureCreated();
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred creating the DB.");
                }
            }
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

The EnsureCreated method takes no action if a database for the context exists. If no database exists, it creates the database and schema. `EnsureCreated` enables the following workflow for handling data model changes:

- Delete the database. Any existing data is lost.
- Change the data model. For example, add an `EmailAddress` field.
- Run the app.
- `EnsureCreated` creates a database with the new schema.

This workflow works well early in development when the schema is rapidly evolving, as long as you don't need to preserve data. The situation is different when data that has been entered into the database needs to be preserved. When that is the case, use migrations.

Later in the tutorial series, you delete the database that was created by `EnsureCreated` and use migrations instead. A database that is created by `EnsureCreated` can't be updated by using migrations.

Test the app

- Run the app.
- Select the **Students** link and then **Create New**.
- Test the Edit, Details, and Delete links.

Seed the database

The `EnsureCreated` method creates an empty database. This section adds code that populates the database with test data.

Create *Data/DbInitializer.cs* with the following code:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.Parse("2019-09-
01")},
                new Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Parse("2017-09-
01")},
                new Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse("2018-09-
01")},
                new Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Parse("2017-09-
01")},
                new Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2017-09-01")},
                new Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Parse("2016-09-
01")},
                new Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse("2018-09-
01")},
                new Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Parse("2019-09-
01")}
            };

            context.Students.AddRange(students);
            context.SaveChanges();

            var courses = new Course[]
            {
                new Course{CourseID=1050,Title="Chemistry",Credits=3},
                new Course{CourseID=4022,Title="Microeconomics",Credits=3},
```

```
                new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
                new Course{CourseID=1045,Title="Calculus",Credits=4},
                new Course{CourseID=3141,Title="Trigonometry",Credits=4},
                new Course{CourseID=2021,Title="Composition",Credits=3},
                new Course{CourseID=2042,Title="Literature",Credits=4}
            };

            context.Courses.AddRange(courses);
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
                new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
                new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
                new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
                new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
                new Enrollment{StudentID=3,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
                new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
                new Enrollment{StudentID=6,CourseID=1045},
                new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };

            context.Enrollments.AddRange(enrollments);
            context.SaveChanges();
        }
    }
}
```

The code checks if there are any students in the database. If there are no students, it adds test data to the database. It creates the test data in arrays rather than `List<T>` collections to optimize performance.

- In *Program.cs*, replace the `EnsureCreated` call with a `DbInitializer.Initialize` call:

```
// context.Database.EnsureCreated();
DbInitializer.Initialize(context);
```

- Visual Studio
- Visual Studio Code

Stop the app if it's running, and run the following command in the **Package Manager Console** (PMC):

```
Drop-Database
```

- Restart the app.
- Select the Students page to see the seeded data.

View the database

- Visual Studio
- Visual Studio Code

- Open **SQL Server Object Explorer** (SSOX) from the **View** menu in Visual Studio.
- In SSOX, select **(localdb)\MSSQLLocalDB > Databases > SchoolContext-{GUID}**. The database name is generated from the context name you provided earlier plus a dash and a GUID.

- Expand the **Tables** node.
- Right-click the **Student** table and click **View Data** to see the columns created and the rows inserted into the table.
- Right-click the **Student** table and click **View Code** to see how the `Student` model maps to the `Student` table schema.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server can handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time. For low traffic situations, the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the async keyword, `Task<T>` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
public async Task OnGetAsync()
{
    Students = await _context.Students.ToListAsync();
}
```

- The `async` keyword tells the compiler to:
  - Generate callbacks for parts of the method body.
  - Create the Task object that's returned.
- The `Task<T>` return type represents ongoing work.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF Core:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes `ToListAsync`, `SingleOrDefaultAsync`, `FirstOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF Core context isn't thread safe: don't try to do multiple operations in parallel.
- To take advantage of the performance benefits of async code, verify that library packages (such as for paging) use async if they call EF Core methods that send queries to the database.

For more information about asynchronous programming in .NET, see Async Overview and Asynchronous programming with async and await.

Next steps

NEXT TUTORIAL

The Contoso University sample web app demonstrates how to create an ASP.NET Core Razor Pages app using Entity Framework (EF) Core.

The sample app is a web site for a fictional Contoso University. It includes functionality such as student admission, course creation, and instructor assignments. This page is the first in a series of tutorials that explain how to build the Contoso University sample app.

Download or view the completed app. Download instructions.

Prerequisites

- Visual Studio
- Visual Studio Code

Visual Studio 2019 with the following workloads:

- **ASP.NET and web development**
- **.NET Core cross-platform development**

.NET Core 2.1 SDK or later

Familiarity with Razor Pages. New programmers should complete Get started with Razor Pages before starting this series.

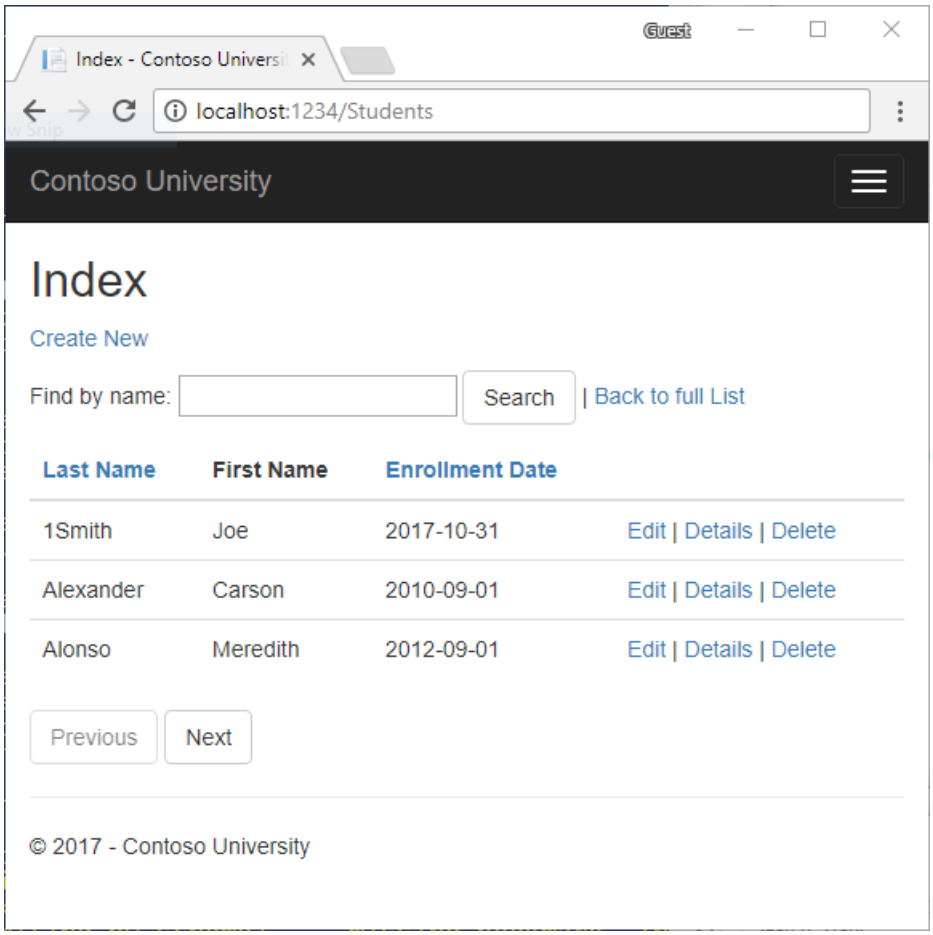
Troubleshooting

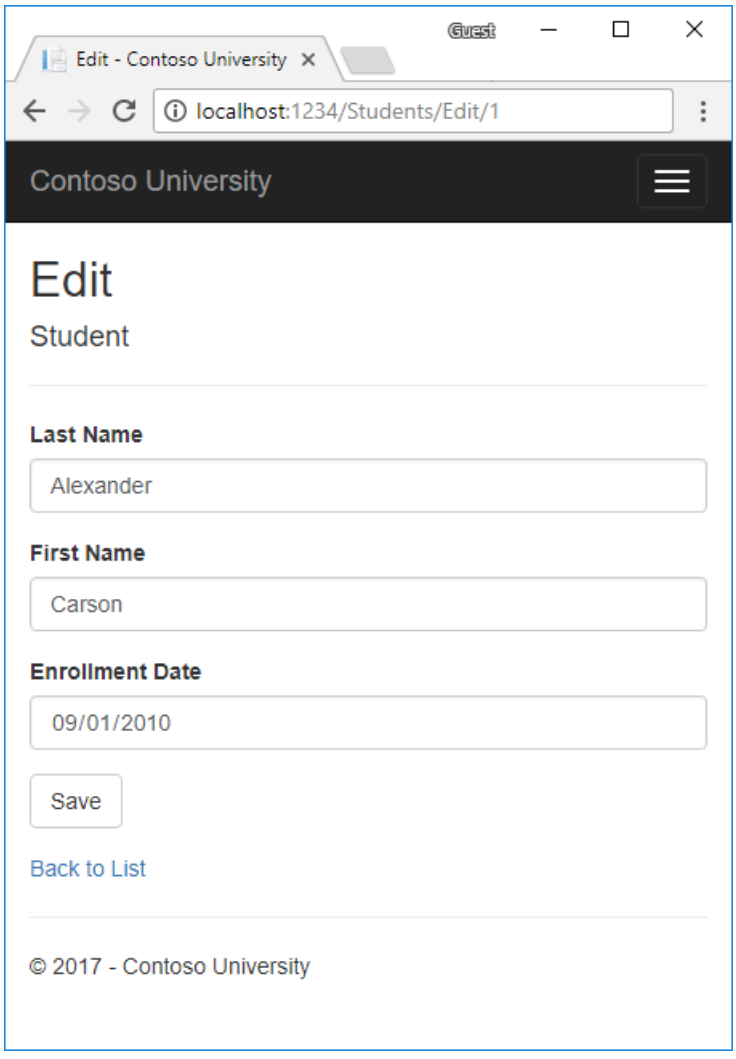
If you run into a problem you can't resolve, you can generally find the solution by comparing your code to the completed project. A good way to get help is by posting a question to StackOverflow.com for ASP.NET Core or EF Core.

The Contoso University web app

The app built in these tutorials is a basic university web site.

Users can view and update student, course, and instructor information. Here are a few of the screens created in the tutorial.





The UI style of this site is close to what's generated by the built-in templates. The tutorial focus is on EF Core with

Razor Pages, not the UI.

Create the ContosoUniversity Razor Pages web app

- Visual Studio
- Visual Studio Code

- From the Visual Studio **File** menu, select **New** > **Project**.
- Create a new ASP.NET Core Web Application. Name the project **ContosoUniversity**. It's important to name the project *ContosoUniversity* so the namespaces match when code is copy/pasted.
- Select **ASP.NET Core 2.1** in the dropdown, and then select **Web Application**.

For images of the preceding steps, see Create a Razor web app. Run the app.

Set up the site style

A few changes set up the site menu, layout, and home page. Update *Pages/Shared/_Layout.cshtml* with the following changes:

- Change each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- Add menu entries for **Students**, **Courses**, **Instructors**, and **Departments**, and delete the **Contact** menu entry.

The changes are highlighted. (All the markup is *not* displayed.)

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] : Contoso University</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
        <link rel="stylesheet" href="~/css/site.css" />
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet" href="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/css/bootstrap.min.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-property="position" asp-fallback-test-
value="absolute" />
        <link rel="stylesheet" href="~/css/site.min.css" asp-append-version="true" />
    </environment>
</head>
<body>
    <nav class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-target=".navbar-
collapse">
                    <span class="sr-only">Toggle navigation</span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                <a asp-page="/Index" class="navbar-brand">Contoso University</a>
            </div>
            <div class="navbar-collapse collapse">
                <ul class="nav navbar-nav">
                    <li><a asp-page="/Index">Home</a></li>
                    <li><a asp-page="/About">About</a></li>
                    <li><a asp-page="/Students/Index">Students</a></li>
                    <li><a asp-page="/Courses/Index">Courses</a></li>
                    <li><a asp-page="/Instructors/Index">Instructors</a></li>
                    <li><a asp-page="/Departments/Index">Departments</a></li>
                </ul>
            </div>
        </div>
    </nav>

    <partial name="_CookieConsentPartial" />

    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; 2018 : Contoso University</p>
        </footer>
    </div>

    @*Remaining markup not shown for brevity.*@
```

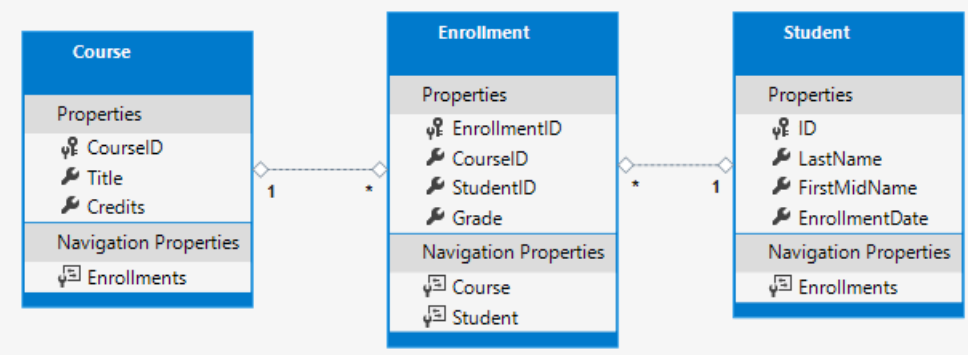
In *Pages/Index.cshtml*, replace the contents of the file with the following code to replace the text about ASP.NET and MVC with text about this app:

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="jumbotron">
    <h1>Contoso University</h1>
</div>
<div class="row">
    <div class="col-md-4">
        <h2>Welcome to Contoso University</h2>
        <p>
            Contoso University is a sample application that
            demonstrates how to use Entity Framework Core in an
            ASP.NET Core Razor Pages web app.
        </p>
    </div>
    <div class="col-md-4">
        <h2>Build it from scratch</h2>
        <p>You can build the application by following the steps in a series of tutorials.</p>
        <p>
            <a class="btn btn-default"
               href="https://docs.microsoft.com/aspnet/core/data/ef-rp/intro">
                See the tutorial &raquo;
            </a>
        </p>
    </div>
    <div class="col-md-4">
        <h2>Download it</h2>
        <p>You can download the completed project from GitHub.</p>
        <p>
            <a class="btn btn-default"
               href="https://github.com/dotnet/AspNetCore.Docs/tree/master/aspnetcore/data/ef-
rp/intro/samples/">
                See project source code &raquo;
            </a>
        </p>
    </div>
</div>
```

Create the data model

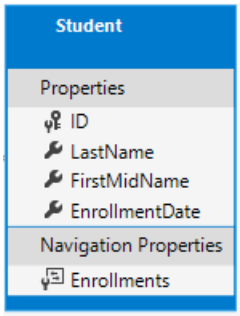
Create entity classes for the Contoso University app. Start with the following three entities:



There's a one-to-many relationship between `Student` and `Enrollment` entities. There's a one-to-many relationship between `Course` and `Enrollment` entities. A student can enroll in any number of courses. A course can have any number of students enrolled in it.

In the following sections, a class for each one of these entities is created.

The Student entity



Create a *Models* folder. In the *Models* folder, create a class file named *Student.cs* with the following code:

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

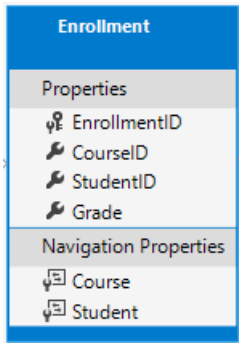
        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `ID` property becomes the primary key column of the database (DB) table that corresponds to this class. By default, EF Core interprets a property that's named `ID` or `classnameID` as the primary key. In `classnameID`, `classname` is the name of the class. The alternative automatically recognized primary key is `StudentID` in the preceding example.

The `Enrollments` property is a navigation property. Navigation properties link to other entities that are related to this entity. In this case, the `Enrollments` property of a `Student entity` holds all of the `Enrollment` entities that are related to that `Student`. For example, if a Student row in the DB has two related Enrollment rows, the `Enrollments` navigation property contains those two `Enrollment` entities. A related `Enrollment` row is a row that contains that student's primary key value in the `StudentID` column. For example, suppose the student with ID=1 has two rows in the `Enrollment` table. The `Enrollment` table has two rows with `StudentID` = 1. `StudentID` is a foreign key in the `Enrollment` table that specifies the student in the `Student` table.

If a navigation property can hold multiple entities, the navigation property must be a list type, such as `ICollection<T>`. `ICollection<T>` can be specified, or a type such as `List<T>` or `HashSet<T>`. When `ICollection<T>` is used, EF Core creates a `HashSet<T>` collection by default. Navigation properties that hold multiple entities come from many-to-many and one-to-many relationships.

The Enrollment entity



In the *Models* folder, create *Enrollment.cs* with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the primary key. This entity uses the `classnameID` pattern instead of `ID` like the `Student` entity. Typically developers choose one pattern and use it throughout the data model. In a later tutorial, using ID without classname is shown to make it easier to implement inheritance in the data model.

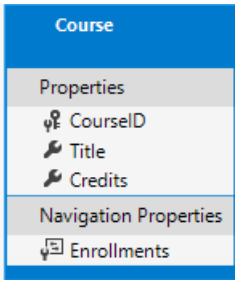
The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade -- null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property contains a single `Student` entity. The `Student` entity differs from the `Student.Enrollments` navigation property, which contains multiple `Enrollment` entities.

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

EF Core interprets a property as a foreign key if it's named `<navigation property name><primary key property name>`. For example, `StudentID` for the `Student` navigation property, since the `Student` entity's primary key is `ID`. Foreign key properties can also be named `<primary key property name>`. For example, `CourseID` since the `Course` entity's primary key is `CourseID`.

The Course entity



In the *Models* folder, create *Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The `DatabaseGenerated` attribute allows the app to specify the primary key rather than having the DB generate it.

Scaffold the student model

In this section, the student model is scaffolded. That is, the scaffolding tool produces pages for Create, Read, Update, and Delete (CRUD) operations for the student model.

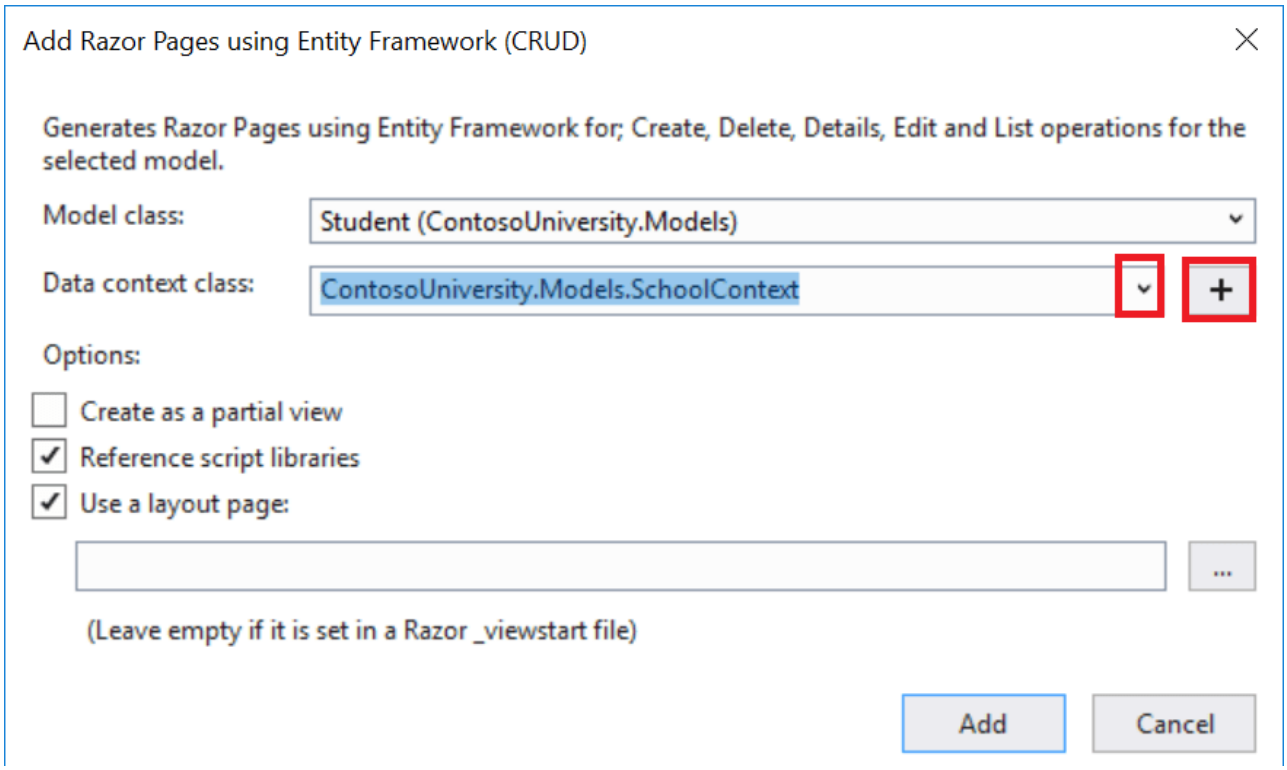
- Build the project.
- Create the *Pages/Students* folder.

- Visual Studio
- Visual Studio Code

- In **Solution Explorer**, right click on the *Pages/Students* folder > **Add** > **New Scaffolded Item**.
- In the **Add Scaffold** dialog, select **Razor Pages using Entity Framework (CRUD)** > **ADD**.

Complete the **Add Razor Pages using Entity Framework (CRUD)** dialog:

- In the **Model class** drop-down, select **Student (ContosoUniversity.Models)**.
- In the **Data context class** row, select the **+** (plus) sign and change the generated name to **ContosoUniversity.Models.SchoolContext**.
- In the **Data context class** drop-down, select **ContosoUniversity.Models.SchoolContext**
- Select **Add**.



See Scaffold the movie model if you have a problem with the preceding step.

The scaffold process created and changed the following files:

Files created

- *Pages/Students* Create, Delete, Details, Edit, Index.
- *Data/SchoolContext.cs*

File updates

- *Startup.cs* : Changes to this file are detailed in the next section.
- *appsettings.json* : The connection string used to connect to a local database is added.

Examine the context registered with dependency injection

ASP.NET Core is built with dependency injection. Services (such as the EF Core DB context) are registered with dependency injection during application startup. Components that require these services (such as Razor Pages) are provided these services via constructor parameters. The constructor code that gets a db context instance is shown later in the tutorial.

The scaffolding tool automatically created a DB Context and registered it with the dependency injection container.

Examine the `ConfigureServices` method in *Startup.cs*. The highlighted line was added by the scaffolder:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        // This lambda determines whether user consent for
        //non -essential cookies is needed for a given request.
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    services.AddDbContext<SchoolContext>(options =>
       options.UseSqlServer(Configuration.GetConnectionString("SchoolContext")));
}
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Update main

In *Program.cs*, modify the `Main` method to do the following:

- Get a DB context instance from the dependency injection container.
- Call the EnsureCreated.
- Dispose the context when the `EnsureCreated` method completes.

The following code shows the updated *Program.cs* file.

```
using ContosoUniversity.Models;                  // SchoolContext
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;   // CreateScope
using Microsoft.Extensions.Logging;
using System;

namespace ContosoUniversity
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateWebHostBuilder(args).Build();

            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;

                try
                {
                    var context = services.GetRequiredService<SchoolContext>();
                    context.Database.EnsureCreated();
                }
                catch (Exception ex)
                {
                    var logger = services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred creating the DB.");
                }
            }

            host.Run();
        }

        public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
            WebHost.CreateDefaultBuilder(args)
                .UseStartup<Startup>();
    }
}
```

`EnsureCreated` ensures that the database for the context exists. If it exists, no action is taken. If it does not exist, then the database and all its schema are created. `EnsureCreated` does not use migrations to create the database. A database that is created with `EnsureCreated` cannot be later updated using migrations.

`EnsureCreated` is called on app start, which allows the following work flow:

- Delete the DB.
- Change the DB schema (for example, add an `EmailAddress` field).
- Run the app.
- `EnsureCreated` creates a DB with the `EmailAddress` column.

`EnsureCreated` is convenient early in development when the schema is rapidly evolving. Later in the tutorial the DB is deleted and migrations are used.

Test the app

Run the app and accept the cookie policy. This app doesn't keep personal information. You can read about the cookie policy at EU General Data Protection Regulation (GDPR) support.

- Select the **Students** link and then **Create New**.
- Test the Edit, Details, and Delete links.

Examine the SchoolContext DB context

The main class that coordinates EF Core functionality for a given data model is the DB context class. The data context is derived from Microsoft.EntityFrameworkCore.DbContext. The data context specifies which entities are included in the data model. In this project, the class is named `SchoolContext`.

Update *SchoolContext.cs* with the following code:

```
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Models
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options)
            : base(options)
        {
        }

        public DbSet<Student> Student { get; set; }
        public DbSet<Enrollment> Enrollment { get; set; }
        public DbSet<Course> Course { get; set; }
    }
}
```

The highlighted code creates a DbSet<TEntity> property for each entity set. In EF Core terminology:

- An entity set typically corresponds to a DB table.
- An entity corresponds to a row in the table.

`DbSet<Enrollment>` and `DbSet<Course>` could be omitted. EF Core includes them implicitly because the `Student` entity references the `Enrollment` entity, and the `Enrollment` entity references the `Course` entity. For this tutorial, keep `DbSet<Enrollment>` and `DbSet<Course>` in the `SchoolContext`.

SQL Server Express LocalDB

The connection string specifies SQL Server LocalDB. LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB creates *.mdf* DB files in the `C:/Users/<user>` directory.

Add code to initialize the DB with test data

EF Core creates an empty DB. In this section, an `Initialize` method is written to populate it with test data.

In the *Data* folder, create a new class file named *DbInitializer.cs* and add the following code:

```
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Models
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Student.Any())
            {
```

```
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
            new Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.Parse("2005-09-
01")},
            new Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse("2003-09-01")},
            new Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Parse("2001-09-01")},
            new Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse("2003-09-01")},
            new Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Parse("2005-09-01")}
            };
            foreach (Student s in students)
            {
                context.Student.Add(s);
            }
            context.SaveChanges();

            var courses = new Course[]
            {
            new Course{CourseID=1050,Title="Chemistry",Credits=3},
            new Course{CourseID=4022,Title="Microeconomics",Credits=3},
            new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
            new Course{CourseID=1045,Title="Calculus",Credits=4},
            new Course{CourseID=3141,Title="Trigonometry",Credits=4},
            new Course{CourseID=2021,Title="Composition",Credits=3},
            new Course{CourseID=2042,Title="Literature",Credits=4}
            };
            foreach (Course c in courses)
            {
                context.Course.Add(c);
            }
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
            new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
            new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
            new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
            new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
            new Enrollment{StudentID=3,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
            new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
            new Enrollment{StudentID=6,CourseID=1045},
            new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };
            foreach (Enrollment e in enrollments)
            {
                context.Enrollment.Add(e);
            }
            context.SaveChanges();
        }
    }
}
```

Note: The preceding code uses `Models` for the namespace (`namespace ContosoUniversity.Models`) rather than `Data` . `Models` is consistent with the scaffolder-generated code. For more information, see this GitHub scaffolding issue.

The code checks if there are any students in the DB. If there are no students in the DB, the DB is initialized with test data. It loads test data into arrays rather than `List<T>` collections to optimize performance.

The `EnsureCreated` method automatically creates the DB for the DB context. If the DB exists, `EnsureCreated` returns without modifying the DB.

In *Program.cs*, modify the `Main` method to call `Initialize`:

```
public class Program
{
    public static void Main(string[] args)
    {
        var host = CreateWebHostBuilder(args).Build();

        using (var scope = host.Services.CreateScope())
        {
            var services = scope.ServiceProvider;

            try
            {
                var context = services.GetRequiredService<SchoolContext>();
                // using ContosoUniversity.Data;
                DbInitializer.Initialize(context);
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();
                logger.LogError(ex, "An error occurred creating the DB.");
            }
        }

        host.Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

- Visual Studio
- Visual Studio Code

Stop the app if it's running, and run the following command in the **Package Manager Console** (PMC):

```
Drop-Database
```

View the DB

The database name is generated from the context name you provided earlier plus a dash and a GUID. Thus, the database name will be "SchoolContext-{GUID}". The GUID will be different for each user. Open **SQL Server Object Explorer** (SSOX) from the **View** menu in Visual Studio. In SSOX, click **(localdb)\MSSQLLocalDB > Databases > SchoolContext-{GUID}**.

Expand the **Tables** node.

Right-click the **Student** table and click **View Data** to see the columns created and the rows inserted into the table.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With

synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server is enabled to handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time. For low traffic situations, the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the async keyword, `Task<T>` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
public async Task OnGetAsync()
{
    Student = await _context.Student.ToListAsync();
}
```

- The `async` keyword tells the compiler to:
  - Generate callbacks for parts of the method body.
  - Automatically create the Task object that's returned. For more information, see Task Return Type.
- The implicit return type `Task` represents ongoing work.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF Core:

- Only statements that cause queries or commands to be sent to the DB are executed asynchronously. That includes, `ToListAsync`, `SingleOrDefaultAsync`, `FirstOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF Core context isn't thread safe: don't try to do multiple operations in parallel.
- To take advantage of the performance benefits of async code, verify that library packages (such as for paging) use async if they call EF Core methods that send queries to the DB.

For more information about asynchronous programming in .NET, see Async Overview and Asynchronous programming with async and await.

In the next tutorial, basic CRUD (create, read, update, delete) operations are examined.

Part 2, Razor Pages with EF Core in ASP.NET Core - CRUD

9/22/2020 • 22 minutes to read • Edit Online

By Tom Dykstra, Jon P Smith, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

In this tutorial, the scaffolded CRUD (create, read, update, delete) code is reviewed and customized.

No repository

Some developers use a service layer or repository pattern to create an abstraction layer between the UI (Razor Pages) and the data access layer. This tutorial doesn't do that. To minimize complexity and keep the tutorial focused on EF Core, EF Core code is added directly to the page model classes.

Update the Details page

The scaffolded code for the Students pages doesn't include enrollment data. In this section, you add enrollments to the Details page.

Read enrollments

To display a student's enrollment data on the page, you need to read it. The scaffolded code in *Pages/Students/Details.cshtml.cs* reads only the Student data, without the Enrollment data:

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students.FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

Replace the `OnGetAsync` method with the following code to read enrollment data for the selected student. The changes are highlighted.

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students
        .Include(s => s.Enrollments)
        .ThenInclude(e => e.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

The Include and ThenInclude methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the `Enrollment.Course` navigation property. These methods are examined in detail in the Reading related data tutorial.

The AsNoTracking method improves performance in scenarios where the entities returned are not updated in the current context. `AsNoTracking` is discussed later in this tutorial.

Display enrollments

Replace the code in *Pages/Students/Details.cshtml* with the following code to display a list of enrollments. The changes are highlighted.

```
@page
@model ContosoUniversity.Pages.Students.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Student</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.Enrollments)
        </dt>
        <dd class="col-sm-10">
            <table class="table">
                <tr>
                    <th>Course Title</th>
                    <th>Grade</th>
                </tr>
                @foreach (var item in Model.Student.Enrollments)
                {
                    <tr>
                        <td>
                            @Html.DisplayFor(modelItem => item.Course.Title)
                        </td>
                        <td>
                            @Html.DisplayFor(modelItem => item.Grade)
                        </td>
                    </tr>
                }
            </table>
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Student.ID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

The preceding code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the Course entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. The list of courses and grades for the

selected student is displayed.

Ways to read one entity

The generated code uses FirstOrDefaultAsync to read one entity. This method returns null if nothing is found; otherwise, it returns the first row found that satisfies the query filter criteria. `FirstOrDefaultAsync` is generally a better choice than the following alternatives:

- SingleOrDefaultAsync - Throws an exception if there's more than one entity that satisfies the query filter. To determine if more than one row could be returned by the query, `SingleOrDefaultAsync` tries to fetch multiple rows. This extra work is unnecessary if the query can only return one entity, as when it searches on a unique key.
- FindAsync - Finds an entity with the primary key (PK). If an entity with the PK is being tracked by the context, it's returned without a request to the database. This method is optimized to look up a single entity, but you can't call `Include` with `FindAsync`. So if related data is needed, `FirstOrDefaultAsync` is the better choice.

Route data vs. query string

The URL for the Details page is `https://localhost:<port>/Students/Details?id=1`. The entity's primary key value is in the query string. Some developers prefer to pass the key value in route data: `https://localhost:<port>/Students/Details/1`. For more information, see Update the generated code.

Update the Create page

The scaffolded `OnPostAsync` code for the Create page is vulnerable to overposting. Replace the `OnPostAsync` method in *Pages/Students/Create.cshtml.cs* with the following code.

```
public async Task<IActionResult> OnPostAsync()
{
    var emptyStudent = new Student();

    if (await TryUpdateModelAsync<Student>(
        emptyStudent,
        "student",   // Prefix for form value.
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        _context.Students.Add(emptyStudent);
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return Page();
}
```

TryUpdateModelAsync

The preceding code creates a Student object and then uses posted form fields to update the Student object's properties. The TryUpdateModelAsync method:

- Uses the posted form values from the PageContext property in the PageModel.
- Updates only the properties listed (`s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate`).
- Looks for form fields with a "student" prefix. For example, `Student.FirstMidName`. It's not case sensitive.
- Uses the model binding system to convert form values from strings to the types in the `Student` model. For example, `EnrollmentDate` has to be converted to DateTime.

Run the app, and create a student entity to test the Create page.

Overposting

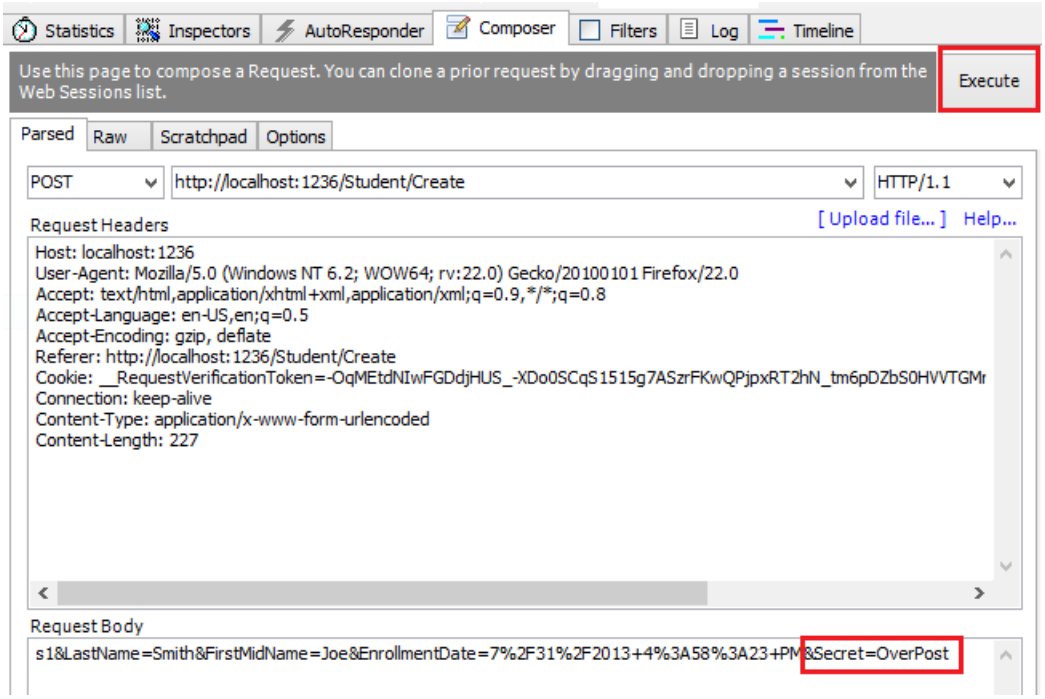
Using `TryUpdateModel` to update fields with posted values is a security best practice because it prevents

overposting. For example, suppose the Student entity includes a `Secret` property that this web page shouldn't update or add:

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if the app doesn't have a `Secret` field on the create or update Razor Page, a hacker could set the `Secret` value by overposting. A hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. The original code doesn't limit the fields that the model binder uses when it creates a Student instance.

Whatever value the hacker specified for the `Secret` form field is updated in the database. The following image shows the Fiddler tool adding the `Secret` field (with the value "OverPost") to the posted form values.



The value "OverPost" is successfully added to the `Secret` property of the inserted row. That happens even though the app designer never intended the `Secret` property to be set with the Create page.

View model

View models provide an alternative way to prevent overposting.

The application model is often called the domain model. The domain model typically contains all the properties required by the corresponding entity in the database. The view model contains only the properties needed for the UI that it is used for (for example, the Create page).

In addition to the view model, some apps use a binding model or input model to pass data between the Razor Pages page model class and the browser.

Consider the following `Student` view model:

```
using System;

namespace ContosoUniversity.Models
{
    public class StudentVM
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }
    }
}
```

The following code uses the `StudentVM` view model to create a new student:

```
[BindProperty]
public StudentVM StudentVM { get; set; }

public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var entry = _context.Add(new Student());
    entry.CurrentValues.SetValues(StudentVM);
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
```

The SetValues method sets the values of this object by reading values from another PropertyValues object. `SetValues` uses property name matching. The view model type doesn't need to be related to the model type, it just needs to have properties that match.

Using `StudentVM` requires Create.cshtml be updated to use `StudentVM` rather than `Student`.

Update the Edit page

In *Pages/Students/Edit.cshtml.cs*, replace the `OnGetAsync` and `OnPostAsync` methods with the following code.

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students.FindAsync(id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}

public async Task<IActionResult> OnPostAsync(int id)
{
    var studentToUpdate = await _context.Students.FindAsync(id);

    if (studentToUpdate == null)
    {
        return NotFound();
    }

    if (await TryUpdateModelAsync<Student>(
        studentToUpdate,
        "student",
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return Page();
}
```

The code changes are similar to the Create page with a few exceptions:

- `FirstOrDefaultAsync` has been replaced with FindAsync. When you don't have to include related data, `FindAsync` is more efficient.
- `OnPostAsync` has an `id` parameter.
- The current student is fetched from the database, rather than creating an empty student.

Run the app, and test it by creating and editing a student.

Entity States

The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database. This tracking information determines what happens when SaveChangesAsync is called. For example, when a new entity is passed to the AddAsync method, that entity's state is set to Added. When `SaveChangesAsync` is called, the database context issues a SQL INSERT command.

An entity may be in one of the following states:

- `Added`: The entity doesn't yet exist in the database. The `SaveChanges` method issues an INSERT statement.
- `Unchanged`: No changes need to be saved with this entity. An entity has this status when it's read from the database.
- `Modified`: Some or all of the entity's property values have been modified. The `SaveChanges` method issues an UPDATE statement.

- `Deleted`: The entity has been marked for deletion. The `SaveChanges` method issues a DELETE statement.
- `Detached`: The entity isn't being tracked by the database context.

In a desktop app, state changes are typically set automatically. An entity is read, changes are made, and the entity state is automatically changed to `Modified`. Calling `SaveChanges` generates a SQL UPDATE statement that updates only the changed properties.

In a web app, the `DbContext` that reads an entity and displays the data is disposed after a page is rendered. When a page's `OnPostAsync` method is called, a new web request is made and with a new instance of the `DbContext`. Rereading the entity in that new context simulates desktop processing.

Update the Delete page

In this section, you implement a custom error message when the call to `SaveChanges` fails.

Replace the code in *Pages/Students/Delete.cshtml.cs* with the following code. The changes are highlighted (other than cleanup of `using` statements).

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Student Student { get; set; }
        public string ErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id, bool? saveChangesError = false)
        {
            if (id == null)
            {
                return NotFound();
            }

            Student = await _context.Students
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.ID == id);

            if (Student == null)
            {
                return NotFound();
            }

            if (saveChangesError.GetValueOrDefault())
            {
                ErrorMessage = "Delete failed. Try again";
            }

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
```

```
        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            var student = await _context.Students.FindAsync(id);

            if (student == null)
            {
                return NotFound();
            }

            try
            {
                _context.Students.Remove(student);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            catch (DbUpdateException /* ex */)
            {
                //Log the error (uncomment ex variable name and write a log.)
                return RedirectToAction("./Delete",
                                        new { id, saveChangesError = true });
            }
        }
    }
}
```

The preceding code adds the optional parameter `saveChangesError` to the `OnGetAsync` method signature. `saveChangesError` indicates whether the method was called after a failure to delete the student object. The delete operation might fail because of transient network problems. Transient network errors are more likely when the database is in the cloud. The `saveChangesError` parameter is false when the Delete page `OnGetAsync` is called from the UI. When `OnGetAsync` is called by `OnPostAsync` (because the delete operation failed), the `saveChangesError` parameter is true.

The `OnPostAsync` method retrieves the selected entity, then calls the Remove method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL DELETE command is generated. If `Remove` fails:

- The database exception is caught.
- The Delete pages `OnGetAsync` method is called with `saveChangesError=true`.

Add an error message to the Delete Razor Page (*Pages/Students/Delete.cshtml*):

```
@page
@model ContosoUniversity.Pages.Students.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h1>Delete</h1>

<p class="text-danger">@Model.ErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Student</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Student.ID" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Run the app and delete a student to test the Delete page.

Next steps

PREVIOUS TUTORIAL NEXT TUTORIAL

In this tutorial, the scaffolded CRUD (create, read, update, delete) code is reviewed and customized.

To minimize complexity and keep these tutorials focused on EF Core, EF Core code is used in the page models. Some developers use a service layer or repository pattern in to create an abstraction layer between the UI (Razor Pages) and the data access layer.

In this tutorial, the Create, Edit, Delete, and Details Razor Pages in the *Students* folder are examined.

The scaffolded code uses the following pattern for Create, Edit, and Delete pages:

- Get and display the requested data with the HTTP GET method `OnGetAsync`.

- Save changes to the data with the HTTP POST method `OnPostAsync`.

The Index and Details pages get and display the requested data with the HTTP GET method `OnGetAsync`

SingleOrDefaultAsync vs. FirstOrDefaultAsync

The generated code uses FirstOrDefaultAsync, which is generally preferred over SingleOrDefaultAsync.

`FirstOrDefaultAsync` is more efficient than `SingleOrDefaultAsync` at fetching one entity:

- Unless the code needs to verify that there's not more than one entity returned from the query.
- `SingleOrDefaultAsync` fetches more data and does unnecessary work.
- `SingleOrDefaultAsync` throws an exception if there's more than one entity that fits the filter part.
- `FirstOrDefaultAsync` doesn't throw if there's more than one entity that fits the filter part.

FindAsync

In much of the scaffolded code, FindAsync can be used in place of `FirstOrDefaultAsync`.

`FindAsync`:

- Finds an entity with the primary key (PK). If an entity with the PK is being tracked by the context, it's returned without a request to the DB.
- Is simple and concise.
- Is optimized to look up a single entity.
- Can have perf benefits in some situations, but that rarely happens for typical web apps.
- Implicitly uses FirstAsync instead of SingleAsync.

But if you want to `Include` other entities, then `FindAsync` is no longer appropriate. This means that you may need to abandon `FindAsync` and move to a query as your app progresses.

Customize the Details page

Browse to `Pages/Students` page. The **Edit**, **Details**, and **Delete** links are generated by the Anchor Tag Helper in the *Pages/Students/Index.cshtml* file.

```
<td>
    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
</td>
```

Run the app and select a **Details** link. The URL is of the form `http://localhost:5000/Students/Details?id=2`. The Student ID is passed using a query string (`?id=2`).

Update the Edit, Details, and Delete Razor Pages to use the `"{id:int}"` route template. Change the page directive for each of these pages from `@page` to `@page "{id:int}"`.

A request to the page with the "{id:int}" route template that does **not** include a integer route value returns an HTTP 404 (not found) error. For example, `http://localhost:5000/Students/Details` returns a 404 error. To make the ID optional, append `?` to the route constraint:

```
@page "{id:int?}"
```

Run the app, click on a Details link, and verify the URL is passing the ID as route data (

`http://localhost:5000/Students/Details/2`).

Don't globally change `@page` to `@page "{id:int}"`, doing so breaks the links to the Home and Create pages.

Add related data

The scaffolded code for the Students Index page doesn't include the `Enrollments` property. In this section, the contents of the `Enrollments` collection is displayed in the Details page.

The `OnGetAsync` method of *Pages/Students/Details.cshtml.cs* uses the `FirstOrDefaultAsync` method to retrieve a single `Student` entity. Add the following highlighted code:

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Student
                        .Include(s => s.Enrollments)
                            .ThenInclude(e => e.Course)
                        .AsNoTracking()
                        .FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

The Include and ThenInclude methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the `Enrollment.Course` navigation property. These methods are examined in detail in the reading-related data tutorial.

The AsNoTracking method improves performance in scenarios when the entities returned are not updated in the current context. `AsNoTracking` is discussed later in this tutorial.

Display related enrollments on the Details page

Open *Pages/Students/Details.cshtml*. Add the following highlighted code to display a list of enrollments:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Students.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h2>Details</h2>

<div>
    <h4>Student</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Student.Enrollments)
        </dt>
        <dd>
            <table class="table">
                <tr>
                    <th>Course Title</th>
                    <th>Grade</th>
                </tr>
                @foreach (var item in Model.Student.Enrollments)
                {
                    <tr>
                        <td>
                            @Html.DisplayFor(modelItem => item.Course.Title)
                        </td>
                        <td>
                            @Html.DisplayFor(modelItem => item.Grade)
                        </td>
                    </tr>
                }
            </table>
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Student.ID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

If code indentation is wrong after the code is pasted, press CTRL-K-D to correct it.

The preceding code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the Course entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. The list of courses and grades for the selected student is displayed.

Update the Create page

Update the `OnPostAsync` method in *Pages/Students/Create.cshtml.cs* with the following code:

```
public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var emptyStudent = new Student();

    if (await TryUpdateModelAsync<Student>(
        emptyStudent,
        "student",   // Prefix for form value.
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        _context.Student.Add(emptyStudent);
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return null;
}
```

TryUpdateModelAsync

Examine the TryUpdateModelAsync code:

```
var emptyStudent = new Student();

if (await TryUpdateModelAsync<Student>(
    emptyStudent,
    "student",   // Prefix for form value.
    s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
{
```

In the preceding code, `TryUpdateModelAsync<Student>` tries to update the `emptyStudent` object using the posted form values from the PageContext property in the PageModel. `TryUpdateModelAsync` only updates the properties listed (`s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate`).

In the preceding sample:

- The second argument (`"student", // Prefix`) is the prefix uses to look up values. It's not case sensitive.
- The posted form values are converted to the types in the `Student` model using model binding.

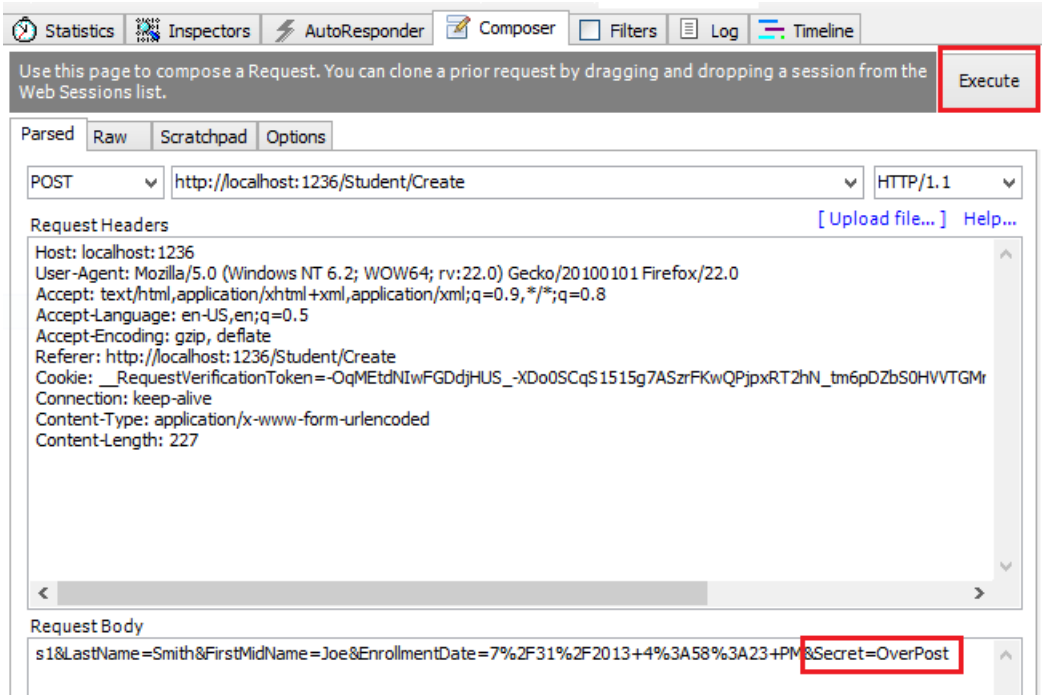
Overposting

Using `TryUpdateModel` to update fields with posted values is a security best practice because it prevents overposting. For example, suppose the Student entity includes a `Secret` property that this web page shouldn't update or add:

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if the app doesn't have a `Secret` field on the create/update Razor Page, a hacker could set the `Secret` value by overposting. A hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. The original code doesn't limit the fields that the model binder uses when it creates a Student instance.

Whatever value the hacker specified for the `Secret` form field is updated in the DB. The following image shows the Fiddler tool adding the `Secret` field (with the value "OverPost") to the posted form values.



The value "OverPost" is successfully added to the `Secret` property of the inserted row. The app designer never intended the `Secret` property to be set with the Create page.

View model

A view model typically contains a subset of the properties included in the model used by the application. The application model is often called the domain model. The domain model typically contains all the properties required by the corresponding entity in the DB. The view model contains only the properties needed for the UI layer (for example, the Create page). In addition to the view model, some apps use a binding model or input model to pass data between the Razor Pages page model class and the browser. Consider the following `Student` view model:

```
using System;

namespace ContosoUniversity.Models
{
    public class StudentVM
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }
    }
}
```

View models provide an alternative way to prevent overposting. The view model contains only the properties to view (display) or update.

The following code uses the `StudentVM` view model to create a new student:

```
[BindProperty]
public StudentVM StudentVM { get; set; }

public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var entry = _context.Add(new Student());
    entry.CurrentValues.SetValues(StudentVM);
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
```

The SetValues method sets the values of this object by reading values from another PropertyValues object. `SetValues` uses property name matching. The view model type doesn't need to be related to the model type, it just needs to have properties that match.

Using `StudentVM` requires CreateVM.cshtml be updated to use `StudentVM` rather than `Student`.

In Razor Pages, the `PageModel` derived class is the view model.

Update the Edit page

Update the page model for the Edit page. The major changes are highlighted:

```
public class EditModel : PageModel
{
    private readonly SchoolContext _context;

    public EditModel(SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Student Student { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Student = await _context.Student.FindAsync(id);

        if (Student == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int? id)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        var studentToUpdate = await _context.Student.FindAsync(id);

        if (await TryUpdateModelAsync<Student>(
            studentToUpdate,
            "student",
            s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
        {
            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }

        return Page();
    }
}
```

The code changes are similar to the Create page with a few exceptions:

- `OnPostAsync` has an optional `id` parameter.
- The current student is fetched from the DB, rather than creating an empty student.
- `FirstOrDefaultAsync` has been replaced with FindAsync. `FindAsync` is a good choice when selecting an entity from the primary key. See FindAsync for more information.

Test the Edit and Create pages

Create and edit a few student entities.

Entity States

The DB context keeps track of whether entities in memory are in sync with their corresponding rows in the DB. The

DB context sync information determines what happens when SaveChangesAsync is called. For example, when a new entity is passed to the AddAsync method, that entity's state is set to Added. When `SaveChangesAsync` is called, the DB context issues a SQL INSERT command.

An entity may be in one of the following states:

- `Added`: The entity doesn't yet exist in the DB. The `SaveChanges` method issues an INSERT statement.
- `Unchanged`: No changes need to be saved with this entity. An entity has this status when it's read from the DB.
- `Modified`: Some or all of the entity's property values have been modified. The `SaveChanges` method issues an UPDATE statement.
- `Deleted`: The entity has been marked for deletion. The `SaveChanges` method issues a DELETE statement.
- `Detached`: The entity isn't being tracked by the DB context.

In a desktop app, state changes are typically set automatically. An entity is read, changes are made, and the entity state to automatically be changed to `Modified`. Calling `SaveChanges` generates a SQL UPDATE statement that updates only the changed properties.

In a web app, the `DbContext` that reads an entity and displays the data is disposed after a page is rendered. When a page's `OnPostAsync` method is called, a new web request is made and with a new instance of the `DbContext`. Re-reading the entity in that new context simulates desktop processing.

Update the Delete page

In this section, code is added to implement a custom error message when the call to `SaveChanges` fails. Add a string to contain possible error messages:

```
public class DeleteModel : PageModel
{
    private readonly SchoolContext _context;

    public DeleteModel(SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Student Student { get; set; }
    public string ErrorMessage { get; set; }
```

Replace the `OnGetAsync` method with the following code:

```
public async Task<IActionResult> OnGetAsync(int? id, bool? saveChangesError = false)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Student
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }

    if (saveChangesError.GetValueOrDefault())
    {
        ErrorMessage = "Delete failed. Try again";
    }

    return Page();
}
```

The preceding code contains the optional parameter `saveChangesError`. `saveChangesError` indicates whether the method was called after a failure to delete the student object. The delete operation might fail because of transient network problems. Transient network errors are more likely in the cloud. `saveChangesError` is false when the Delete page `OnGetAsync` is called from the UI. When `OnGetAsync` is called by `OnPostAsync` (because the delete operation failed), the `saveChangesError` parameter is true.

The Delete pages OnPostAsync method

Replace the `OnPostAsync` with the following code:

```
public async Task<IActionResult> OnPostAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Student
                    .AsNoTracking()
                    .FirstOrDefaultAsync(m => m.ID == id);

    if (student == null)
    {
        return NotFound();
    }

    try
    {
        _context.Student.Remove(student);
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction("./Delete",
                             new { id, saveChangesError = true });
    }
}
```

The preceding code retrieves the selected entity, then calls the Remove method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL DELETE command is generated. If `Remove` fails:

- The DB exception is caught.
- The Delete pages `OnGetAsync` method is called with `saveChangesError=true`.

Update the Delete Razor Page

Add the following highlighted error message to the Delete Razor Page.

```
@page "{id:int}"
@model ContosoUniversity.Pages.Students.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<p class="text-danger">@Model.ErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
```

Test Delete.

Common errors

Students/Index or other links don't work:

Verify the Razor Page contains the correct `@page` directive. For example, The Students/Index Razor Page should **not** contain a route template:

```
@page "{id:int}"
```

Each Razor Page must include the `@page` directive.

Part 3, Razor Pages with EF Core in ASP.NET Core - Sort, Filter, Paging

9/22/2020 • 29 minutes to read • Edit Online

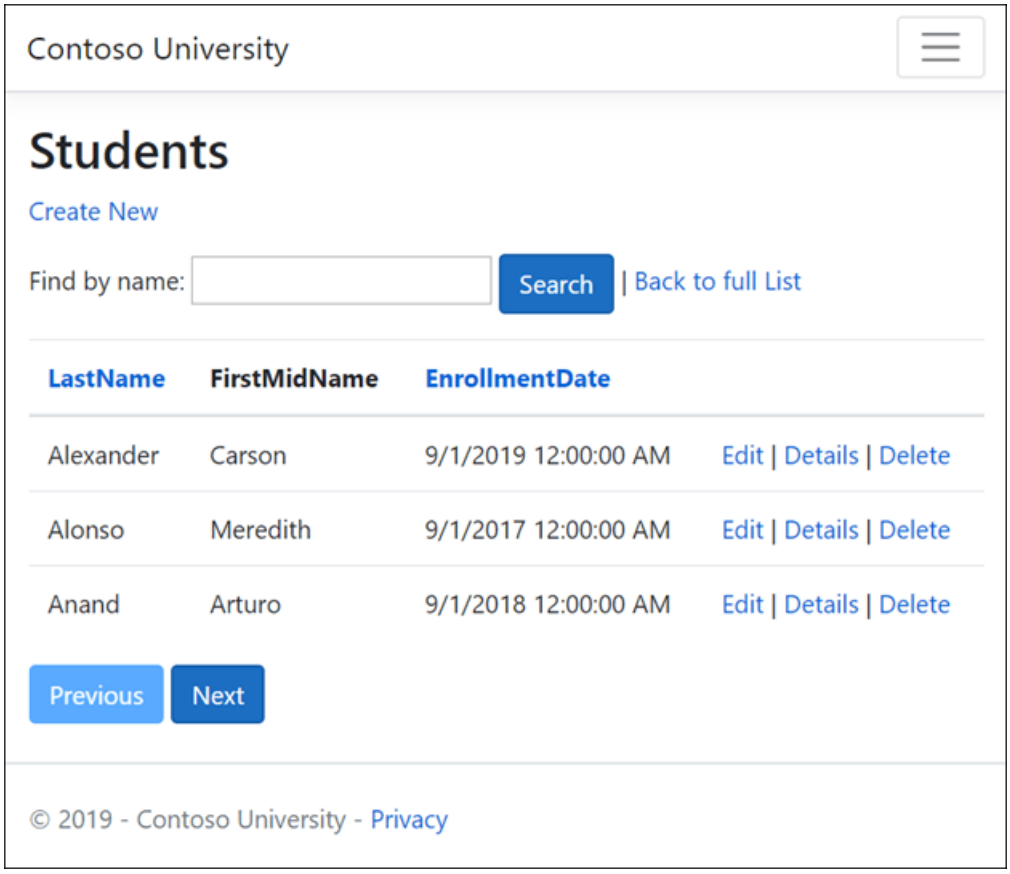
By Tom Dykstra, Rick Anderson, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial adds sorting, filtering, and paging functionality to the Students pages.

The following illustration shows a completed page. The column headings are clickable links to sort the column. Click a column heading repeatedly to switch between ascending and descending sort order.



Add sorting

Replace the code in *Pages/Students/Index.cshtml.cs* with the following code to add sorting.

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class IndexModel : PageModel
    {
        private readonly SchoolContext _context;

        public IndexModel(SchoolContext context)
        {
            _context = context;
        }

        public string NameSort { get; set; }
        public string DateSort { get; set; }
        public string CurrentFilter { get; set; }
        public string CurrentSort { get; set; }

        public IList<Student> Students { get; set; }

        public async Task OnGetAsync(string sortOrder)
        {
            NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
            DateSort = sortOrder == "Date" ? "date_desc" : "Date";

            IQueryable<Student> studentsIQ = from s in _context.Students
                                             select s;

            switch (sortOrder)
            {
                case "name_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                    break;
                case "Date":
                    studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                    break;
                case "date_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
                    break;
                default:
                    studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                    break;
            }

            Students = await studentsIQ.AsNoTracking().ToListAsync();
        }
    }
}
```

The preceding code:

- Adds properties to contain the sorting parameters.
- Changes the name of the `Student` property to `Students`.
- Replaces the code in the `OnGetAsync` method.

The `OnGetAsync` method receives a `sortOrder` parameter from the query string in the URL. The URL (including the query string) is generated by the Anchor Tag Helper.

The `sortOrder` parameter is either "Name" or "Date." The `sortOrder` parameter is optionally followed by "_desc" to specify descending order. The default sort order is ascending.

When the Index page is requested from the **Students** link, there's no query string. The students are displayed in ascending order by last name. Ascending order by last name is the default (fall-through case) in the `switch` statement. When the user clicks a column heading link, the appropriate `sortOrder` value is provided in the query string value.

`NameSort` and `DateSort` are used by the Razor Page to configure the column heading hyperlinks with the appropriate query string values:

```
NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
DateSort = sortOrder == "Date" ? "date_desc" : "Date";
```

The code uses the C# conditional operator ?:. The `?:` operator is a ternary operator (it takes three operands). The first line specifies that when `sortOrder` is null or empty, `NameSort` is set to "name_desc." If `sortOrder` is **not** null or empty, `NameSort` is set to an empty string.

These two statements enable the page to set the column heading hyperlinks as follows:

CURRENT SORT ORDER	LAST NAME HYPERLINK	DATE HYPERLINK
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code initializes an `IQueryable<Student>` before the switch statement, and modifies it in the switch statement:

```
IQueryable<Student> studentsIQ = from s in _context.Students
                                 select s;

switch (sortOrder)
{
    case "name_desc":
        studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
        break;
    case "Date":
        studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
        break;
    case "date_desc":
        studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
        break;
    default:
        studentsIQ = studentsIQ.OrderBy(s => s.LastName);
        break;
}

Students = await studentsIQ.AsNoTracking().ToListAsync();
```

When an `IQueryable` is created or modified, no query is sent to the database. The query isn't executed until the `IQueryable` object is converted into a collection. `IQueryable` are converted to a collection by calling a method such as `ToListAsync`. Therefore, the `IQueryable` code results in a single query that's not executed until the following

statement:

```
Students = await studentsIQ.AsNoTracking().ToListAsync();
```

`OnGetAsync` could get verbose with a large number of sortable columns. For information about an alternative way to code this functionality, see Use dynamic LINQ to simplify code in the MVC version of this tutorial series.

Add column heading hyperlinks to the Student Index page

Replace the code in *Students/Index.cshtml*, with the following code. The changes are highlighted.

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>
<p>
    <a asp-page="Create">Create New</a>
</p>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model => model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model => model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding code:

- Adds hyperlinks to the `LastName` and `EnrollmentDate` column headings.
- Uses the information in `NameSort` and `DateSort` to set up hyperlinks with the current sort order values.
- Changes the page heading from Index to Students.
- Changes `Model.Student` to `Model.Students`.

To verify that sorting works:

- Run the app and select the **Students** tab.
- Click the column headings.

Add filtering

To add filtering to the Students Index page:

- A text box and a submit button is added to the Razor Page. The text box supplies a search string on the first or last name.
- The page model is updated to use the text box value.

Update the OnGetAsync method

Replace the code in *Students/Index.cshtml.cs* with the following code to add filtering:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class IndexModel : PageModel
    {
        private readonly SchoolContext _context;

        public IndexModel(SchoolContext context)
        {
            _context = context;
        }

        public string NameSort { get; set; }
        public string DateSort { get; set; }
        public string CurrentFilter { get; set; }
        public string CurrentSort { get; set; }

        public IList<Student> Students { get; set; }

        public async Task OnGetAsync(string sortOrder, string searchString)
        {
            NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
            DateSort = sortOrder == "Date" ? "date_desc" : "Date";

            CurrentFilter = searchString;

            IQueryable<Student> studentsIQ = from s in _context.Students
                                             select s;
            if (!String.IsNullOrEmpty(searchString))
            {
                studentsIQ = studentsIQ.Where(s => s.LastName.Contains(searchString)
                                       || s.FirstMidName.Contains(searchString));
            }

            switch (sortOrder)
            {
                case "name_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                    break;
                case "Date":
                    studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                    break;
                case "date_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
                    break;
                default:
                    studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                    break;
            }

            Students = await studentsIQ.AsNoTracking().ToListAsync();
        }
    }
}
```

The preceding code:

- Adds the `searchString` parameter to the `OnGetAsync` method, and saves the parameter value in the

`CurrentFilter` property. The search string value is received from a text box that's added in the next section.

- Adds to the LINQ statement a `Where` clause. The `Where` clause selects only students whose first name or last name contains the search string. The LINQ statement is executed only if there's a value to search for.

IQueryable vs. IEnumerable

The code calls the `Where` method on an `IQueryable` object, and the filter is processed on the server. In some scenarios, the app might be calling the `Where` method as an extension method on an in-memory collection. For example, suppose `_context.Students` changes from EF Core `DbSet` to a repository method that returns an `IEnumerable` collection. The result would normally be the same but in some cases may be different.

For example, the .NET Framework implementation of `Contains` performs a case-sensitive comparison by default. In SQL Server, `Contains` case-sensitivity is determined by the collation setting of the SQL Server instance. SQL Server defaults to case-insensitive. SQLite defaults to case-sensitive. `ToUpper` could be called to make the test explicitly case-insensitive:

```
Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())`
```

The preceding code would ensure that the filter is case-insensitive even if the `Where` method is called on an `IEnumerable` or runs on SQLite.

When `Contains` is called on an `IEnumerable` collection, the .NET Core implementation is used. When `Contains` is called on an `IQueryable` object, the database implementation is used.

Calling `Contains` on an `IQueryable` is usually preferable for performance reasons. With `IQueryable`, the filtering is done by the database server. If an `IEnumerable` is created first, all the rows have to be returned from the database server.

There's a performance penalty for calling `ToUpper`. The `ToUpper` code adds a function in the WHERE clause of the TSQL SELECT statement. The added function prevents the optimizer from using an index. Given that SQL is installed as case-insensitive, it's best to avoid the `ToUpper` call when it's not needed.

For more information, see How to use case-insensitive query with Sqlite provider.

Update the Razor page

Replace the code in *Pages/Students/Index.cshtml* to create a **Search** button and assorted chrome.

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString" value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-primary" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model => model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model => model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST. With POST, the parameters are passed in the HTTP message body and not in the URL. When HTTP GET is used, the form data is passed in the URL as query strings. Passing the data with query strings enables users to bookmark the URL. The W3C guidelines recommend that GET should be used when the action doesn't result in an update.

Test the app:

- Select the **Students** tab and enter a search string. If you're using SQLite, the filter is case-insensitive only if you implemented the optional `ToUpper` code shown earlier.
- Select **Search**.

Notice that the URL contains the search string. For example:

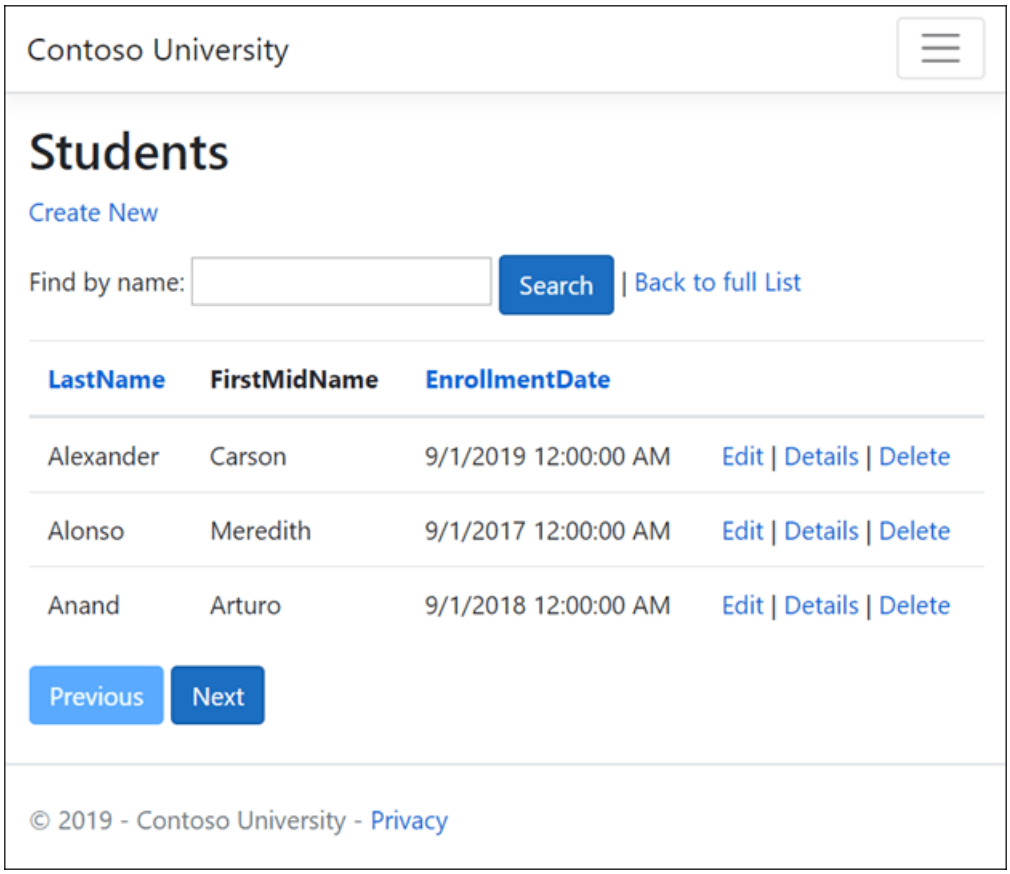
```
https://localhost:<port>/Students?SearchString=an
```

If the page is bookmarked, the bookmark contains the URL to the page and the `SearchString` query string. The `method="get"` in the `form` tag is what caused the query string to be generated.

Currently, when a column heading sort link is selected, the filter value from the **Search** box is lost. The lost filter value is fixed in the next section.

Add paging

In this section, a `PaginatedList` class is created to support paging. The `PaginatedList` class uses `Skip` and `Take` statements to filter data on the server instead of retrieving all rows of the table. The following illustration shows the paging buttons.



Create the PaginatedList class

In the project folder, create `PaginatedList.cs` with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }

        public bool HasPreviousPage
        {
            get
            {
                return (PageIndex > 1);
            }
        }

        public bool HasNextPage
        {
            get
            {
                return (PageIndex < TotalPages);
            }
        }

        public static async Task<PaginatedList<T>> CreateAsync(
            IQueryable<T> source, int pageIndex, int pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip(
                (pageIndex - 1) * pageSize)
                .Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in the preceding code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it returns a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` are used to enable or disable **Previous** and **Next** paging buttons.

The `CreateAsync` method is used to create the `PaginatedList<T>`. A constructor can't create the `PaginatedList<T>` object; constructors can't run asynchronous code.

Add paging to the PageModel class

Replace the code in *Students/Index.cshtml.cs* to add paging.

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
```

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class IndexModel : PageModel
    {
        private readonly SchoolContext _context;

        public IndexModel(SchoolContext context)
        {
            _context = context;
        }

        public string NameSort { get; set; }
        public string DateSort { get; set; }
        public string CurrentFilter { get; set; }
        public string CurrentSort { get; set; }

        public PaginatedList<Student> Students { get; set; }

        public async Task OnGetAsync(string sortOrder,
            string currentFilter, string searchString, int? pageIndex)
        {
            CurrentSort = sortOrder;
            NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
            DateSort = sortOrder == "Date" ? "date_desc" : "Date";
            if (searchString != null)
            {
                pageIndex = 1;
            }
            else
            {
                searchString = currentFilter;
            }

            CurrentFilter = searchString;

            IQueryable<Student> studentsIQ = from s in _context.Students
                                             select s;
            if (!String.IsNullOrEmpty(searchString))
            {
                studentsIQ = studentsIQ.Where(s => s.LastName.Contains(searchString)
                                       || s.FirstMidName.Contains(searchString));
            }
            switch (sortOrder)
            {
                case "name_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                    break;
                case "Date":
                    studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                    break;
                case "date_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
                    break;
                default:
                    studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                    break;
            }

            int pageSize = 3;
            Students = await PaginatedList<Student>.CreateAsync(
                studentsIQ.AsNoTracking(), pageIndex ?? 1, pageSize);
        }
    }
}
```

```
}
```

The preceding code:

- Changes the type of the `Students` property from `IList<Student>` to `PaginatedList<Student>`.
- Adds the page index, the current `sortOrder`, and the `currentFilter` to the `OnGetAsync` method signature.
- Saves the sort order in the CurrentSort property.
- Resets page index to 1 when there's a new search string.
- Uses the `PaginatedList` class to get Student entities.

All the parameters that `OnGetAsync` receives are null when:

- The page is called from the **Students** link.
- The user hasn't clicked a paging or sorting link.

When a paging link is clicked, the page index variable contains the page number to display.

The `CurrentSort` property provides the Razor Page with the current sort order. The current sort order must be included in the paging links to keep the sort order while paging.

The `CurrentFilter` property provides the Razor Page with the current filter string. The `CurrentFilter` value:

- Must be included in the paging links in order to maintain the filter settings during paging.
- Must be restored to the text box when the page is redisplayed.

If the search string is changed while paging, the page is reset to 1. The page has to be reset to 1 because the new filter can result in different data to display. When a search value is entered and **Submit** is selected:

- The search string is changed.
- The `searchString` parameter isn't null.

The `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is passed to the Razor Page.

The two question marks after `pageIndex` in the `PaginatedList.CreateAsync` call represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type. The expression `(pageIndex ?? 1)` means return the value of `pageIndex` if it has a value. If `pageIndex` doesn't have a value, return 1.

Add paging links to the Razor Page

Replace the code in *Students/Index.cshtml* with the following code. The changes are highlighted:

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString" value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-primary" /> |
            <a asp-page="./Index">Back to full List</a>
```

```
            <a asp-page ./Index >Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model => model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model => model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@{
    var prevDisabled = !Model.Students.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.Students.HasNextPage ? "disabled" : "";
}

<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @nextDisabled">
    Next
</a>
```

The column header links use the query string to pass the current search string to the `OnGetAsync` method:

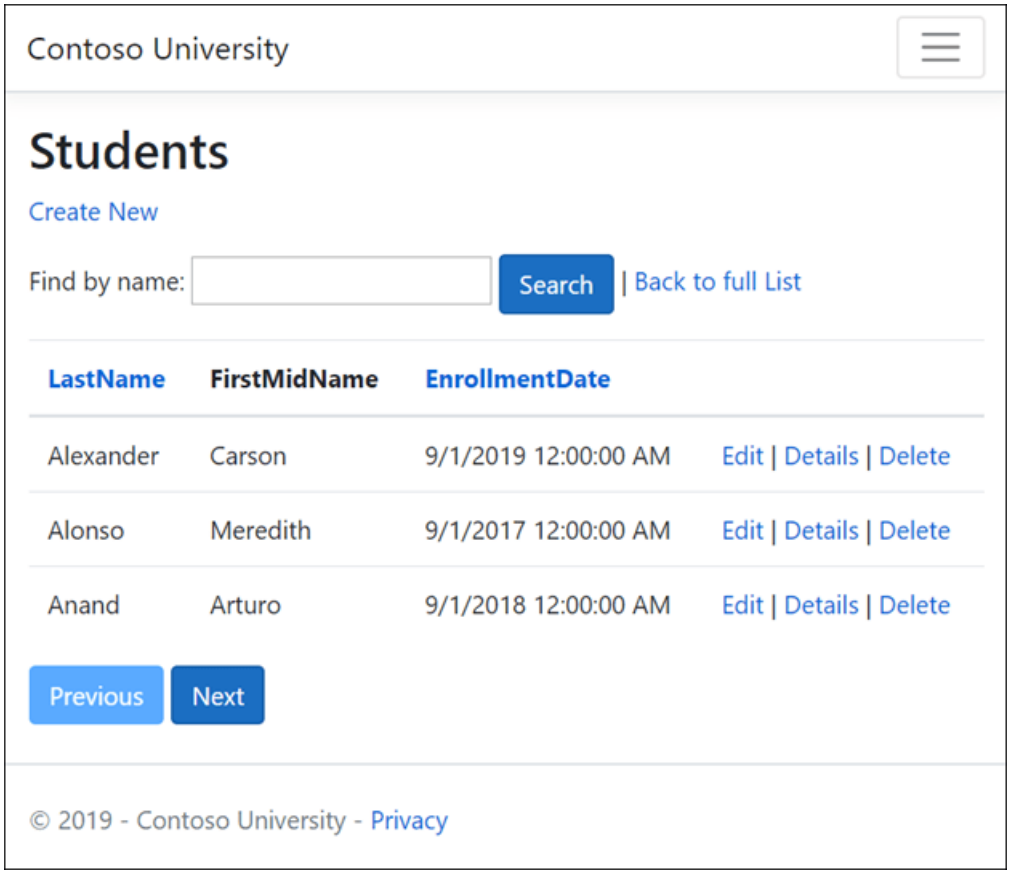
```
<a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
   asp-route-currentFilter="@Model.CurrentFilter">
    @Html.DisplayNameFor(model => model.Students[0].LastName)
</a>
```

The paging buttons are displayed by tag helpers:

```
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @nextDisabled">
    Next
</a>
```

Run the app and navigate to the students page.

- To make sure paging works, click the paging links in different sort orders.
- To verify that paging works correctly with sorting and filtering, enter a search string and try paging.



Add grouping

This section creates an About page that displays how many students have enrolled for each enrollment date. The

update uses grouping and includes the following steps:

- Create a view model for the data used by the **About** page.
- Update the About page to use the view model.

Create the view model

Create a *Models/SchoolViewModels* folder.

Create *SchoolViewModels/EnrollmentDateGroup.cs* with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Create the Razor Page

Create a *Pages/About.cshtml* file with the following code:

```
@page
@model ContosoUniversity.Pages.AboutModel

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model.Students)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Create the page model

Create a *Pages/About.cshtml.cs* file with the following code:

```
using ContosoUniversity.Models.SchoolViewModels;
using ContosoUniversity.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using ContosoUniversity.Models;

namespace ContosoUniversity.Pages
{
    public class AboutModel : PageModel
    {
        private readonly SchoolContext _context;

        public AboutModel(SchoolContext context)
        {
            _context = context;
        }

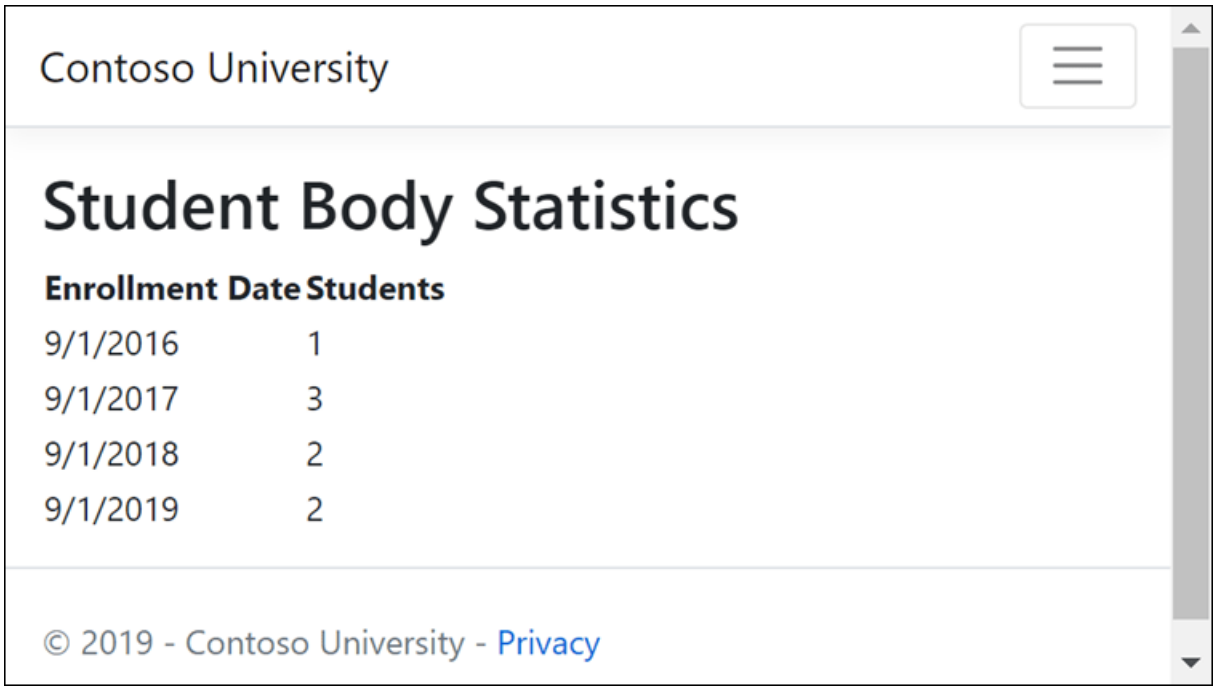
        public IList<EnrollmentDateGroup> Students { get; set; }

        public async Task OnGetAsync()
        {
            IQueryable<EnrollmentDateGroup> data =
                from student in _context.Students
                group student by student.EnrollmentDate into dateGroup
                select new EnrollmentDateGroup()
                {
                    EnrollmentDate = dateGroup.Key,
                    StudentCount = dateGroup.Count()
                };

            Students = await data.AsNoTracking().ToListAsync();
        }
    }
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Run the app and navigate to the About page. The count of students for each enrollment date is displayed in a table.



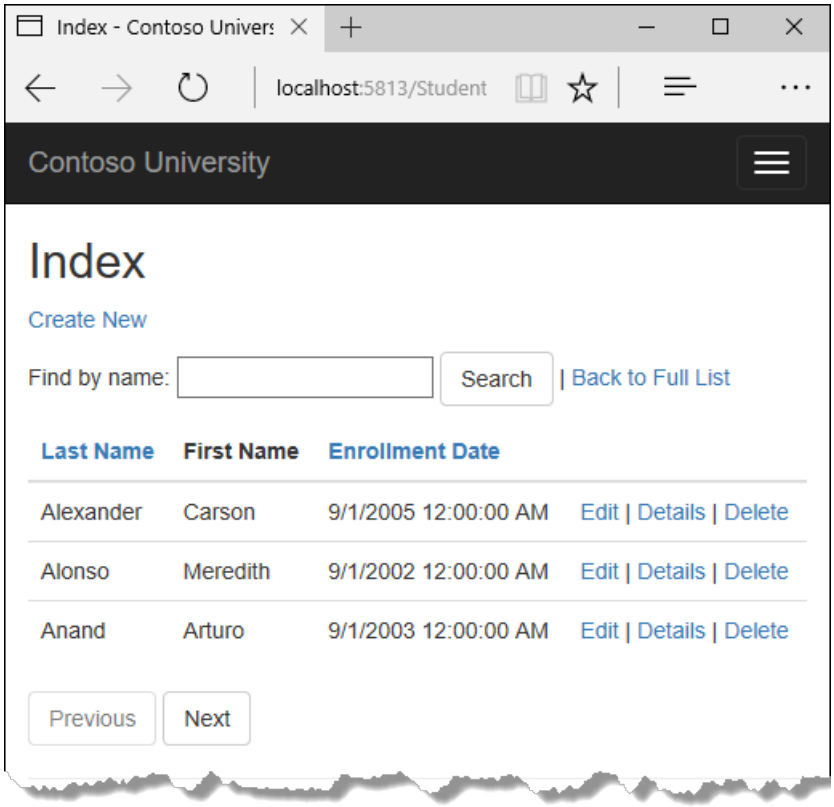
Next steps

In the next tutorial, the app uses migrations to update the data model.

PREVIOUS TUTORIAL | NEXT TUTORIAL

In this tutorial, sorting, filtering, grouping, and paging, functionality is added.

The following illustration shows a completed page. The column headings are clickable links to sort the column. Clicking a column heading repeatedly switches between ascending and descending sort order.



If you run into problems you can't solve, download the completed app.

Add sorting to the Index page

Add strings to the *Students/Index.cshtml.cs* `PageModel` to contain the sorting parameters:

```
public class IndexModel : PageModel
{
    private readonly SchoolContext _context;

    public IndexModel(SchoolContext context)
    {
        _context = context;
    }

    public string NameSort { get; set; }
    public string DateSort { get; set; }
    public string CurrentFilter { get; set; }
    public string CurrentSort { get; set; }
```

Update the *Students/Index.cshtml.cs* `OnGetAsync` with the following code:

```
public async Task OnGetAsync(string sortOrder)
{
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;

    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    Student = await studentIQ.AsNoTracking().ToListAsync();
}
```

The preceding code receives a `sortOrder` parameter from the query string in the URL. The URL (including the query string) is generated by the Anchor Tag Helper

The `sortOrder` parameter is either "Name" or "Date." The `sortOrder` parameter is optionally followed by "_desc" to specify descending order. The default sort order is ascending.

When the Index page is requested from the **Students** link, there's no query string. The students are displayed in ascending order by last name. Ascending order by last name is the default (fall-through case) in the `switch` statement. When the user clicks a column heading link, the appropriate `sortOrder` value is provided in the query string value.

`NameSort` and `DateSort` are used by the Razor Page to configure the column heading hyperlinks with the appropriate query string values:

```
public async Task OnGetAsync(string sortOrder)
{
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;

    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    Student = await studentIQ.AsNoTracking().ToListAsync();
}
```

The following code contains the C# conditional ?: operator:

```
NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
DateSort = sortOrder == "Date" ? "date_desc" : "Date";
```

The first line specifies that when `sortOrder` is null or empty, `NameSort` is set to "name_desc." If `sortOrder` is **not** null or empty, `NameSort` is set to an empty string.

The `?: operator` is also known as the ternary operator.

These two statements enable the page to set the column heading hyperlinks as follows:

CURRENT SORT ORDER	LAST NAME HYPERLINK	DATE HYPERLINK
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code initializes an `IQueryable<Student>` before the switch statement, and modifies it in the switch statement:

```
public async Task OnGetAsync(string sortOrder)
{
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;

    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    Student = await studentIQ.AsNoTracking().ToListAsync();
}
```

When an `IQueryable` is created or modified, no query is sent to the database. The query isn't executed until the `IQueryable` object is converted into a collection. `IQueryable` are converted to a collection by calling a method such as `ToListAsync`. Therefore, the `IQueryable` code results in a single query that's not executed until the following statement:

```
Student = await studentIQ.AsNoTracking().ToListAsync();
```

`OnGetAsync` could get verbose with a large number of sortable columns.

Add column heading hyperlinks to the Student Index page

Replace the code in *Students/Index.cshtml*, with the following highlighted code:

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>
<p>
    <a asp-page="Create">Create New</a>
</p>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model => model.Student[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Student[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model => model.Student[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Student)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding code:

- Adds hyperlinks to the `LastName` and `EnrollmentDate` column headings.
- Uses the information in `NameSort` and `DateSort` to set up hyperlinks with the current sort order values.

To verify that sorting works:

- Run the app and select the **Students** tab.
- Click **Last Name**.
- Click **Enrollment Date**.

To get a better understanding of the code:

- In *Students/Index.cshtml.cs*, set a breakpoint on `switch (sortOrder)`.
- Add a watch for `NameSort` and `DateSort`.
- In *Students/Index.cshtml*, set a breakpoint on `@Html.DisplayNameFor(model => model.Student[0].LastName)`.

Step through the debugger.

Add a Search Box to the Students Index page

To add filtering to the Students Index page:

- A text box and a submit button is added to the Razor Page. The text box supplies a search string on the first or last name.
- The page model is updated to use the text box value.

Add filtering functionality to the Index method

Update the *Students/Index.cshtml.cs* `OnGetAsync` with the following code:

```
public async Task OnGetAsync(string sortOrder, string searchString)
{
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";
    CurrentFilter = searchString;

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        studentIQ = studentIQ.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }

    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    Student = await studentIQ.AsNoTracking().ToListAsync();
}
```

The preceding code:

- Adds the `searchString` parameter to the `OnGetAsync` method. The search string value is received from a text box that's added in the next section.
- Added to the LINQ statement a `Where` clause. The `Where` clause selects only students whose first name or last name contains the search string. The LINQ statement is executed only if there's a value to search for.

Note: The preceding code calls the `Where` method on an `IQueryable` object, and the filter is processed on the server. In some scenarios, the app might be calling the `Where` method as an extension method on an in-memory

collection. For example, suppose `_context.Students` changes from EF Core `DbSet` to a repository method that returns an `IEnumerable` collection. The result would normally be the same but in some cases may be different.

For example, the .NET Framework implementation of `Contains` performs a case-sensitive comparison by default. In SQL Server, `Contains` case-sensitivity is determined by the collation setting of the SQL Server instance. SQL Server defaults to case-insensitive. `ToUpper` could be called to make the test explicitly case-insensitive:

```
Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())
```

The preceding code would ensure that results are case-insensitive if the code changes to use `IEnumerable`. When `Contains` is called on an `IEnumerable` collection, the .NET Core implementation is used. When `Contains` is called on an `IQueryable` object, the database implementation is used. Returning an `IEnumerable` from a repository can have a significant performance penalty:

1. All the rows are returned from the DB server.
2. The filter is applied to all the returned rows in the application.

There's a performance penalty for calling `ToUpper`. The `ToUpper` code adds a function in the WHERE clause of the TSQL SELECT statement. The added function prevents the optimizer from using an index. Given that SQL is installed as case-insensitive, it's best to avoid the `ToUpper` call when it's not needed.

Add a Search Box to the Student Index page

In *Pages/Students/Index.cshtml*, add the following highlighted code to create a **Search** button and assorted chrome.

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString" value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
```

The preceding code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST. With POST, the parameters are passed in the HTTP message body and not in the URL. When HTTP GET is used, the form data is passed in the URL as query strings. Passing the data with query strings enables users to bookmark the URL. The W3C guidelines recommend that GET should be used when the action doesn't result in an update.

Test the app:

- Select the **Students** tab and enter a search string.

- Select **Search**.

Notice that the URL contains the search string.

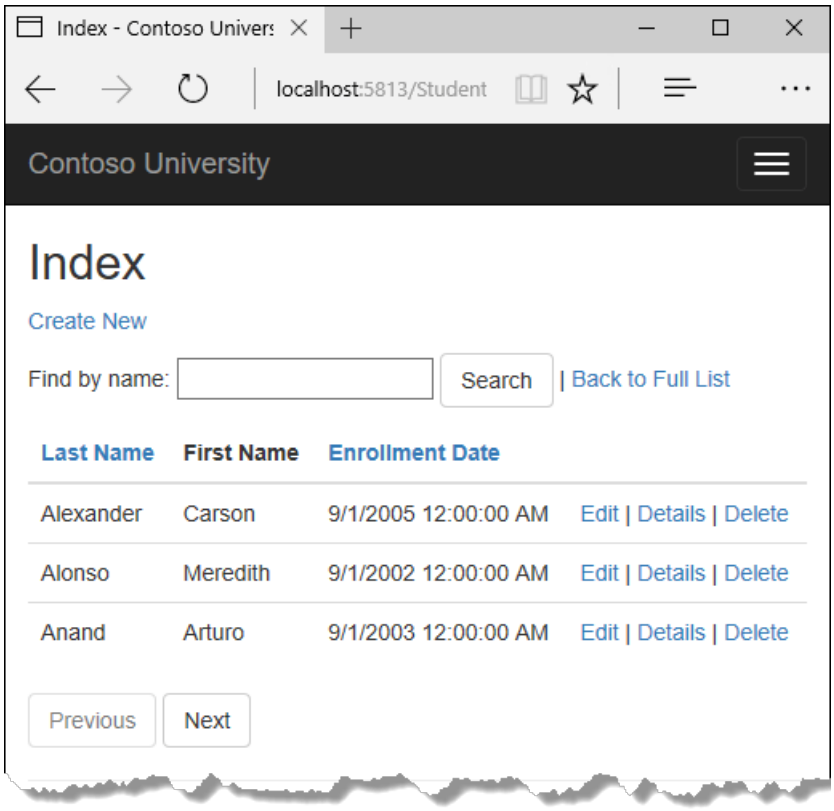
```
http://localhost:5000/Students?SearchString=an
```

If the page is bookmarked, the bookmark contains the URL to the page and the `SearchString` query string. The `method="get"` in the `form` tag is what caused the query string to be generated.

Currently, when a column heading sort link is selected, the filter value from the **Search** box is lost. The lost filter value is fixed in the next section.

Add paging functionality to the Students Index page

In this section, a `PaginatedList` class is created to support paging. The `PaginatedList` class uses `Skip` and `Take` statements to filter data on the server instead of retrieving all rows of the table. The following illustration shows the paging buttons.



In the project folder, create `PaginatedList.cs` with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }

        public bool HasPreviousPage
        {
            get
            {
                return (PageIndex > 1);
            }
        }

        public bool HasNextPage
        {
            get
            {
                return (PageIndex < TotalPages);
            }
        }

        public static async Task<PaginatedList<T>> CreateAsync(
            IQueryable<T> source, int pageIndex, int pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip(
                (pageIndex - 1) * pageSize)
                .Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in the preceding code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it returns a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` are used to enable or disable **Previous** and **Next** paging buttons.

The `CreateAsync` method is used to create the `PaginatedList<T>`. A constructor can't create the `PaginatedList<T>` object, constructors can't run asynchronous code.

Add paging functionality to the Index method

In *Students/Index.cshtml.cs*, update the type of `Student` from `IList<Student>` to `PaginatedList<Student>`:

```
public PaginatedList<Student> Student { get; set; }
```

Update the *Students/Index.cshtml.cs* `OnGetAsync` with the following code:

```
public async Task OnGetAsync(string sortOrder,
    string currentFilter, string searchString, int? pageIndex)
{
    CurrentSort = sortOrder;
    NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    DateSort = sortOrder == "Date" ? "date_desc" : "Date";
    if (searchString != null)
    {
        pageIndex = 1;
    }
    else
    {
        searchString = currentFilter;
    }

    CurrentFilter = searchString;

    IQueryable<Student> studentIQ = from s in _context.Student
                                    select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        studentIQ = studentIQ.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            studentIQ = studentIQ.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            studentIQ = studentIQ.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            studentIQ = studentIQ.OrderBy(s => s.LastName);
            break;
    }

    int pageSize = 3;
    Student = await PaginatedList<Student>.CreateAsync(
        studentIQ.AsNoTracking(), pageIndex ?? 1, pageSize);
}
```

The preceding code adds the page index, the current `sortOrder`, and the `currentFilter` to the method signature.

```
public async Task OnGetAsync(string sortOrder,
    string currentFilter, string searchString, int? pageIndex)
```

All the parameters are null when:

- The page is called from the **Students** link.
- The user hasn't clicked a paging or sorting link.

When a paging link is clicked, the page index variable contains the page number to display.

`CurrentSort` provides the Razor Page with the current sort order. The current sort order must be included in the paging links to keep the sort order while paging.

`CurrentFilter` provides the Razor Page with the current filter string. The `CurrentFilter` value:

- Must be included in the paging links in order to maintain the filter settings during paging.
- Must be restored to the text box when the page is redisplayed.

If the search string is changed while paging, the page is reset to 1. The page has to be reset to 1 because the new filter can result in different data to display. When a search value is entered and **Submit** is selected:

- The search string is changed.
- The `searchString` parameter isn't null.

```
if (searchString != null)
{
    pageIndex = 1;
}
else
{
    searchString = currentFilter;
}
```

The `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is passed to the Razor Page.

```
Student = await PaginatedList<Student>.CreateAsync(
    studentIQ.AsNoTracking(), pageIndex ?? 1, pageSize);
```

The two question marks in `PaginatedList.CreateAsync` represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type. The expression `(pageIndex ?? 1)` means return the value of `pageIndex` if it has a value. If `pageIndex` doesn't have a value, return 1.

Add paging links to the student Razor Page

Update the markup in *Students/Index.cshtml*. The changes are highlighted:

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name: <input type="text" name="SearchString" value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
```

```
                    asp-route-currentFilter="@Model.CurrentFilter">
                     @Html.DisplayNameFor(model => model.Student[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Student[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model => model.Student[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Student)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@{
    var prevDisabled = !Model.Student.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.Student.HasNextPage ? "disabled" : "";
}

<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Student.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-default @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Student.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-default @nextDisabled">
    Next
</a>
```

The column header links use the query string to pass the current search string to the `OnGetAsync` method so that the user can sort within filter results:

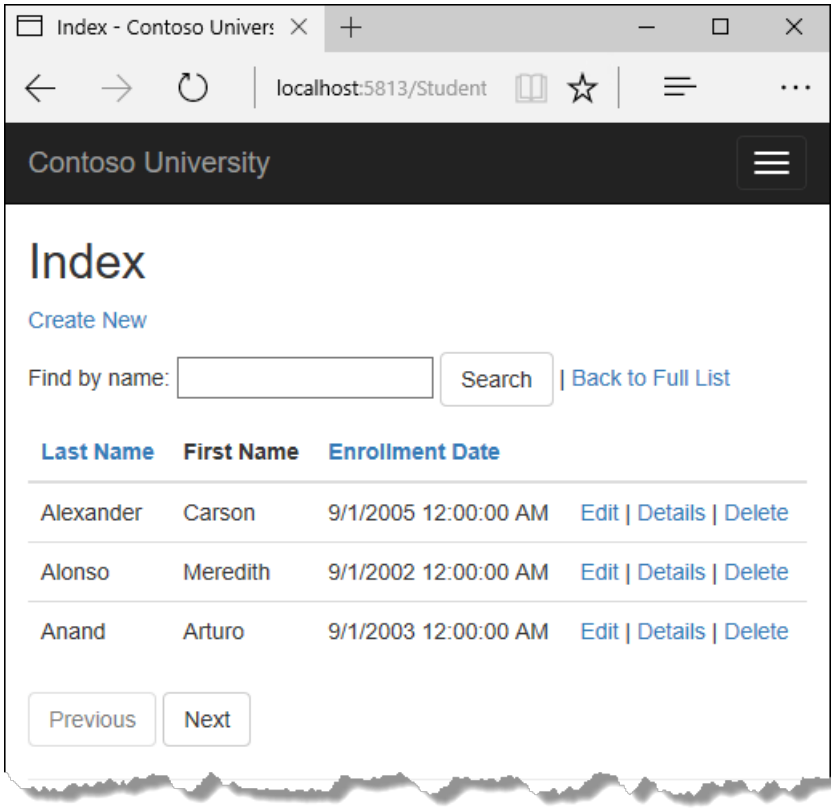
```
<a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
   asp-route-currentFilter="@Model.CurrentFilter">
    @Html.DisplayNameFor(model => model.Student[0].LastName)
</a>
```

The paging buttons are displayed by tag helpers:

```
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Student.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-default @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Student.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-default @nextDisabled">
    Next
</a>
```

Run the app and navigate to the students page.

- To make sure paging works, click the paging links in different sort orders.
- To verify that paging works correctly with sorting and filtering, enter a search string and try paging.



To get a better understanding of the code:

- In *Students/Index.cshtml.cs*, set a breakpoint on `switch (sortOrder)`.
- Add a watch for `NameSort`, `DateSort`, `CurrentSort`, and `Model.Student.PageIndex`.
- In *Students/Index.cshtml*, set a breakpoint on `@Html.DisplayNameFor(model => model.Student[0].LastName)`.

Step through the debugger.

Update the About page to show student statistics

In this step, *Pages/About.cshtml* is updated to display how many students have enrolled for each enrollment date. The update uses grouping and includes the following steps:

- Create a view model for the data used by the **About** Page.
- Update the About page to use the view model.

Create the view model

Create a *SchoolViewModels* folder in the *Models* folder.

In the *SchoolViewModels* folder, add a *EnrollmentDateGroup.cs* with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Update the About page model

The web templates in ASP.NET Core 2.2 do not include the About page. If you are using ASP.NET Core 2.2, create the About Razor Page.

Update the *Pages/About.cshtml.cs* file with the following code:

```
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using ContosoUniversity.Models;

namespace ContosoUniversity.Pages
{
    public class AboutModel : PageModel
    {
        private readonly SchoolContext _context;

        public AboutModel(SchoolContext context)
        {
            _context = context;
        }

        public IList<EnrollmentDateGroup> Student { get; set; }

        public async Task OnGetAsync()
        {
            IQueryable<EnrollmentDateGroup> data =
                from student in _context.Student
                group student by student.EnrollmentDate into dateGroup
                select new EnrollmentDateGroup()
                {
                    EnrollmentDate = dateGroup.Key,
                    StudentCount = dateGroup.Count()
                };

            Student = await data.AsNoTracking().ToListAsync();
        }
    }
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Modify the About Razor Page

Replace the code in the *Pages/About.cshtml* file with the following code:

```
@page
@model ContosoUniversity.Pages.AboutModel

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model.Student)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Run the app and navigate to the About page. The count of students for each enrollment date is displayed in a table.

If you run into problems you can't solve, download the completed app for this stage.

Part 4, Razor Pages with EF Core migrations in ASP.NET Core

9/22/2020 • 11 minutes to read • Edit Online

By Tom Dykstra, Jon P Smith, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial introduces the EF Core migrations feature for managing data model changes.

When a new app is developed, the data model changes frequently. Each time the model changes, the model gets out of sync with the database. This tutorial series started by configuring the Entity Framework to create the database if it doesn't exist. Each time the data model changes, you have to drop the database. The next time the app runs, the call to `EnsureCreated` re-creates the database to match the new data model. The `DbInitializer` class then runs to seed the new database.

This approach to keeping the database in sync with the data model works well until you deploy the app to production. When the app is running in production, it's usually storing data that needs to be maintained. The app can't start with a test database each time a change is made (such as adding a new column). The EF Core Migrations feature solves this problem by enabling EF Core to update the database schema instead of creating a new database.

Rather than dropping and recreating the database when the data model changes, migrations updates the schema and retains existing data.

> **NOTE**
>
> **SQLite limitations**
>
> This tutorial uses the Entity Framework Core *migrations* feature where possible. Migrations updates the database schema to match changes in the data model. However, migrations only does the kinds of changes that the database engine supports, and SQLite's schema change capabilities are limited. For example, adding a column is supported, but removing a column is not supported. If a migration is created to remove a column, the `ef migrations add` command succeeds but the `ef database update` command fails.
>
> The workaround for the SQLite limitations is to manually write migrations code to perform a table rebuild when something in the table changes. The code would go in the `Up` and `Down` methods for a migration and would involve:
>
> - Creating a new table.
> - Copying data from the old table to the new table.
> - Dropping the old table.
> - Renaming the new table.
>
> Writing database-specific code of this type is outside the scope of this tutorial. Instead, this tutorial drops and re-creates the database whenever an attempt to apply a migration would fail. For more information, see the following resources:
>
> - SQLite EF Core Database Provider Limitations
> - Customize migration code
> - Data seeding
> - SQLite ALTER TABLE statement

Drop the database

- Visual Studio
- Visual Studio Code

Use **SQL Server Object Explorer** (SSOX) to delete the database, or run the following command in the **Package Manager Console** (PMC):

```
Drop-Database
```

Create an initial migration

- Visual Studio
- Visual Studio Code

Run the following commands in the PMC:

```
Add-Migration InitialCreate
Update-Database
```

Up and Down methods

The EF Core `migrations add` command generated code to create the database. This migrations code is in the *Migrations<timestamp>_InitialCreate.cs* file. The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets. The `Down` method deletes them, as shown in the following example:

```
using System;
using Microsoft.EntityFrameworkCore.Metadata;
using Microsoft.EntityFrameworkCore.Migrations;

namespace ContosoUniversity.Migrations
{
    public partial class InitialCreate : Migration
    {
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.CreateTable(
                name: "Course",
                columns: table => new
                {
                    CourseID = table.Column<int>(nullable: false),
                    Title = table.Column<string>(nullable: true),
                    Credits = table.Column<int>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Course", x => x.CourseID);
                });

            migrationBuilder.CreateTable(
                name: "Student",
                columns: table => new
                {
                    ID = table.Column<int>(nullable: false)
                        .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
                    LastName = table.Column<string>(nullable: true),
                    FirstMidName = table.Column<string>(nullable: true),
```

```
                    EnrollmentDate = table.Column<DateTime>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Student", x => x.ID);
                });

            migrationBuilder.CreateTable(
                name: "Enrollment",
                columns: table => new
                {
                    EnrollmentID = table.Column<int>(nullable: false)
                        .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
                    CourseID = table.Column<int>(nullable: false),
                    StudentID = table.Column<int>(nullable: false),
                    Grade = table.Column<int>(nullable: true)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Enrollment", x => x.EnrollmentID);
                    table.ForeignKey(
                        name: "FK_Enrollment_Course_CourseID",
                        column: x => x.CourseID,
                        principalTable: "Course",
                        principalColumn: "CourseID",
                        onDelete: ReferentialAction.Cascade);
                    table.ForeignKey(
                        name: "FK_Enrollment_Student_StudentID",
                        column: x => x.StudentID,
                        principalTable: "Student",
                        principalColumn: "ID",
                        onDelete: ReferentialAction.Cascade);
                });

            migrationBuilder.CreateIndex(
                name: "IX_Enrollment_CourseID",
                table: "Enrollment",
                column: "CourseID");

            migrationBuilder.CreateIndex(
                name: "IX_Enrollment_StudentID",
                table: "Enrollment",
                column: "StudentID");
        }

        protected override void Down(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.DropTable(
                name: "Enrollment");

            migrationBuilder.DropTable(
                name: "Course");

            migrationBuilder.DropTable(
                name: "Student");
        }
    }
}
```

The preceding code is for the initial migration. The code:

- Was generated by the `migrations add InitialCreate` command.
- Is executed by the `database update` command.
- Creates a database for the data model specified by the database context class.

The migration name parameter ("InitialCreate" in the example) is used for the file name. The migration name can be any valid file name. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, a migration that added a department table might be called "AddDepartmentTable."

The migrations history table

- Use SSOX or your SQLite tool to inspect the database.
- Notice the addition of an `__EFMigrationsHistory` table. The `__EFMigrationsHistory` table keeps track of which migrations have been applied to the database.
- View the data in the `__EFMigrationsHistory` table. It shows one row for the first migration.

The data model snapshot

Migrations creates a *snapshot* of the current data model in *Migrations/SchoolContextModelSnapshot.cs*. When you add a migration, EF determines what changed by comparing the current data model to the snapshot file.

Because the snapshot file tracks the state of the data model, you can't delete a migration by deleting the `<timestamp>_<migrationname>.cs` file. To back out the most recent migration, you have to use the `migrations remove` command. That command deletes the migration and ensures the snapshot is correctly reset. For more information, see dotnet ef migrations remove.

Remove EnsureCreated

This tutorial series started by using `EnsureCreated`. `EnsureCreated` doesn't create a migrations history table and so can't be used with migrations. It's designed for testing or rapid prototyping where the database is dropped and re-created frequently.

From this point forward, the tutorials will use migrations.

In *Data/DBInitializer.cs*, comment out the following line:

```
context.Database.EnsureCreated();
```

Run the app and verify that the database is seeded.

Applying migrations in production

We recommend that production apps **not** call Database.Migrate at application startup. `Migrate` shouldn't be called from an app that is deployed to a server farm. If the app is scaled out to multiple server instances, it's hard to ensure database schema updates don't happen from multiple servers or conflict with read/write access.

Database migration should be done as part of deployment, and in a controlled way. Production database migration approaches include:

- Using migrations to create SQL scripts and using the SQL scripts in deployment.
- Running `dotnet ef database update` from a controlled environment.

Troubleshooting

If the app uses SQL Server LocalDB and displays the following exception:

```
SqlException: Cannot open database "ContosoUniversity" requested by the login.
The login failed.
Login failed for user 'user name'.
```

The solution may be to run `dotnet ef database update` at a command prompt.

Additional resources

- EF Core CLI.
- Package Manager Console (Visual Studio)

Next steps

The next tutorial builds out the data model, adding entity properties and new entities.

PREVIOUS TUTORIAL NEXT TUTORIAL

In this tutorial, the EF Core migrations feature for managing data model changes is used.

If you run into problems you can't solve, download the completed app.

When a new app is developed, the data model changes frequently. Each time the model changes, the model gets out of sync with the database. This tutorial started by configuring the Entity Framework to create the database if it doesn't exist. Each time the data model changes:

- The DB is dropped.
- EF creates a new one that matches the model.
- The app seeds the DB with test data.

This approach to keeping the DB in sync with the data model works well until you deploy the app to production. When the app is running in production, it's usually storing data that needs to be maintained. The app can't start with a test DB each time a change is made (such as adding a new column). The EF Core Migrations feature solves this problem by enabling EF Core to update the DB schema instead of creating a new DB.

Rather than dropping and recreating the DB when the data model changes, migrations updates the schema and retains existing data.

Drop the database

Use **SQL Server Object Explorer** (SSOX) or the `database drop` command:

- Visual Studio
- Visual Studio Code

In the **Package Manager Console** (PMC), run the following command:

```
Drop-Database
```

Run `Get-Help about_EntityFrameworkCore` from the PMC to get help information.

Create an initial migration and update the DB

Build the project and create the first migration.

- Visual Studio
- Visual Studio Code

```
Add-Migration InitialCreate
Update-Database
```

Examine the Up and Down methods

The EF Core `migrations add` command generated code to create the DB. This migrations code is in the *Migrations<timestamp>_InitialCreate.cs* file. The `Up` method of the `InitialCreate` class creates the DB tables that correspond to the data model entity sets. The `Down` method deletes them, as shown in the following example:

```
public partial class InitialCreate : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.CreateTable(
            name: "Course",
            columns: table => new
            {
                CourseID = table.Column<int>(nullable: false),
                Title = table.Column<string>(nullable: true),
                Credits = table.Column<int>(nullable: false)
            },
            constraints: table =>
            {
                table.PrimaryKey("PK_Course", x => x.CourseID);
            });

        migrationBuilder.CreateTable(
    protected override void Down(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.DropTable(
            name: "Enrollment");

        migrationBuilder.DropTable(
            name: "Course");

        migrationBuilder.DropTable(
            name: "Student");
    }
}
```

Migrations calls the `Up` method to implement the data model changes for a migration. When you enter a command to roll back the update, migrations calls the `Down` method.

The preceding code is for the initial migration. That code was created when the `migrations add InitialCreate` command was run. The migration name parameter ("InitialCreate" in the example) is used for the file name. The migration name can be any valid file name. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, a migration that added a department table might be called "AddDepartmentTable."

If the initial migration is created and the DB exists:

- The DB creation code is generated.
- The DB creation code doesn't need to run because the DB already matches the data model. If the DB creation code is run, it doesn't make any changes because the DB already matches the data model.

When the app is deployed to a new environment, the DB creation code must be run to create the DB.

Previously the DB was dropped and doesn't exist, so migrations creates the new DB.

The data model snapshot

Migrations create a *snapshot* of the current database schema in *Migrations/SchoolContextModelSnapshot.cs*. When

you add a migration, EF determines what changed by comparing the data model to the snapshot file.

To delete a migration, use the following command:

- Visual Studio
- Visual Studio Code

Remove-Migration

The remove migrations command deletes the migration and ensures the snapshot is correctly reset.

Remove EnsureCreated and test the app

For early development, `EnsureCreated` was used. In this tutorial, migrations are used. `EnsureCreated` has the following limitations:

- Bypasses migrations and creates the DB and schema.
- Doesn't create a migrations table.
- Can *not* be used with migrations.
- Is designed for testing or rapid prototyping where the DB is dropped and re-created frequently.

Remove `EnsureCreated`:

```
context.Database.EnsureCreated();
```

Run the app and verify the DB is seeded.

Inspect the database

Use **SQL Server Object Explorer** to inspect the DB. Notice the addition of an `__EFMigrationsHistory` table. The `__EFMigrationsHistory` table keeps track of which migrations have been applied to the DB. View the data in the `__EFMigrationsHistory` table, it shows one row for the first migration. The last log in the preceding CLI output example shows the INSERT statement that creates this row.

Run the app and verify that everything works.

Applying migrations in production

We recommend production apps should **not** call Database.Migrate at application startup. `Migrate` shouldn't be called from an app in server farm. For example, if the app has been cloud deployed with scale-out (multiple instances of the app are running).

Database migration should be done as part of deployment, and in a controlled way. Production database migration approaches include:

- Using migrations to create SQL scripts and using the SQL scripts in deployment.
- Running `dotnet ef database update` from a controlled environment.

EF Core uses the `__MigrationsHistory` table to see if any migrations need to run. If the DB is up-to-date, no migration is run.

Troubleshooting

Download the completed app.

The app generates the following exception:

```
SqlException: Cannot open database "ContosoUniversity" requested by the login.
The login failed.
Login failed for user 'user name'.
```

Solution: Run `dotnet ef database update`

Part 5, Razor Pages with EF Core in ASP.NET Core - Data Model

9/22/2020 • 57 minutes to read • Edit Online

By Tom Dykstra and Rick Anderson

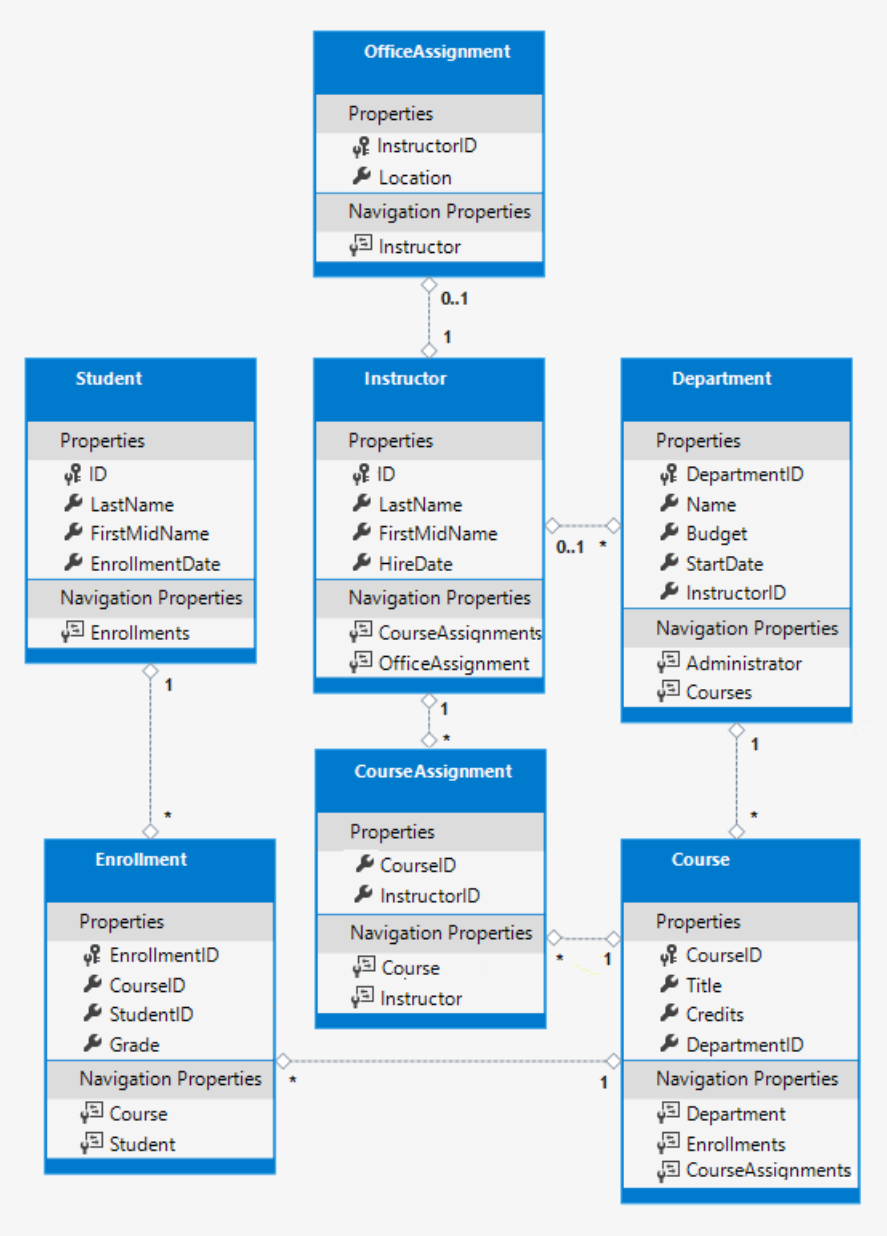
The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

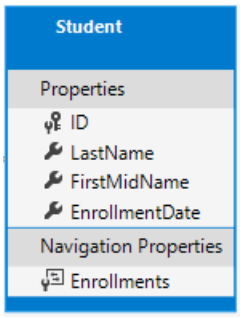
The previous tutorials worked with a basic data model that was composed of three entities. In this tutorial:

- More entities and relationships are added.
- The data model is customized by specifying formatting, validation, and database mapping rules.

The completed data model is shown in the following illustration:



The Student entity



Replace the code in *Models/Student.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The preceding code adds a `FullName` property and adds the following attributes to existing properties:

- `[DataType]`
- `[DisplayFormat]`
- `[StringLength]`
- `[Column]`
- `[Required]`
- `[Display]`

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties.

`FullName` can't be set, so it has only a get accessor. No `FullName` column is created in the database.

The DataType attribute

```
[DataType(DataType.Date)]
```

For student enrollment dates, all of the pages currently display the time of day along with the date, although only the date is relevant. By using data annotation attributes, you can make one code change that will fix the display format in every page that shows the data.

The DataType attribute specifies a data type that's more specific than the database intrinsic type. In this case only the date should be displayed, not the date and time. The DataType Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, etc. The `DataType` attribute can also enable the app to automatically provide type-specific features. For example:

- The `mailto:` link is automatically created for `DataType.EmailAddress`.
- The date selector is provided for `DataType.Date` in most browsers.

The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes. The `DataType` attributes don't provide validation.

The DisplayFormat attribute

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
```

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the date field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format. The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied to the edit UI. Some fields shouldn't use `ApplyFormatInEditMode`. For example, the currency symbol should generally not be displayed in an edit text box.

The `DisplayFormat` attribute can be used by itself. It's generally a good idea to use the `DataType` attribute with the `DisplayFormat` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen. The `DataType` attribute provides the following benefits that are not available in `DisplayFormat`:

- The browser can enable HTML5 features. For example, show a calendar control, the locale-appropriate currency symbol, email links, and client-side input validation.
- By default, the browser renders data using the correct format based on the locale.

For more information, see the <input> Tag Helper documentation.

The StringLength attribute

```
[StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
```

Data validation rules and validation error messages can be specified with attributes. The StringLength attribute specifies the minimum and maximum length of characters that are allowed in a data field. The code shown limits names to no more than 50 characters. An example that sets the minimum string length is shown later.

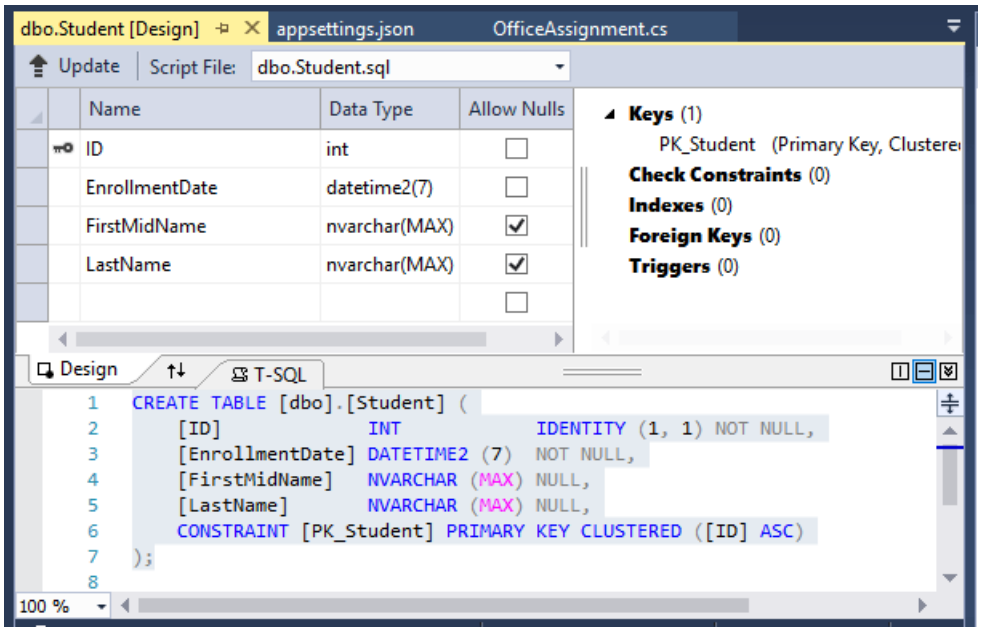
The `StringLength` attribute also provides client-side and server-side validation. The minimum value has no impact on the database schema.

The `StringLength` attribute doesn't prevent a user from entering white space for a name. The RegularExpression attribute can be used to apply restrictions to the input. For example, the following code requires the first character to be upper case and the remaining characters to be alphabetical:

```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

- Visual Studio
- Visual Studio Code

In **SQL Server Object Explorer** (SSOX), open the Student table designer by double-clicking the **Student** table.



The preceding image shows the schema for the `Student` table. The name fields have type `nvarchar(MAX)`. When a migration is created and applied later in this tutorial, the name fields become `nvarchar(50)` as a result of the string length attributes.

The Column attribute

```
[Column("FirstName")]
public string FirstMidName { get; set; }
```

Attributes can control how classes and properties are mapped to the database. In the `Student` model, the `Column` attribute is used to map the name of the `FirstMidName` property to "FirstName" in the database.

When the database is created, property names on the model are used for column names (except when the `Column` attribute is used). The `Student` model uses `FirstMidName` for the first-name field because the field might also contain a middle name.

With the `[Column]` attribute, `Student.FirstMidName` in the data model maps to the `FirstName` column of the `Student` table. The addition of the `Column` attribute changes the model backing the `SchoolContext`. The model backing the `SchoolContext` no longer matches the database. That discrepancy will be resolved by adding a migration later in this tutorial.

The Required attribute

```
[Required]
```

The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (for example, `DateTime`, `int`, and `double`). Types that can't be null are automatically treated as required fields.

The `Required` attribute must be used with `MinimumLength` for the `MinimumLength` to be enforced.

```
[Display(Name = "Last Name")]
[Required]
[StringLength(50, MinimumLength=2)]
public string LastName { get; set; }
```

`MinimumLength` and `Required` allow whitespace to satisfy the validation. Use the `RegularExpression` attribute for full control over the string.

The Display attribute

```
[Display(Name = "Last Name")]
```

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date." The default captions had no space dividing the words, for example "Lastname."

Create a migration

Run the app and go to the Students page. An exception is thrown. The `[Column]` attribute causes EF to expect to find a column named `FirstName`, but the column name in the database is still `FirstMidName`.

- Visual Studio
- Visual Studio Code

The error message is similar to the following example:

```
SqlException: Invalid column name 'FirstName'.
```

- In the PMC, enter the following commands to create a new migration and update the database:

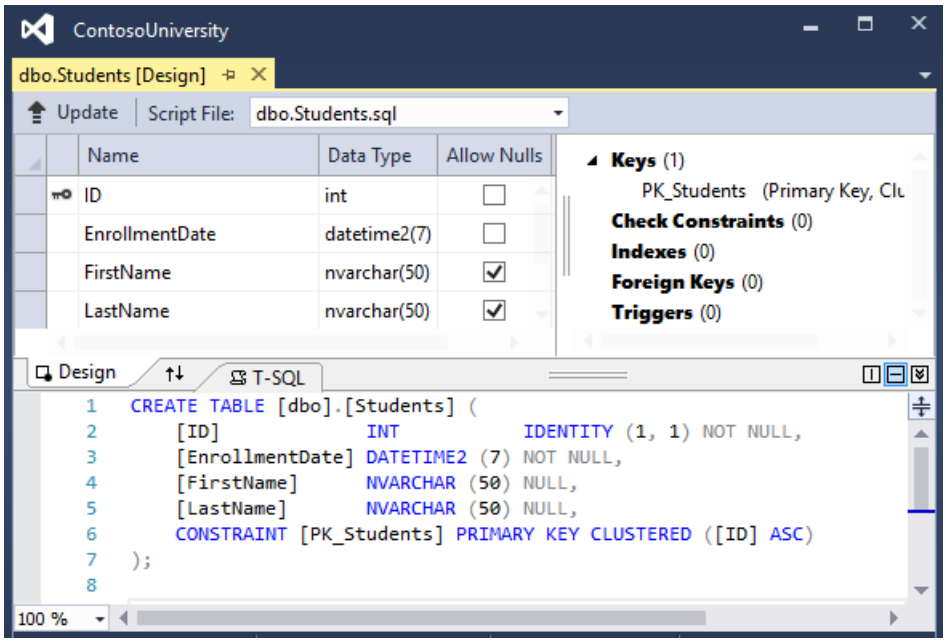
  ```
  Add-Migration ColumnFirstName
  Update-Database
  ```

  The first of these commands generates the following warning message:

  ```
  An operation was scaffolded that may result in the loss of data.
  Please review the migration for accuracy.
  ```

  The warning is generated because the name fields are now limited to 50 characters. If a name in the database had more than 50 characters, the 51 to last character would be lost.

- Open the Student table in SSOX:

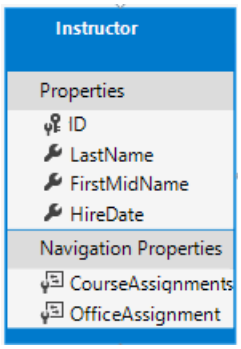


Before the migration was applied, the name columns were of type nvarchar(MAX). The name columns are now `nvarchar(50)`. The column name has changed from `FirstMidName` to `FirstName`.

- Run the app and go to the Students page.
- Notice that times are not input or displayed along with dates.
- Select **Create New**, and try to enter a name longer than 50 characters.

> **NOTE**
> In the following sections, building the app at some stages generates compiler errors. The instructions specify when to build the app.

The Instructor Entity



Create *Models/Instructor.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Multiple attributes can be on one line. The `HireDate` attributes could be written as follows:

```
[DataType(DataType.Date),Display(Name = "Hire Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

Navigation properties

The `CourseAssignments` and `OfficeAssignment` properties are navigation properties.

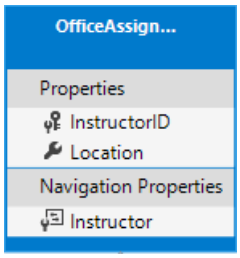
An instructor can teach any number of courses, so `CourseAssignments` is defined as a collection.

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

An instructor can have at most one office, so the `OfficeAssignment` property holds a single `OfficeAssignment` entity. `OfficeAssignment` is null if no office is assigned.

```
public OfficeAssignment OfficeAssignment { get; set; }
```

The OfficeAssignment entity



Create *Models/OfficeAssignment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public Instructor Instructor { get; set; }
    }
}
```

The Key attribute

The `[Key]` attribute is used to identify a property as the primary key (PK) when the property name is something other than classnameID or ID.

There's a one-to-zero-or-one relationship between the `Instructor` and `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to. The `OfficeAssignment` PK is also its foreign key (FK) to the `Instructor` entity.

EF Core can't automatically recognize `InstructorID` as the PK of `OfficeAssignment` because `InstructorID` doesn't follow the ID or classnameID naming convention. Therefore, the `Key` attribute is used to identify `InstructorID` as the PK:

```
[Key]
public int InstructorID { get; set; }
```

By default, EF Core treats the key as non-database-generated because the column is for an identifying relationship.

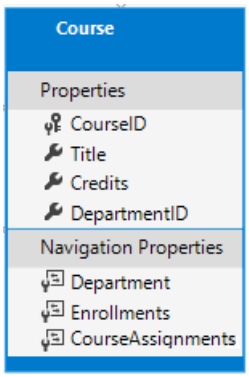
The Instructor navigation property

The `Instructor.OfficeAssignment` navigation property can be null because there might not be an `OfficeAssignment` row for a given instructor. An instructor might not have an office assignment.

The `OfficeAssignment.Instructor` navigation property will always have an instructor entity because the foreign key `InstructorID` type is `int`, a non-nullable value type. An office assignment can't exist without an instructor.

When an `Instructor` entity has a related `OfficeAssignment` entity, each entity has a reference to the other one in its navigation property.

The Course Entity



Update *Models/Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<CourseAssignment> CourseAssignments { get; set; }
    }
}
```

The `Course` entity has a foreign key (FK) property `DepartmentID`. `DepartmentID` points to the related `Department` entity. The `Course` entity has a `Department` navigation property.

EF Core doesn't require a foreign key property for a data model when the model has a navigation property for a related entity. EF Core automatically creates FKs in the database wherever they're needed. EF Core creates shadow properties for automatically created FKs. However, explicitly including the FK in the data model can make updates simpler and more efficient. For example, consider a model where the FK property `DepartmentID` is *not* included. When a course entity is fetched to edit:

- The `Department` property is null if it's not explicitly loaded.
- To update the course entity, the `Department` entity must first be fetched.

When the FK property `DepartmentID` is included in the data model, there's no need to fetch the `Department` entity before an update.

The DatabaseGenerated attribute

The `[DatabaseGenerated(DatabaseGeneratedOption.None)]` attribute specifies that the PK is provided by the application rather than generated by the database.

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, EF Core assumes that PK values are generated by the database. Database-generated is generally the best approach. For `Course` entities, the user specifies the PK. For example, a course number such as a 1000 series for the math department, a 2000 series for the English department.

The `DatabaseGenerated` attribute can also be used to generate default values. For example, the database can automatically generate a date field to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key (FK) properties and navigation properties in the `Course` entity reflect the following relationships:

A course is assigned to one department, so there's a `DepartmentID` FK and a `Department` navigation property.

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

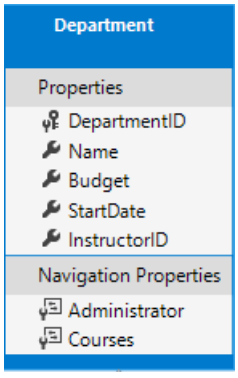
```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `CourseAssignments` navigation property is a collection:

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

`CourseAssignment` is explained later.

The Department entity



Create *Models/Department.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Previously the `Column` attribute was used to change column name mapping. In the code for the `Department` entity, the `Column` attribute is used to change SQL data type mapping. The `Budget` column is defined using the SQL Server money type in the database:

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required. EF Core chooses the appropriate SQL Server data type based on the CLR type for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. `Budget` is for currency, and the money data type is more appropriate for currency.

Foreign key and navigation properties

The FK and navigation properties reflect the following relationships:

- A department may or may not have an administrator.
- An administrator is always an instructor. Therefore the `InstructorID` property is included as the FK to the `Instructor` entity.

The navigation property is named `Administrator` but holds an `Instructor` entity:

```
public int? InstructorID { get; set; }
public Instructor Administrator { get; set; }
```

The question mark (?) in the preceding code specifies the property is nullable.

A department may have many courses, so there's a Courses navigation property:

```
public ICollection<Course> Courses { get; set; }
```

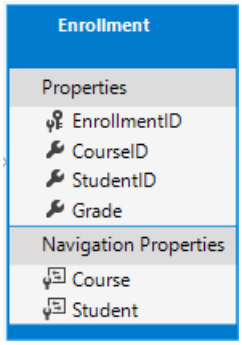
By convention, EF Core enables cascade delete for non-nullable FKs and for many-to-many relationships. This default behavior can result in circular cascade delete rules. Circular cascade delete rules cause an exception when a migration is added.

For example, if the `Department.InstructorID` property was defined as non-nullable, EF Core would configure a cascade delete rule. In that case, the department would be deleted when the instructor assigned as its administrator is deleted. In this scenario, a restrict rule would make more sense. The following fluent API would set a restrict rule and disable cascade delete.

```
modelBuilder.Entity<Department>()
   .HasOne(d => d.Administrator)
   .WithMany()
   .OnDelete(DeleteBehavior.Restrict)
```

The Enrollment entity

An enrollment record is for one course taken by one student.



Update *Models/Enrollment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

Foreign key and navigation properties

The FK properties and navigation properties reflect the following relationships:

An enrollment record is for one course, so there's a `CourseID` FK property and a `Course` navigation property:

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

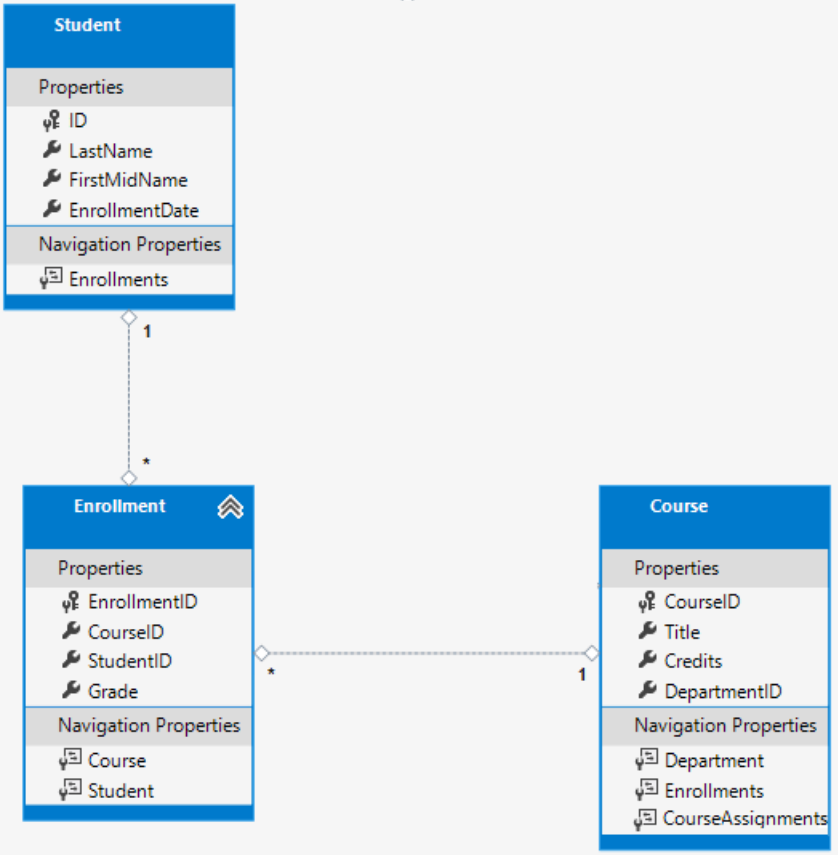
An enrollment record is for one student, so there's a `StudentID` FK property and a `Student` navigation property:

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many Relationships

There's a many-to-many relationship between the `Student` and `Course` entities. The `Enrollment` entity functions as a many-to-many join table *with payload* in the database. "With payload" means that the `Enrollment` table contains additional data besides FKs for the joined tables (in this case, the PK and `Grade`).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using EF Power Tools for EF 6.x. Creating the diagram isn't part of the tutorial.)



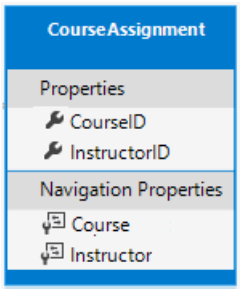
Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two FKs (`CourseID` and `StudentID`). A many-to-many join table without payload is sometimes called a pure join table (PJT).

The `Instructor` and `Course` entities have a many-to-many relationship using a pure join table.

Note: EF 6.x supports implicit join tables for many-to-many relationships, but EF Core doesn't. For more information, see Many-to-many relationships in EF Core 2.0.

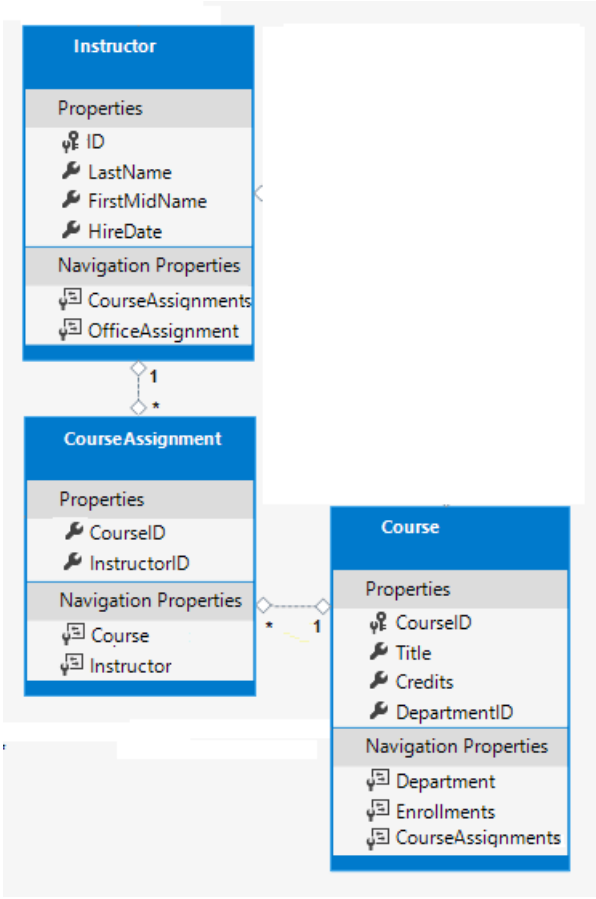
The CourseAssignment entity



Create *Models/CourseAssignment.cs* with the following code:

```
namespace ContosoUniversity.Models
{
    public class CourseAssignment
    {
        public int InstructorID { get; set; }
        public int CourseID { get; set; }
        public Instructor Instructor { get; set; }
        public Course Course { get; set; }
    }
}
```

The Instructor-to-Courses many-to-many relationship requires a join table, and the entity for that join table is CourseAssignment.



It's common to name a join entity `EntityName1EntityName2`. For example, the Instructor-to-Courses join table using this pattern would be `CourseInstructor`. However, we recommend using a name that describes the relationship.

Data models start out simple and grow. Join tables without payload (PJTs) frequently evolve to include payload. By starting with a descriptive entity name, the name doesn't need to change when the join table changes. Ideally, the join entity would have its own natural (possibly single word) name in the business domain. For example, Books and Customers could be linked with a join entity called Ratings. For the Instructor-to-Courses many-to-many

relationship, `CourseAssignment` is preferred over `CourseInstructor`.

Composite key

The two FKs in `CourseAssignment` (`InstructorID` and `CourseID`) together uniquely identify each row of the `CourseAssignment` table. `CourseAssignment` doesn't require a dedicated PK. The `InstructorID` and `CourseID` properties function as a composite PK. The only way to specify composite PKs to EF Core is with the *fluent API*. The next section shows how to configure the composite PK.

The composite key ensures that:

- Multiple rows are allowed for one course.
- Multiple rows are allowed for one instructor.
- Multiple rows aren't allowed for the same instructor and course.

The `Enrollment` join entity defines its own PK, so duplicates of this sort are possible. To prevent such duplicates:

- Add a unique index on the FK fields, or
- Configure `Enrollment` with a primary composite key similar to `CourseAssignment`. For more information, see Indexes.

Update the database context

Update *Data/SchoolContext.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>().ToTable("CourseAssignment");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

The preceding code adds the new entities and configures the `CourseAssignment` entity's composite PK.

Fluent API alternative to attributes

The `OnModelCreating` method in the preceding code uses the *fluent API* to configure EF Core behavior. The API is called "fluent" because it's often used by stringing a series of method calls together into a single statement. The following code is an example of the fluent API:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```

In this tutorial, the fluent API is used only for database mapping that can't be done with attributes. However, the fluent API can specify most of the formatting, validation, and mapping rules that can be done with attributes.

Some attributes such as `MinimumLength` can't be applied with the fluent API. `MinimumLength` doesn't change the schema, it only applies a minimum length validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." Attributes and the fluent API can be mixed. There are some configurations that can only be done with the fluent API (specifying a composite PK). There are some configurations that can only be done with attributes (`MinimumLength`). The recommended practice for using fluent API or attributes:

- Choose one of these two approaches.
- Use the chosen approach consistently as much as possible.

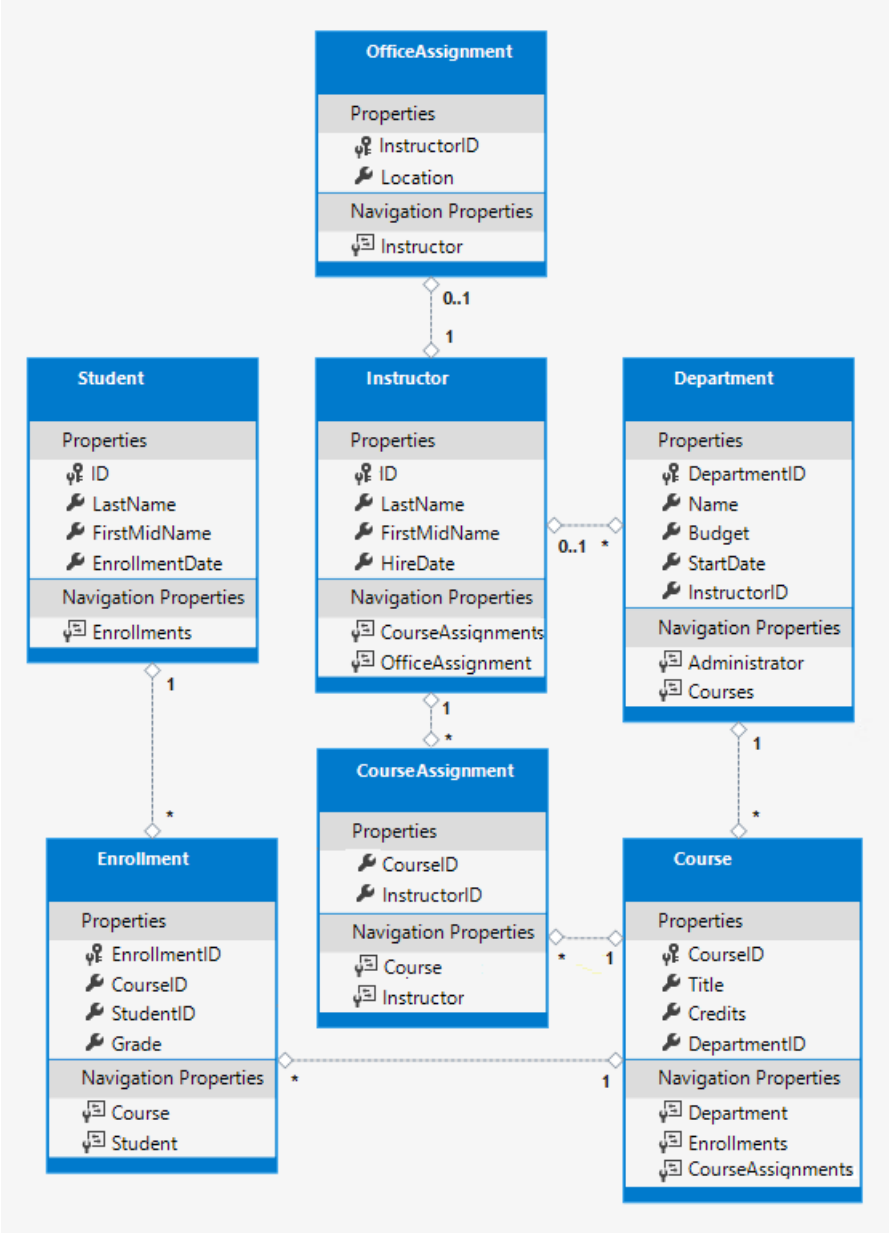
Some of the attributes used in this tutorial are used for:

- Validation only (for example, `MinimumLength`).
- EF Core configuration only (for example, `HasKey`).
- Validation and EF Core configuration (for example, `[StringLength(50)]`).

For more information about attributes vs. fluent API, see Methods of configuration.

Entity diagram

The following illustration shows the diagram that EF Power Tools create for the completed School model.



The preceding diagram shows:

- Several one-to-many relationship lines (1 to *).
- The one-to-zero-or-one relationship line (1 to 0..1) between the `Instructor` and `OfficeAssignment` entities.
- The zero-or-one-to-many relationship line (0..1 to *) between the `Instructor` and `Department` entities.

Seed the database

Update the code in *Data/DbInitializer.cs*:

```
using System;
using System.Linq;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            //context.Database.EnsureCreated();
```

```
            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new Student { FirstMidName = "Carson",   LastName = "Alexander",
                    EnrollmentDate = DateTime.Parse("2016-09-01") },
                new Student { FirstMidName = "Meredith", LastName = "Alonso",
                    EnrollmentDate = DateTime.Parse("2018-09-01") },
                new Student { FirstMidName = "Arturo",   LastName = "Anand",
                    EnrollmentDate = DateTime.Parse("2019-09-01") },
                new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                    EnrollmentDate = DateTime.Parse("2018-09-01") },
                new Student { FirstMidName = "Yan",      LastName = "Li",
                    EnrollmentDate = DateTime.Parse("2018-09-01") },
                new Student { FirstMidName = "Peggy",    LastName = "Justice",
                    EnrollmentDate = DateTime.Parse("2017-09-01") },
                new Student { FirstMidName = "Laura",    LastName = "Norman",
                    EnrollmentDate = DateTime.Parse("2019-09-01") },
                new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                    EnrollmentDate = DateTime.Parse("2011-09-01") }
            };

            context.Students.AddRange(students);
            context.SaveChanges();

            var instructors = new Instructor[]
            {
                new Instructor { FirstMidName = "Kim",     LastName = "Abercrombie",
                    HireDate = DateTime.Parse("1995-03-11") },
                new Instructor { FirstMidName = "Fadi",    LastName = "Fakhouri",
                    HireDate = DateTime.Parse("2002-07-06") },
                new Instructor { FirstMidName = "Roger",   LastName = "Harui",
                    HireDate = DateTime.Parse("1998-07-01") },
                new Instructor { FirstMidName = "Candace", LastName = "Kapoor",
                    HireDate = DateTime.Parse("2001-01-15") },
                new Instructor { FirstMidName = "Roger",   LastName = "Zheng",
                    HireDate = DateTime.Parse("2004-02-12") }
            };

            context.Instructors.AddRange(instructors);
            context.SaveChanges();

            var departments = new Department[]
            {
                new Department { Name = "English",     Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Abercrombie").ID },
                new Department { Name = "Mathematics", Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Fakhouri").ID },
                new Department { Name = "Engineering", Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Harui").ID },
                new Department { Name = "Economics",   Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Kapoor").ID }
            };

            context.Departments.AddRange(departments);
            context.SaveChanges();

            var courses = new Course[]
            {
                new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3,
                    DepartmentID = departments.Single( s => s.Name == "Engineering").DepartmentID
```

```
        },
        new Course {CourseID = 4022, Title = "Microeconomics", Credits = 3,
            DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID
        },
        new Course {CourseID = 4041, Title = "Macroeconomics", Credits = 3,
            DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID
        },
        new Course {CourseID = 1045, Title = "Calculus",       Credits = 4,
            DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID
        },
        new Course {CourseID = 3141, Title = "Trigonometry",   Credits = 4,
            DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID
        },
        new Course {CourseID = 2021, Title = "Composition",    Credits = 3,
            DepartmentID = departments.Single( s => s.Name == "English").DepartmentID
        },
        new Course {CourseID = 2042, Title = "Literature",     Credits = 4,
            DepartmentID = departments.Single( s => s.Name == "English").DepartmentID
        },
    };

    context.Courses.AddRange(courses);
    context.SaveChanges();

    var officeAssignments = new OfficeAssignment[]
    {
        new OfficeAssignment {
            InstructorID = instructors.Single( i => i.LastName == "Fakhouri").ID,
            Location = "Smith 17" },
        new OfficeAssignment {
            InstructorID = instructors.Single( i => i.LastName == "Harui").ID,
            Location = "Gowan 27" },
        new OfficeAssignment {
            InstructorID = instructors.Single( i => i.LastName == "Kapoor").ID,
            Location = "Thompson 304" },
    };

    context.OfficeAssignments.AddRange(officeAssignments);
    context.SaveChanges();

    var courseInstructors = new CourseAssignment[]
    {
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Kapoor").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Harui").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Zheng").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Zheng").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Fakhouri").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Harui").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Abercrombie").ID
```

```
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Literature" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Abercrombie").ID
            },
    };

    context.CourseAssignments.AddRange(courseInstructors);
    context.SaveChanges();

    var enrollments = new Enrollment[]
    {
        new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alexander").ID,
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
            Grade = Grade.A
        },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alexander").ID,
            CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
            Grade = Grade.C
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alexander").ID,
            CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Anand").ID,
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Anand").ID,
            CourseID = courses.Single(c => c.Title == "Microeconomics").CourseID,
            Grade = Grade.B
            },
        new Enrollment {
            StudentID = students.Single(s => s.LastName == "Barzdukas").ID,
            CourseID = courses.Single(c => c.Title == "Chemistry").CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Li").ID,
            CourseID = courses.Single(c => c.Title == "Composition").CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Justice").ID,
            CourseID = courses.Single(c => c.Title == "Literature").CourseID,
            Grade = Grade.B
            }
    };

    foreach (Enrollment e in enrollments)
```

```
            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollments.Where(
                    s =>
                            s.Student.ID == e.StudentID &&
                            s.Course.CourseID == e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
                    context.Enrollments.Add(e);
                }
            }
            context.SaveChanges();
        }
    }
}
```

The preceding code provides seed data for the new entities. Most of this code creates new entity objects and loads sample data. The sample data is used for testing. See `Enrollments` and `CourseAssignments` for examples of how many-to-many join tables can be seeded.

Add a migration

Build the project.

- Visual Studio
- Visual Studio Code

In PMC, run the following command.

```
Add-Migration ComplexDataModel
```

The preceding command displays a warning about possible data loss.

```
An operation was scaffolded that may result in the loss of data.
Please review the migration for accuracy.
To undo this action, use 'ef migrations remove'
```

If the `database update` command is run, the following error is produced:

```
The ALTER TABLE statement conflicted with the FOREIGN KEY constraint
"FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in
database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.
```

In the next section, you see what to do about this error.

Apply the migration or drop and re-create

Now that you have an existing database, you need to think about how to apply changes to it. This tutorial shows two alternatives:

- Drop and re-create the database. Choose this section if you're using SQLite.
- Apply the migration to the existing database. The instructions in this section work for SQL Server only, **not for SQLite**.

Either choice works for SQL Server. While the apply-migration method is more complex and time-consuming, it's the preferred approach for real-world, production environments.

Drop and re-create the database

Skip this section if you're using SQL Server and want to do the apply-migration approach in the following section.

To force EF Core to create a new database, drop and update the database:

- Visual Studio
- Visual Studio Code

- In the **Package Manager Console** (PMC), run the following command:

```
Drop-Database
```

- Delete the *Migrations* folder, then run the following command:

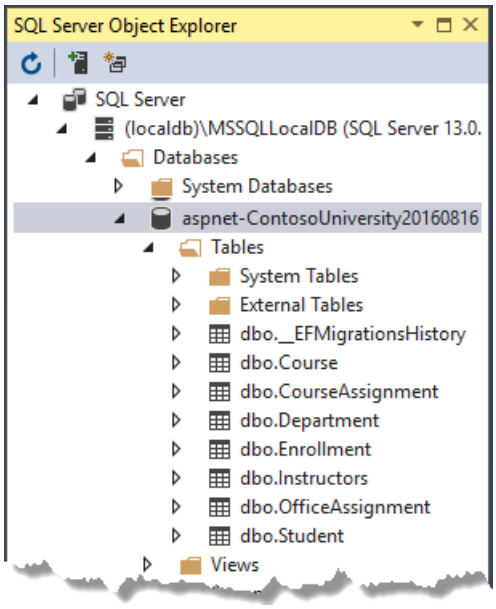
```
Add-Migration InitialCreate
Update-Database
```

Run the app. Running the app runs the `DbInitializer.Initialize` method. The `DbInitializer.Initialize` populates the new database.

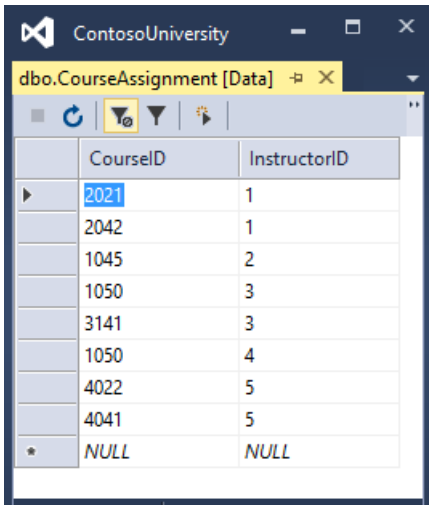
- Visual Studio
- Visual Studio Code

Open the database in SSOX:

- If SSOX was opened previously, click the **Refresh** button.
- Expand the **Tables** node. The created tables are displayed.



- Examine the **CourseAssignment** table:
  - Right-click the **CourseAssignment** table and select **View Data**.
  - Verify the **CourseAssignment** table contains data.



Apply the migration

This section is optional. These steps work only for SQL Server LocalDB and only if you skipped the preceding Drop and re-create the database section.

When migrations are run with existing data, there may be FK constraints that are not satisfied with the existing data. With production data, steps must be taken to migrate the existing data. This section provides an example of fixing FK constraint violations. Don't make these code changes without a backup. Don't make these code changes if you completed the preceding Drop and re-create the database section.

The *{timestamp}_ComplexDataModel.cs* file contains the following code:

```
migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    type: "int",
    nullable: false,
    defaultValue: 0);
```

The preceding code adds a non-nullable `DepartmentID` FK to the `Course` table. The database from the previous tutorial contains rows in `Course`, so that table cannot be updated by migrations.

To make the `ComplexDataModel` migration work with existing data:

- Change the code to give the new column (`DepartmentID`) a default value.
- Create a fake department named "Temp" to act as the default department.

Fix the foreign key constraints

In the `ComplexDataModel` migration class, update the `Up` method:

- Open the *{timestamp}_ComplexDataModel.cs* file.
- Comment out the line of code that adds the `DepartmentID` column to the `Course` table.

```
migrationBuilder.AlterColumn<string>(
    name: "Title",
    table: "Course",
    maxLength: 50,
    nullable: true,
    oldClrType: typeof(string),
    oldNullable: true);

//migrationBuilder.AddColumn<int>(
//    name: "DepartmentID",
//    table: "Course",
//    nullable: false,
//    defaultValue: 0);
```

Add the following highlighted code. The new code goes after the `.CreateTable( name: "Department"` block:

```
migrationBuilder.CreateTable(
    name: "Department",
    columns: table => new
    {
        DepartmentID = table.Column<int>(type: "int", nullable: false)
            .Annotation("SqlServer:ValueGenerationStrategy", SqlServerValueGenerationStrategy.IdentityColumn),
        Budget = table.Column<decimal>(type: "money", nullable: false),
        InstructorID = table.Column<int>(type: "int", nullable: true),
        Name = table.Column<string>(type: "nvarchar(50)", maxLength: 50, nullable: true),
        StartDate = table.Column<DateTime>(type: "datetime2", nullable: false)
    },
    constraints: table =>
    {
        table.PrimaryKey("PK_Department", x => x.DepartmentID);
        table.ForeignKey(
            name: "FK_Department_Instructor_InstructorID",
            column: x => x.InstructorID,
            principalTable: "Instructor",
            principalColumn: "ID",
            onDelete: ReferentialAction.Restrict);
    });

 migrationBuilder.Sql("INSERT INTO dbo.Department (Name, Budget, StartDate) VALUES ('Temp', 0.00, GETDATE())");
// Default value for FK points to department created above, with
// defaultValue changed to 1 in following AddColumn statement.

migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    nullable: false,
    defaultValue: 1);
```

With the preceding changes, existing `Course` rows will be related to the "Temp" department after the `ComplexDataModel.Up` method runs.

The way of handling the situation shown here is simplified for this tutorial. A production app would:

- Include code or scripts to add `Department` rows and related `Course` rows to the new `Department` rows.
- Not use the "Temp" department or the default value for `Course.DepartmentID`.

- Visual Studio
- Visual Studio Code

- In the **Package Manager Console** (PMC), run the following command:

```
Update-Database
```

Because the `DbInitializer.Initialize` method is designed to work only with an empty database, use SSOX to delete all the rows in the Student and Course tables. (Cascade delete will take care of the Enrollment table.)

Run the app. Running the app runs the `DbInitializer.Initialize` method. The `DbInitializer.Initialize` populates the new database.

Next steps

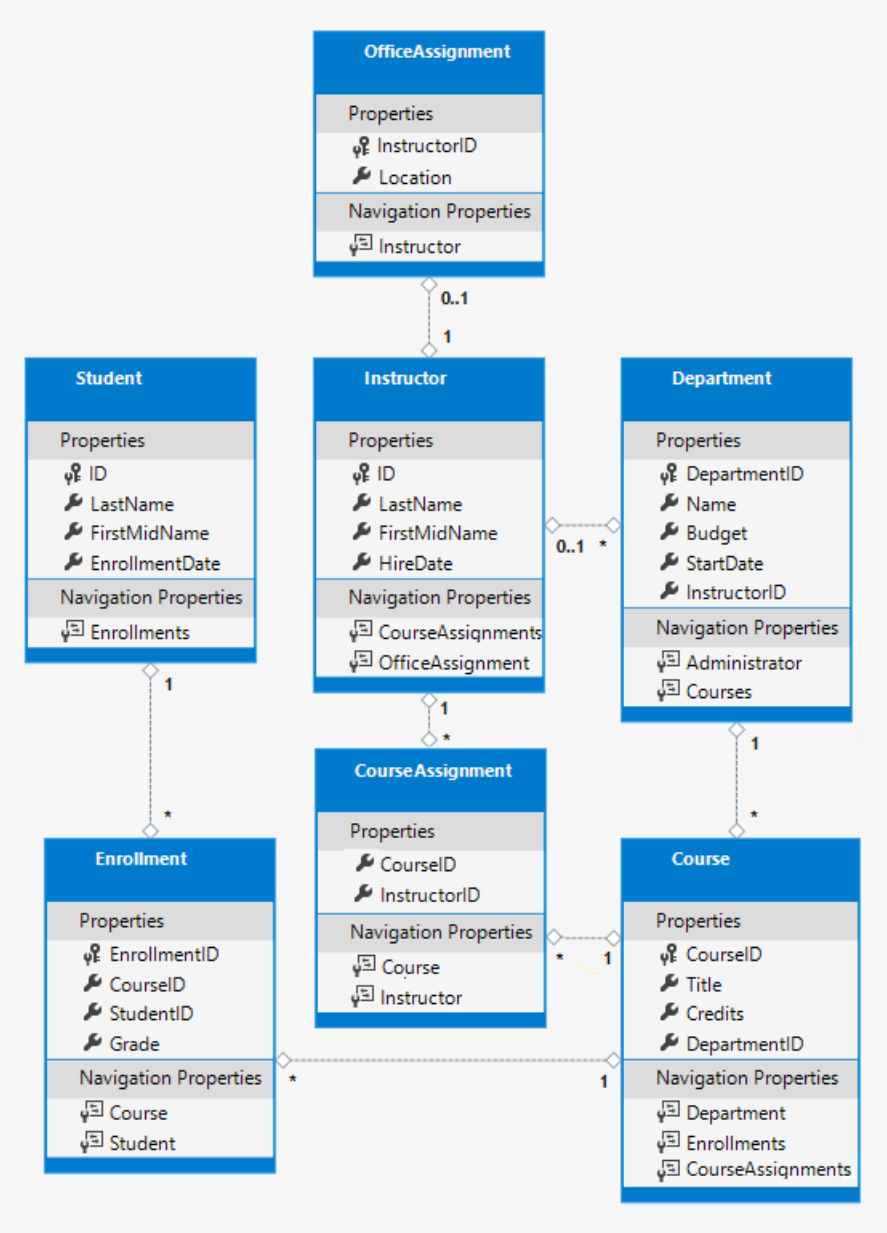
The next two tutorials show how to read and update related data.

PREVIOUS TUTORIAL NEXT TUTORIAL

The previous tutorials worked with a basic data model that was composed of three entities. In this tutorial:

- More entities and relationships are added.
- The data model is customized by specifying formatting, validation, and database mapping rules.

The entity classes for the completed data model are shown in the following illustration:



If you run into problems you can't solve, download the completed app.

Customize the data model with attributes

In this section, the data model is customized using attributes.

The DataType attribute

The student pages currently displays the time of the enrollment date. Typically, date fields show only the date and not the time.

Update *Models/Student.cs* with the following highlighted code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The DataType attribute specifies a data type that's more specific than the database intrinsic type. In this case only the date should be displayed, not the date and time. The DataType Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, etc. The `DataType` attribute can also enable the app to automatically provide type-specific features. For example:

- The `mailto:` link is automatically created for `DataType.EmailAddress`.
- The date selector is provided for `DataType.Date` in most browsers.

The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers consume. The `DataType` attributes don't provide validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the date field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
```

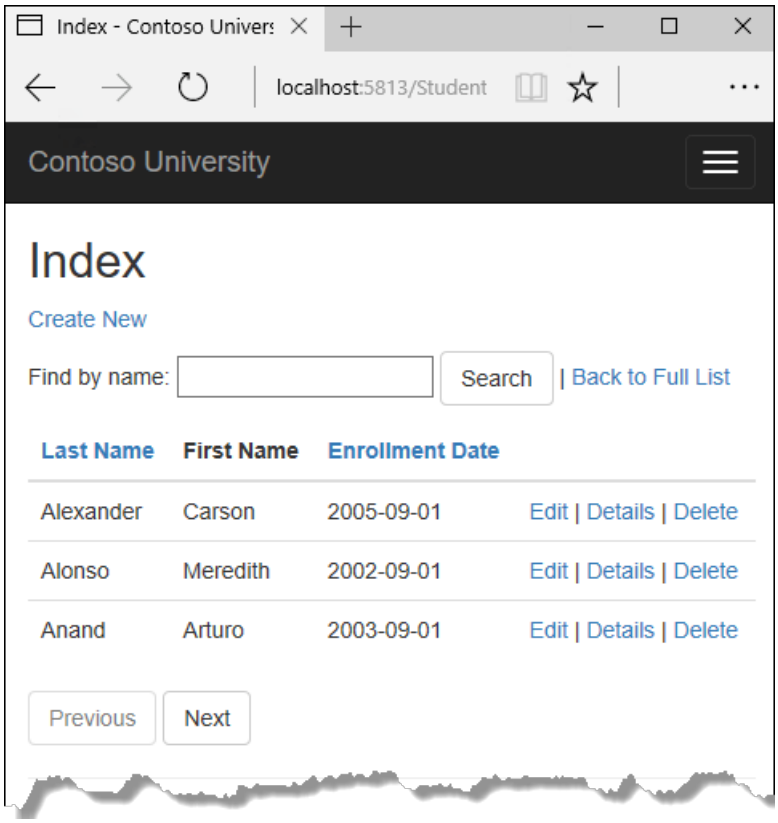
The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied to the edit UI. Some fields shouldn't use `ApplyFormatInEditMode`. For example, the currency symbol should generally not be displayed in an edit text box.

The `DisplayFormat` attribute can be used by itself. It's generally a good idea to use the `DataType` attribute with the `DisplayFormat` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen. The `DataType` attribute provides the following benefits that are not available in `DisplayFormat`:

- The browser can enable HTML5 features. For example, show a calendar control, the locale-appropriate currency symbol, email links, client-side input validation, etc.
- By default, the browser renders data using the correct format based on the locale.

For more information, see the <input> Tag Helper documentation.

Run the app. Navigate to the Students Index page. Times are no longer displayed. Every view that uses the `Student` model displays the date without time.



The StringLength attribute

Data validation rules and validation error messages can be specified with attributes. The StringLength attribute specifies the minimum and maximum length of characters that are allowed in a data field. The `StringLength` attribute also provides client-side and server-side validation. The minimum value has no impact on the database schema.

Update the `Student` model with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

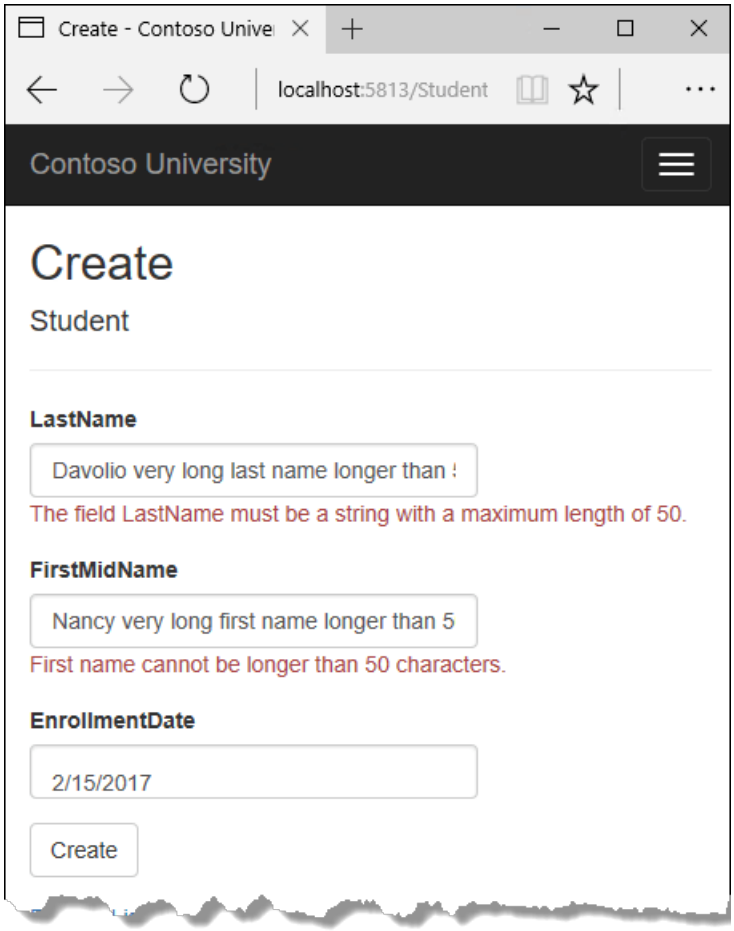
        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The preceding code limits names to no more than 50 characters. The `StringLength` attribute doesn't prevent a user from entering white space for a name. The RegularExpression attribute is used to apply restrictions to the input. For example, the following code requires the first character to be upper case and the remaining characters to be alphabetical:

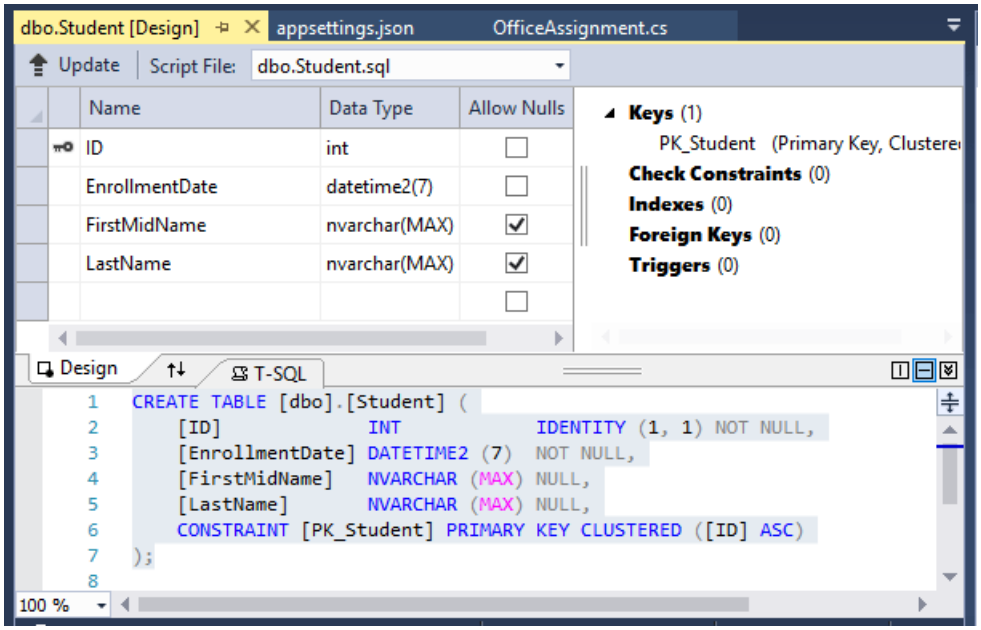
```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

Run the app:

- Navigate to the Students page.
- Select **Create New**, and enter a name longer than 50 characters.
- Select **Create**, client-side validation shows an error message.



In **SQL Server Object Explorer** (SSOX), open the Student table designer by double-clicking the **Student** table.



The preceding image shows the schema for the `Student` table. The name fields have type `nvarchar(MAX)` because migrations has not been run on the DB. When migrations are run later in this tutorial, the name fields become

`nvarchar(50)`.

The Column attribute

Attributes can control how classes and properties are mapped to the database. In this section, the `Column` attribute is used to map the name of the `FirstMidName` property to "FirstName" in the DB.

When the DB is created, property names on the model are used for column names (except when the `Column` attribute is used).

The `Student` model uses `FirstMidName` for the first-name field because the field might also contain a middle name.

Update the *Student.cs* file with the following highlighted code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

With the preceding change, `Student.FirstMidName` in the app maps to the `FirstName` column of the `Student` table.

The addition of the `Column` attribute changes the model backing the `SchoolContext`. The model backing the `SchoolContext` no longer matches the database. If the app is run before applying migrations, the following exception is generated:

```
SqlException: Invalid column name 'FirstName'.
```

To update the DB:

- Build the project.
- Open a command window in the project folder. Enter the following commands to create a new migration and update the DB:

- Visual Studio
- Visual Studio Code

```
Add-Migration ColumnFirstName
Update-Database
```

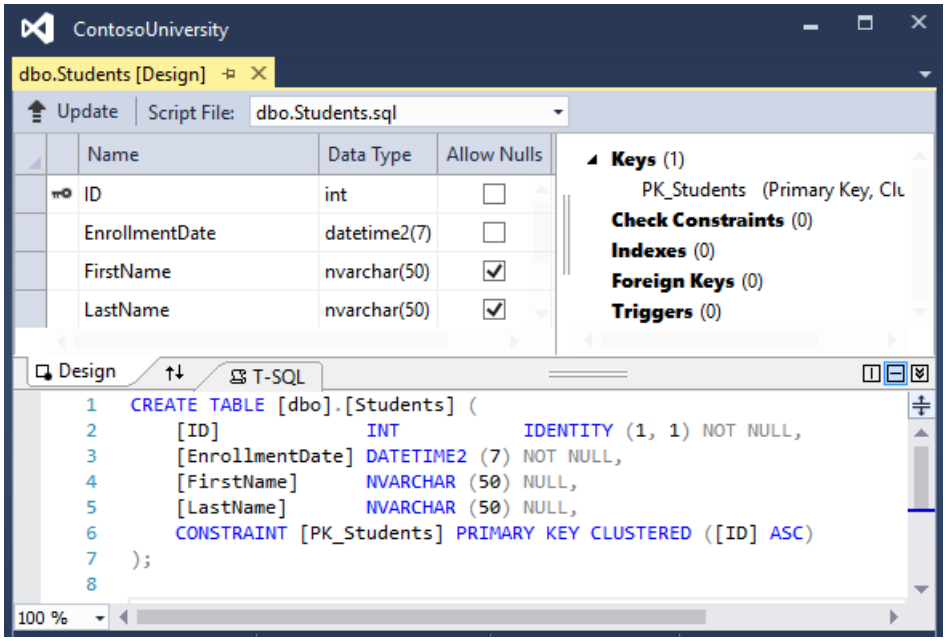
The `migrations add ColumnFirstName` command generates the following warning message:

```
An operation was scaffolded that may result in the loss of data.
Please review the migration for accuracy.
```

The warning is generated because the name fields are now limited to 50 characters. If a name in the DB had more than 50 characters, the 51 to last character would be lost.

- Test the app.

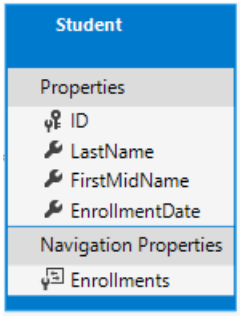
Open the Student table in SSOX:



Before migration was applied, the name columns were of type nvarchar(MAX). The name columns are now `nvarchar(50)`. The column name has changed from `FirstMidName` to `FirstName`.

> **NOTE**
> In the following section, building the app at some stages generates compiler errors. The instructions specify when to build the app.

Student entity update



Update *Models/Student.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The Required attribute

The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (`DateTime` , `int` , `double` , etc.). Types that can't be null are automatically treated as required fields.

The `Required` attribute could be replaced with a minimum length parameter in the `StringLength` attribute:

```
[Display(Name = "Last Name")]
[StringLength(50, MinimumLength=1)]
public string LastName { get; set; }
```

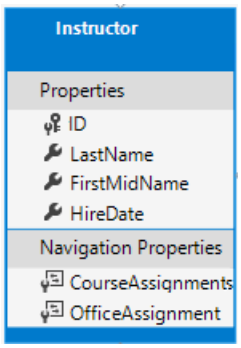
The Display attribute

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date." The default captions had no space dividing the words, for example "Lastname."

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. `FullName` cannot be set, it has only a get accessor. No `FullName` column is created in the database.

Create the Instructor Entity



Create *Models/Instructor.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Multiple attributes can be on one line. The `HireDate` attributes could be written as follows:

```
[DataType(DataType.Date),Display(Name = "Hire Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

The CourseAssignments and OfficeAssignment navigation properties

The `CourseAssignments` and `OfficeAssignment` properties are navigation properties.

An instructor can teach any number of courses, so `CourseAssignments` is defined as a collection.

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

If a navigation property holds multiple entities:

- It must be a list type where the entries can be added, deleted, and updated.

Navigation property types include:

- `ICollection<T>`
- `List<T>`
- `HashSet<T>`

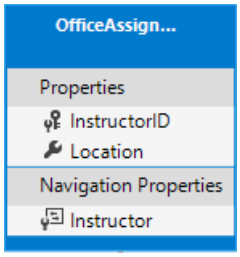
If `ICollection<T>` is specified, EF Core creates a `HashSet<T>` collection by default.

The `CourseAssignment` entity is explained in the section on many-to-many relationships.

Contoso University business rules state that an instructor can have at most one office. The `OfficeAssignment` property holds a single `OfficeAssignment` entity. `OfficeAssignment` is null if no office is assigned.

```
public OfficeAssignment OfficeAssignment { get; set; }
```

Create the OfficeAssignment entity



Create *Models/OfficeAssignment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public Instructor Instructor { get; set; }
    }
}
```

The Key attribute

The `[Key]` attribute is used to identify a property as the primary key (PK) when the property name is something other than classnameID or ID.

There's a one-to-zero-or-one relationship between the `Instructor` and `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to. The `OfficeAssignment` PK is also its foreign key

(FK) to the `Instructor` entity. EF Core can't automatically recognize `InstructorID` as the PK of `OfficeAssignment` because:

- `InstructorID` doesn't follow the ID or classnameID naming convention.

Therefore, the `Key` attribute is used to identify `InstructorID` as the PK:

```
[Key]
public int InstructorID { get; set; }
```

By default, EF Core treats the key as non-database-generated because the column is for an identifying relationship.

The Instructor navigation property

The `OfficeAssignment` navigation property for the `Instructor` entity is nullable because:

- Reference types (such as classes are nullable).
- An instructor might not have an office assignment.

The `OfficeAssignment` entity has a non-nullable `Instructor` navigation property because:

- `InstructorID` is non-nullable.
- An office assignment can't exist without an instructor.

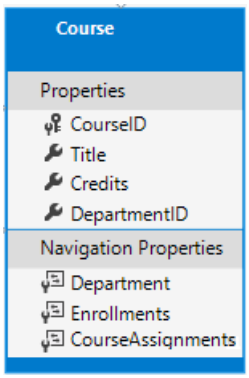
When an `Instructor` entity has a related `OfficeAssignment` entity, each entity has a reference to the other one in its navigation property.

The `[Required]` attribute could be applied to the `Instructor` navigation property:

```
[Required]
public Instructor Instructor { get; set; }
```

The preceding code specifies that there must be a related instructor. The preceding code is unnecessary because the `InstructorID` foreign key (which is also the PK) is non-nullable.

Modify the Course Entity



Update *Models/Course.cs* with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<CourseAssignment> CourseAssignments { get; set; }
    }
}
```

The `Course` entity has a foreign key (FK) property `DepartmentID`. `DepartmentID` points to the related `Department` entity. The `Course` entity has a `Department` navigation property.

EF Core doesn't require a FK property for a data model when the model has a navigation property for a related entity.

EF Core automatically creates FKs in the database wherever they're needed. EF Core creates shadow properties for automatically created FKs. Having the FK in the data model can make updates simpler and more efficient. For example, consider a model where the FK property `DepartmentID` is *not* included. When a course entity is fetched to edit:

- The `Department` entity is null if it's not explicitly loaded.
- To update the course entity, the `Department` entity must first be fetched.

When the FK property `DepartmentID` is included in the data model, there's no need to fetch the `Department` entity before an update.

The DatabaseGenerated attribute

The `[DatabaseGenerated(DatabaseGeneratedOption.None)]` attribute specifies that the PK is provided by the application rather than generated by the database.

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, EF Core assumes that PK values are generated by the DB. DB generated PK values is generally the best approach. For `Course` entities, the user specifies the PK. For example, a course number such as a 1000 series for the math department, a 2000 series for the English department.

The `DatabaseGenerated` attribute can also be used to generate default values. For example, the DB can automatically generate a date field to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key (FK) properties and navigation properties in the `Course` entity reflect the following relationships:

A course is assigned to one department, so there's a `DepartmentID` FK and a `Department` navigation property.

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

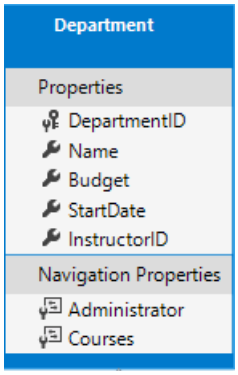
```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `CourseAssignments` navigation property is a collection:

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

`CourseAssignment` is explained later.

Create the Department entity



Create *Models/Department.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Previously the `Column` attribute was used to change column name mapping. In the code for the `Department` entity, the `Column` attribute is used to change SQL data type mapping. The `Budget` column is defined using the SQL Server money type in the DB:

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required. EF Core generally chooses the appropriate SQL Server data type based on the CLR type for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. `Budget` is for currency, and the money data type is more appropriate for currency.

Foreign key and navigation properties

The FK and navigation properties reflect the following relationships:

- A department may or may not have an administrator.
- An administrator is always an instructor. Therefore the `InstructorID` property is included as the FK to the `Instructor` entity.

The navigation property is named `Administrator` but holds an `Instructor` entity:

```
public int? InstructorID { get; set; }
public Instructor Administrator { get; set; }
```

The question mark (?) in the preceding code specifies the property is nullable.

A department may have many courses, so there's a Courses navigation property:

```
public ICollection<Course> Courses { get; set; }
```

Note: By convention, EF Core enables cascade delete for non-nullable FKs and for many-to-many relationships. Cascading delete can result in circular cascade delete rules. Circular cascade delete rules causes an exception when a migration is added.

For example, if the `Department.InstructorID` property was defined as non-nullable:

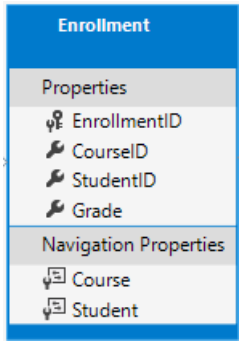
- EF Core configures a cascade delete rule to delete the department when the instructor is deleted.
- Deleting the department when the instructor is deleted isn't the intended behavior.
- The following fluent API would set a restrict rule instead of cascade.

```
modelBuilder.Entity<Department>()
    .HasOne(d => d.Administrator)
    .WithMany()
    .OnDelete(DeleteBehavior.Restrict)
```

The preceding code disables cascade delete on the department-instructor relationship.

Update the Enrollment entity

An enrollment record is for one course taken by one student.



Update *Models/Enrollment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

Foreign key and navigation properties

The FK properties and navigation properties reflect the following relationships:

An enrollment record is for one course, so there's a `CourseID` FK property and a `Course` navigation property:

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

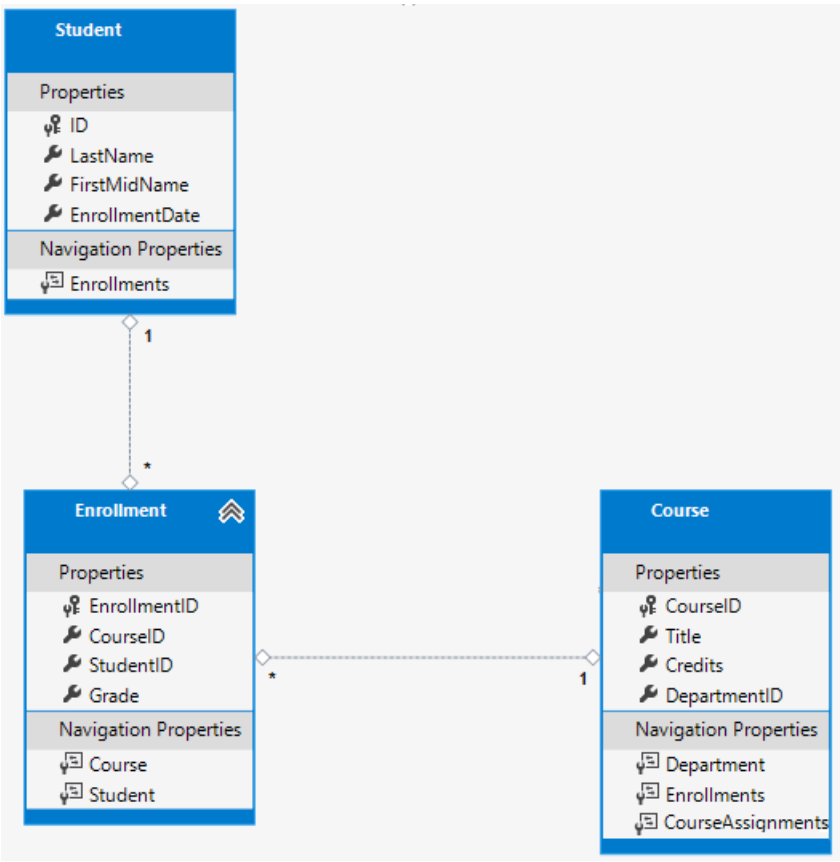
An enrollment record is for one student, so there's a `StudentID` FK property and a `Student` navigation property:

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many Relationships

There's a many-to-many relationship between the `Student` and `Course` entities. The `Enrollment` entity functions as a many-to-many join table *with payload* in the database. "With payload" means that the `Enrollment` table contains additional data besides FKs for the joined tables (in this case, the PK and `Grade`).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using EF Power Tools for EF 6.x. Creating the diagram isn't part of the tutorial.)



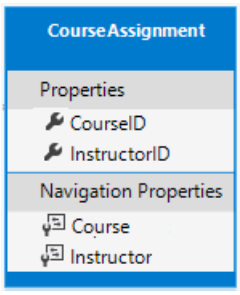
Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two FKs (`CourseID` and `StudentID`). A many-to-many join table without payload is sometimes called a pure join table (PJT).

The `Instructor` and `Course` entities have a many-to-many relationship using a pure join table.

Note: EF 6.x supports implicit join tables for many-to-many relationships, but EF Core doesn't. For more information, see Many-to-many relationships in EF Core 2.0.

The CourseAssignment entity

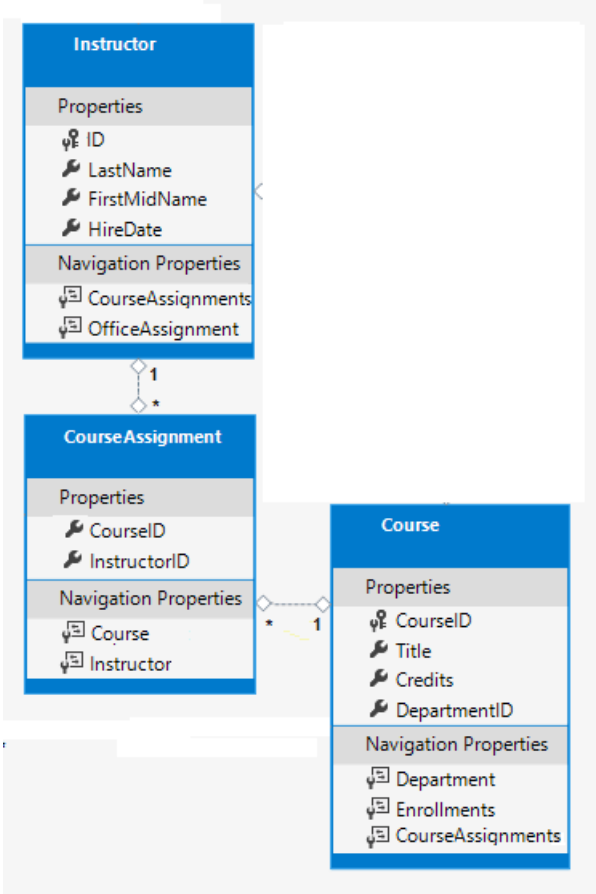


Create *Models/CourseAssignment.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class CourseAssignment
    {
        public int InstructorID { get; set; }
        public int CourseID { get; set; }
        public Instructor Instructor { get; set; }
        public Course Course { get; set; }
    }
}
```

Instructor-to-Courses



The Instructor-to-Courses many-to-many relationship:

- Requires a join table that must be represented by an entity set.
- Is a pure join table (table without payload).

It's common to name a join entity `EntityName1EntityName2`. For example, the Instructor-to-Courses join table using this pattern is `CourseInstructor`. However, we recommend using a name that describes the relationship.

Data models start out simple and grow. No-payload joins (PJTs) frequently evolve to include payload. By starting with a descriptive entity name, the name doesn't need to change when the join table changes. Ideally, the join entity would have its own natural (possibly single word) name in the business domain. For example, Books and Customers could be linked with a join entity called Ratings. For the Instructor-to-Courses many-to-many relationship, `CourseAssignment` is preferred over `CourseInstructor`.

Composite key

FKs are not nullable. The two FKs in `CourseAssignment` (`InstructorID` and `CourseID`) together uniquely identify each row of the `CourseAssignment` table. `CourseAssignment` doesn't require a dedicated PK. The `InstructorID` and `CourseID` properties function as a composite PK. The only way to specify composite PKs to EF Core is with the *fluent API*. The next section shows how to configure the composite PK.

The composite key ensures:

- Multiple rows are allowed for one course.
- Multiple rows are allowed for one instructor.
- Multiple rows for the same instructor and course isn't allowed.

The `Enrollment` join entity defines its own PK, so duplicates of this sort are possible. To prevent such duplicates:

- Add a unique index on the FK fields, or
- Configure `Enrollment` with a primary composite key similar to `CourseAssignment`. For more information, see Indexes.

Update the DB context

Add the following highlighted code to *Data/SchoolContext.cs*:

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Models
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollment { get; set; }
        public DbSet<Student> Student { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>().ToTable("CourseAssignment");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

The preceding code adds the new entities and configures the `CourseAssignment` entity's composite PK.

Fluent API alternative to attributes

The `OnModelCreating` method in the preceding code uses the *fluent API* to configure EF Core behavior. The API is

called "fluent" because it's often used by stringing a series of method calls together into a single statement. The following code is an example of the fluent API:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```

In this tutorial, the fluent API is used only for DB mapping that can't be done with attributes. However, the fluent API can specify most of the formatting, validation, and mapping rules that can be done with attributes.

Some attributes such as `MinimumLength` can't be applied with the fluent API. `MinimumLength` doesn't change the schema, it only applies a minimum length validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." Attributes and the fluent API can be mixed. There are some configurations that can only be done with the fluent API (specifying a composite PK). There are some configurations that can only be done with attributes (`MinimumLength`). The recommended practice for using fluent API or attributes:

- Choose one of these two approaches.
- Use the chosen approach consistently as much as possible.

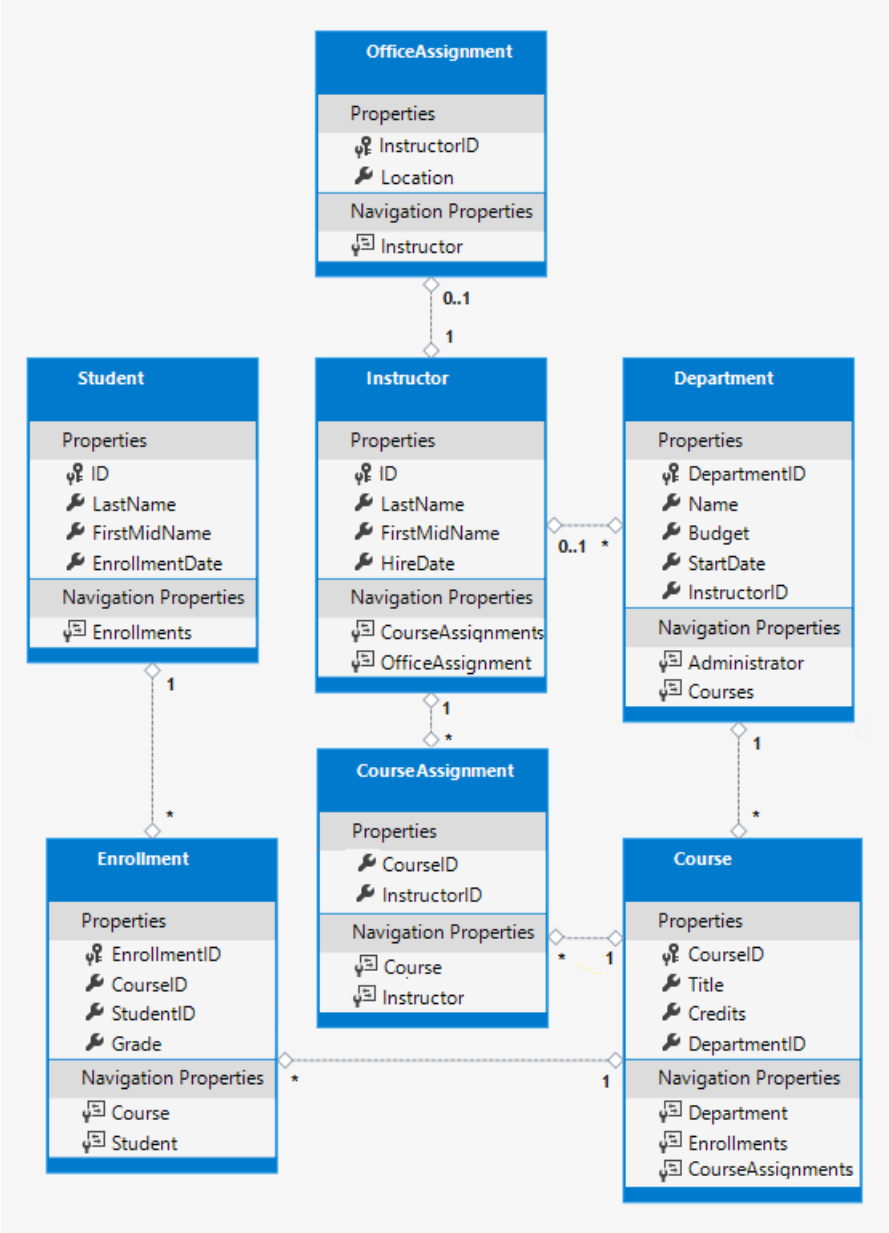
Some of the attributes used in the this tutorial are used for:

- Validation only (for example, `MinimumLength`).
- EF Core configuration only (for example, `HasKey`).
- Validation and EF Core configuration (for example, `[StringLength(50)]`).

For more information about attributes vs. fluent API, see Methods of configuration.

Entity Diagram Showing Relationships

The following illustration shows the diagram that EF Power Tools create for the completed School model.



The preceding diagram shows:

- Several one-to-many relationship lines (1 to *).
- The one-to-zero-or-one relationship line (1 to 0..1) between the `Instructor` and `OfficeAssignment` entities.
- The zero-or-one-to-many relationship line (0..1 to *) between the `Instructor` and `Department` entities.

Seed the DB with Test Data

Update the code in *Data/DbInitializer.cs*:

```
using System;
using System.Linq;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            //context.Database.EnsureCreated();
```

```
            // Look for any students.
            if (context.Student.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new Student { FirstMidName = "Carson",   LastName = "Alexander",
                    EnrollmentDate = DateTime.Parse("2010-09-01") },
                new Student { FirstMidName = "Meredith", LastName = "Alonso",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Arturo",   LastName = "Anand",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Yan",      LastName = "Li",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Peggy",    LastName = "Justice",
                    EnrollmentDate = DateTime.Parse("2011-09-01") },
                new Student { FirstMidName = "Laura",    LastName = "Norman",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                    EnrollmentDate = DateTime.Parse("2005-09-01") }
            };

            foreach (Student s in students)
            {
                context.Student.Add(s);
            }
            context.SaveChanges();

            var instructors = new Instructor[]
            {
                new Instructor { FirstMidName = "Kim",     LastName = "Abercrombie",
                    HireDate = DateTime.Parse("1995-03-11") },
                new Instructor { FirstMidName = "Fadi",    LastName = "Fakhouri",
                    HireDate = DateTime.Parse("2002-07-06") },
                new Instructor { FirstMidName = "Roger",   LastName = "Harui",
                    HireDate = DateTime.Parse("1998-07-01") },
                new Instructor { FirstMidName = "Candace", LastName = "Kapoor",
                    HireDate = DateTime.Parse("2001-01-15") },
                new Instructor { FirstMidName = "Roger",   LastName = "Zheng",
                    HireDate = DateTime.Parse("2004-02-12") }
            };

            foreach (Instructor i in instructors)
            {
                context.Instructors.Add(i);
            }
            context.SaveChanges();

            var departments = new Department[]
            {
                new Department { Name = "English",     Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Abercrombie").ID },
                new Department { Name = "Mathematics", Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Fakhouri").ID },
                new Department { Name = "Engineering", Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Harui").ID },
                new Department { Name = "Economics",   Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Kapoor").ID }
            };

            foreach (Department d in departments)
```

```
{
    context.Departments.Add(d);
}
context.SaveChanges();

var courses = new Course[]
{
    new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3,
        DepartmentID = departments.Single( s => s.Name == "Engineering").DepartmentID
    },
    new Course {CourseID = 4022, Title = "Microeconomics", Credits = 3,
        DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID
    },

        Grade = Grade.B
        },
        new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alonso").ID,
        CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
        Grade = Grade.B
        },
        new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alonso").ID,
        CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
        Grade = Grade.B
        },
        new Enrollment {
        StudentID = students.Single(s => s.LastName == "Alonso").ID,
        CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
        Grade = Grade.B
        },
        new Enrollment {
        StudentID = students.Single(s => s.LastName == "Anand").ID,
        CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID
        },
        new Enrollment {
        StudentID = students.Single(s => s.LastName == "Anand").ID,
        CourseID = courses.Single(c => c.Title == "Microeconomics").CourseID,
        Grade = Grade.B
        },
```

```
                    },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Barzdukas").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Li").ID,
                    CourseID = courses.Single(c => c.Title == "Composition").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Justice").ID,
                    CourseID = courses.Single(c => c.Title == "Literature").CourseID,
                    Grade = Grade.B
                    }
            };

            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollment.Where(
                    s =>
                            s.Student.ID == e.StudentID &&
                            s.Course.CourseID == e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
                    context.Enrollment.Add(e);
                }
            }
            context.SaveChanges();
        }
    }
}
```

The preceding code provides seed data for the new entities. Most of this code creates new entity objects and loads sample data. The sample data is used for testing. See `Enrollments` and `CourseAssignments` for examples of how many-to-many join tables can be seeded.

Add a migration

Build the project.

- Visual Studio
- Visual Studio Code

```
Add-Migration ComplexDataModel
```

The preceding command displays a warning about possible data loss.

```
An operation was scaffolded that may result in the loss of data.
Please review the migration for accuracy.
Done. To undo this action, use 'ef migrations remove'
```

If the `database update` command is run, the following error is produced:

```
The ALTER TABLE statement conflicted with the FOREIGN KEY constraint
"FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in
database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.
```

Apply the migration

Now that you have an existing database, you need to think about how to apply future changes to it. This tutorial shows two approaches:

- Drop and re-create the database
- Apply the migration to the existing database. While this method is more complex and time-consuming, it's the preferred approach for real-world, production environments. **Note**: This is an optional section of the tutorial. You can do the drop and re-create steps and skip this section. If you do want to follow the steps in this section, don't do the drop and re-create steps.

Drop and re-create the database

The code in the updated `DbInitializer` adds seed data for the new entities. To force EF Core to create a new DB, drop and update the DB:

- Visual Studio
- Visual Studio Code

In the **Package Manager Console** (PMC), run the following command:

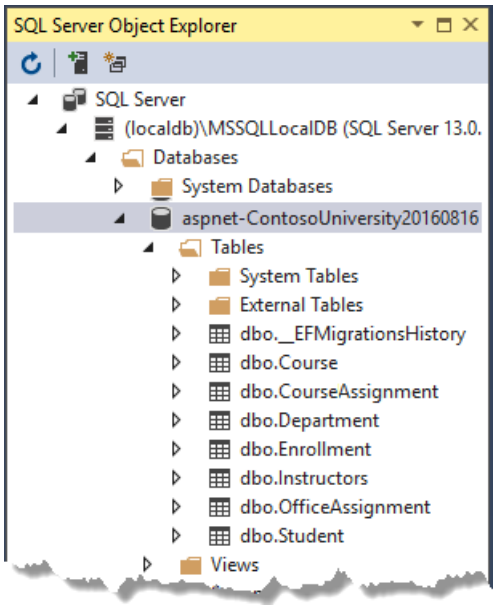
```
Drop-Database
Update-Database
```

Run `Get-Help about_EntityFrameworkCore` from the PMC to get help information.

Run the app. Running the app runs the `DbInitializer.Initialize` method. The `DbInitializer.Initialize` populates the new DB.

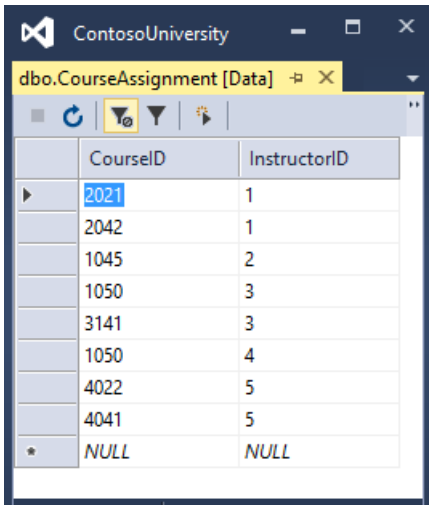
Open the DB in SSOX:

- If SSOX was opened previously, click the **Refresh** button.
- Expand the **Tables** node. The created tables are displayed.



Examine the **CourseAssignment** table:

- Right-click the **CourseAssignment** table and select **View Data**.
- Verify the **CourseAssignment** table contains data.



Apply the migration to the existing database

This section is optional. These steps work only if you skipped the preceding Drop and re-create the database section.

When migrations are run with existing data, there may be FK constraints that are not satisfied with the existing data. With production data, steps must be taken to migrate the existing data. This section provides an example of fixing FK constraint violations. Don't make these code changes without a backup. Don't make these code changes if you completed the previous section and updated the database.

The *{timestamp}_ComplexDataModel.cs* file contains the following code:

```
migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    type: "int",
    nullable: false,
    defaultValue: 0);
```

The preceding code adds a non-nullable `DepartmentID` FK to the `Course` table. The DB from the previous tutorial contains rows in `Course`, so that table cannot be updated by migrations.

To make the `ComplexDataModel` migration work with existing data:

- Change the code to give the new column (`DepartmentID`) a default value.
- Create a fake department named "Temp" to act as the default department.

Fix the foreign key constraints

Update the `ComplexDataModel` classes `Up` method:

- Open the *{timestamp}_ComplexDataModel.cs* file.
- Comment out the line of code that adds the `DepartmentID` column to the `Course` table.

```
migrationBuilder.AlterColumn<string>(
    name: "Title",
    table: "Course",
    maxLength: 50,
    nullable: true,
    oldClrType: typeof(string),
    oldNullable: true);

//migrationBuilder.AddColumn<int>(
//    name: "DepartmentID",
//    table: "Course",
//    nullable: false,
//    defaultValue: 0);
```

Add the following highlighted code. The new code goes after the `.CreateTable( name: "Department"` block:

```
migrationBuilder.CreateTable(
    name: "Department",
    columns: table => new
    {
        DepartmentID = table.Column<int>(type: "int", nullable: false)
            .Annotation("SqlServer:ValueGenerationStrategy", SqlServerValueGenerationStrategy.IdentityColumn),
        Budget = table.Column<decimal>(type: "money", nullable: false),
        InstructorID = table.Column<int>(type: "int", nullable: true),
        Name = table.Column<string>(type: "nvarchar(50)", maxLength: 50, nullable: true),
        StartDate = table.Column<DateTime>(type: "datetime2", nullable: false)
    },
    constraints: table =>
    {
        table.PrimaryKey("PK_Department", x => x.DepartmentID);
        table.ForeignKey(
            name: "FK_Department_Instructor_InstructorID",
            column: x => x.InstructorID,
            principalTable: "Instructor",
            principalColumn: "ID",
            onDelete: ReferentialAction.Restrict);
    });

 migrationBuilder.Sql("INSERT INTO dbo.Department (Name, Budget, StartDate) VALUES ('Temp', 0.00, GETDATE())");
// Default value for FK points to department created above, with
// defaultValue changed to 1 in following AddColumn statement.

migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    nullable: false,
    defaultValue: 1);
```

With the preceding changes, existing `Course` rows will be related to the "Temp" department after the `ComplexDataModel` `Up` method runs.

A production app would:

- Include code or scripts to add `Department` rows and related `Course` rows to the new `Department` rows.
- Not use the "Temp" department or the default value for `Course.DepartmentID`.

The next tutorial covers related data.

Part 6, Razor Pages with EF Core in ASP.NET Core - Read Related Data

9/22/2020 • 28 minutes to read • Edit Online

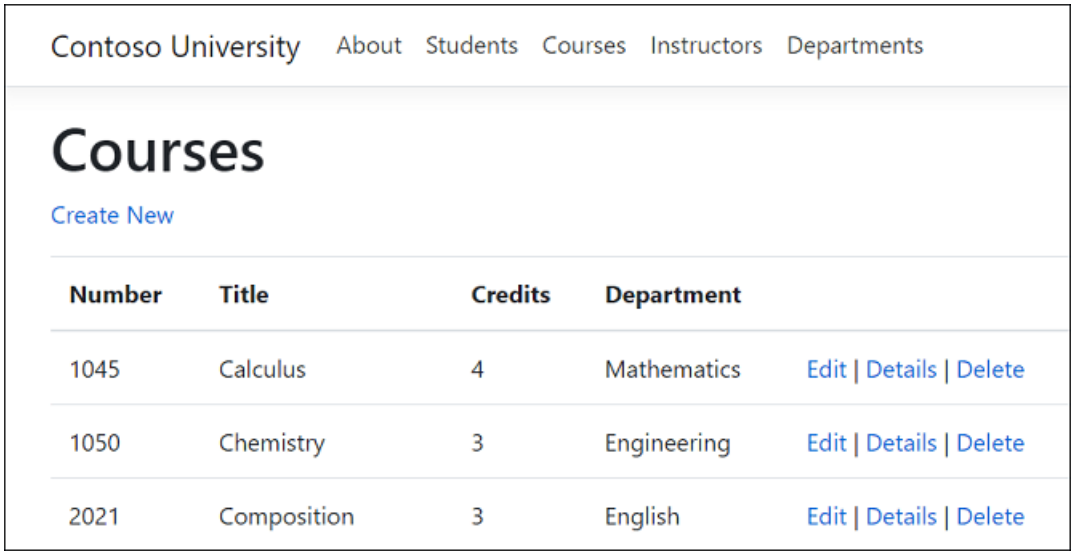
By Tom Dykstra, Jon P Smith, and Rick Anderson

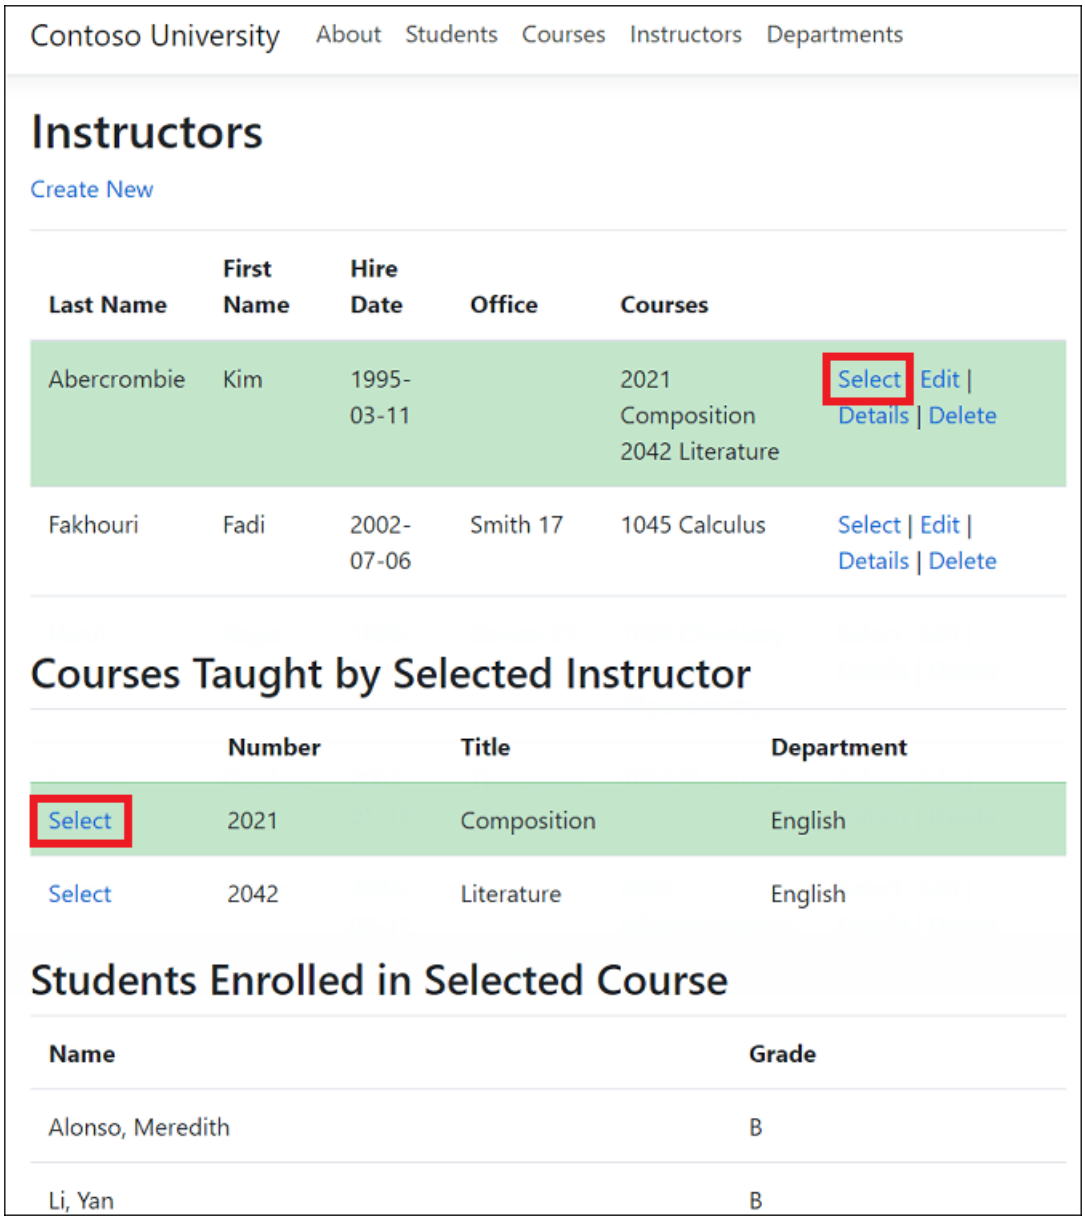
The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to read and display related data. Related data is data that EF Core loads into navigation properties.

The following illustrations show the completed pages for this tutorial:





Eager, explicit, and lazy loading

There are several ways that EF Core can load related data into the navigation properties of an entity:

- Eager loading. Eager loading is when a query for one type of entity also loads related entities. When an entity is read, its related data is retrieved. This typically results in a single join query that retrieves all of the data that's needed. EF Core will issue multiple queries for some types of eager loading. Issuing multiple queries can be more efficient than a giant single query. Eager loading is specified with the `Include` and `ThenInclude` methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

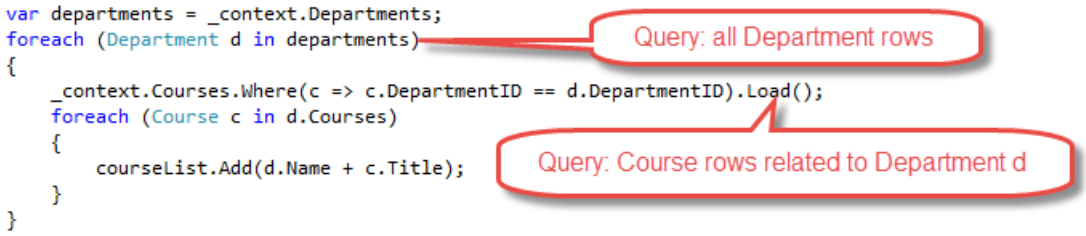
Query: all Department entities and related Course entities

  Eager loading sends multiple queries when a collection navigation is included:

  - One query for the main query
  - One query for each collection "edge" in the load tree.

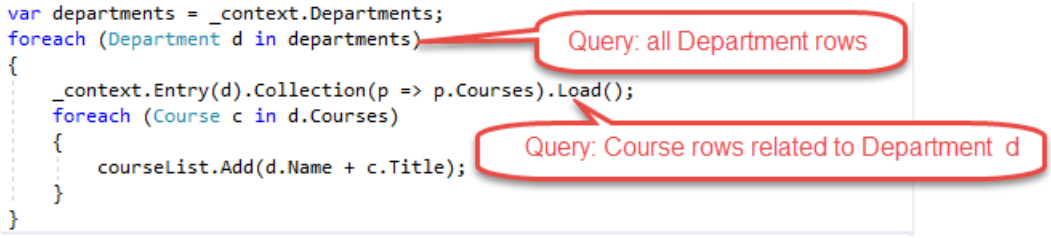
- Separate queries with `Load`: The data can be retrieved in separate queries, and EF Core "fixes up" the navigation properties. "Fixes up" means that EF Core automatically populates the navigation properties.

Separate queries with `Load` is more like explicit loading than eager loading.



Note: EF Core automatically fixes up navigation properties to any other entities that were previously loaded into the context instance. Even if the data for a navigation property is *not* explicitly included, the property may still be populated if some or all of the related entities were previously loaded.

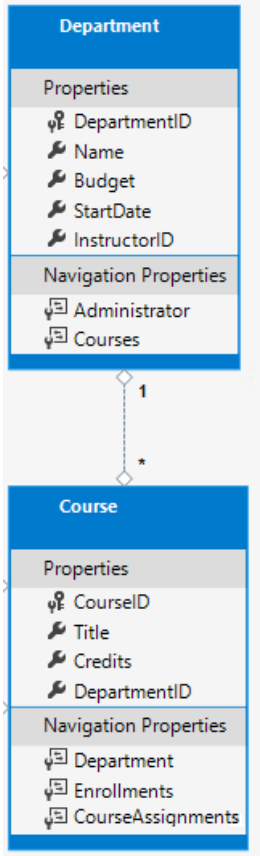
- Explicit loading. When the entity is first read, related data isn't retrieved. Code must be written to retrieve the related data when it's needed. Explicit loading with separate queries results in multiple queries sent to the database. With explicit loading, the code specifies the navigation properties to be loaded. Use the `Load` method to do explicit loading. For example:



- Lazy loading. When the entity is first read, related data isn't retrieved. The first time a navigation property is accessed, the data required for that navigation property is automatically retrieved. A query is sent to the database each time a navigation property is accessed for the first time. Lazy loading can hurt performance, for example when developers use N+1 patterns, loading a parent and enumerating through children.

Create Course pages

The `Course` entity includes a navigation property that contains the related `Department` entity.



To display the name of the assigned department for a course:

- Load the related `Department` entity into the `Course.Department` navigation property.
- Get the name from the `Department` entity's `Name` property.

Scaffold Course pages

- Visual Studio
- Visual Studio Code

- Follow the instructions in Scaffold Student pages with the following exceptions:
  - Create a *Pages/Courses* folder.
  - Use `Course` for the model class.
  - Use the existing context class instead of creating a new one.

- Open *Pages/Courses/Index.cshtml.cs* and examine the `OnGetAsync` method. The scaffolding engine specified eager loading for the `Department` navigation property. The `Include` method specifies eager loading.

- Run the app and select the **Courses** link. The department column displays the `DepartmentID`, which isn't useful.

Display the department name

Update Pages/Courses/Index.cshtml.cs with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IList<Course> Courses { get; set; }

        public async Task OnGetAsync()
        {
            Courses = await _context.Courses
                .Include(c => c.Department)
                .AsNoTracking()
                .ToListAsync();
        }
    }
}
```

The preceding code changes the `Course` property to `Courses` and adds `AsNoTracking`. `AsNoTracking` improves performance because the entities returned are not tracked. The entities don't need to be tracked because they're not updated in the current context.

Update *Pages/Courses/Index.cshtml* with the following code.

```
@page
@model ContosoUniversity.Pages.Courses.IndexModel

@{
    ViewData["Title"] = "Courses";
}

<h1>Courses</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Courses)
{
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.CourseID)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Credits)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Department.Name)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.CourseID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.CourseID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.CourseID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

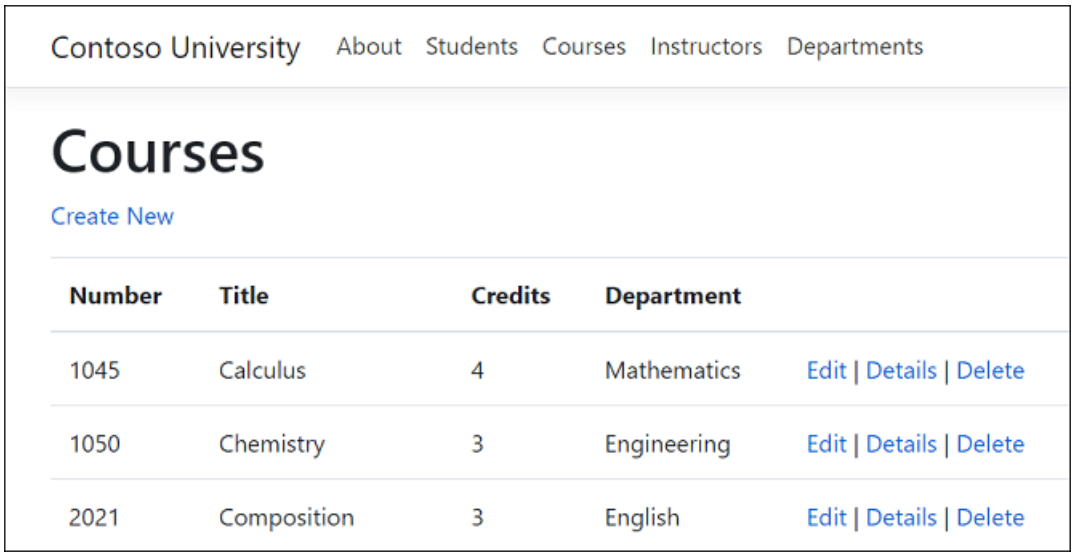
The following changes have been made to the scaffolded code:

- Changed the `Course` property name to `Courses`.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful.
- Changed the **Department** column to display the department name. The code displays the `Name` property of

the `Department` entity that's loaded into the `Department` navigation property:

```
@Html.DisplayFor(modelItem => item.Department.Name)
```

Run the app and select the **Courses** tab to see the list with department names.



Loading related data with Select

The `OnGetAsync` method loads related data with the `Include` method. The `Select` method is an alternative that loads only the related data needed. For single items, like the `Department.Name` it uses a SQL INNER JOIN. For collections, it uses another database access, but so does the `Include` operator on collections.

The following code loads related data with the `Select` method:

```
public IList<CourseViewModel> CourseVM { get; set; }

public async Task OnGetAsync()
{
    CourseVM = await _context.Courses
            .Select(p => new CourseViewModel
            {
                CourseID = p.CourseID,
                Title = p.Title,
                Credits = p.Credits,
                DepartmentName = p.Department.Name
            }).ToListAsync();
}
```

The preceding code doesn't return any entity types, therefore no tracking is done. For more information about the EF tracking, see Tracking vs. No-Tracking Queries.

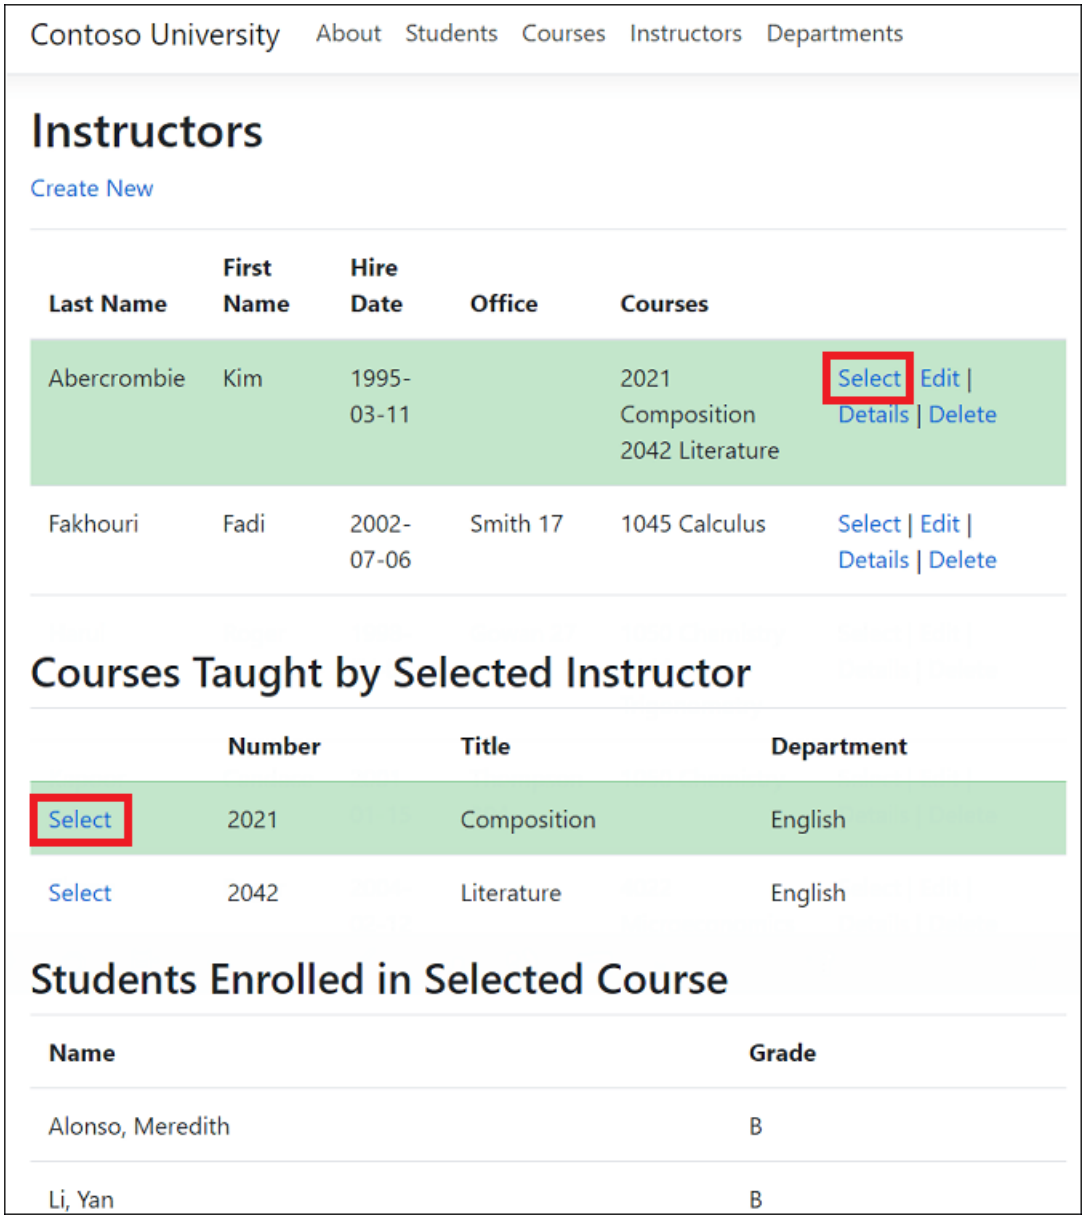
The `CourseViewModel`:

```
public class CourseViewModel
{
    public int CourseID { get; set; }
    public string Title { get; set; }
    public int Credits { get; set; }
    public string DepartmentName { get; set; }
}
```

See IndexSelect.cshtml and IndexSelect.cshtml.cs for a complete example.

Create Instructor pages

This section scaffolds Instructor pages and adds related Courses and Enrollments to the Instructors Index page.



This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity (Office in the preceding image). The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. Eager loading is used for the `OfficeAssignment` entities. Eager loading is typically more efficient when the related data needs to be displayed. In this case, office assignments for the instructors are displayed.
- When the user selects an instructor, related `Course` entities are displayed. The `Instructor` and `Course` entities are in a many-to-many relationship. Eager loading is used for the `Course` entities and their related `Department` entities. In this case, separate queries might be more efficient because only courses for the selected instructor are needed. This example shows how to use eager loading for navigation properties in entities that are in navigation properties.
- When the user selects a course, related data from the `Enrollments` entity is displayed. In the preceding image, student name and grade are displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship.

Create a view model

The instructors page shows data from three different tables. A view model is needed that includes three properties representing the three tables.

Create *SchoolViewModels/InstructorIndexData.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Scaffold Instructor pages

- Visual Studio
- Visual Studio Code

- Follow the instructions in Scaffold the student pages with the following exceptions:
  - Create a *Pages/Instructors* folder.
  - Use `Instructor` for the model class.
  - Use the existing context class instead of creating a new one.

To see what the scaffolded page looks like before you update it, run the app and navigate to the Instructors page.

Update *Pages/Instructors/Index.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;  // Add VM
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public InstructorIndexData InstructorData { get; set; }
        public int InstructorID { get; set; }
        public int CourseID { get; set; }

        public async Task OnGetAsync(int? id, int? courseID)
        {
            InstructorData = new InstructorIndexData();
            InstructorData.Instructors = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                        .ThenInclude(i => i.Department)
                .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                        .ThenInclude(i => i.Enrollments)
                            .ThenInclude(i => i.Student)
                .AsNoTracking()
                .OrderBy(i => i.LastName)
                .ToListAsync();

            if (id != null)
            {
                InstructorID = id.Value;
                Instructor instructor = InstructorData.Instructors
                    .Where(i => i.ID == id.Value).Single();
                InstructorData.Courses = instructor.CourseAssignments.Select(s => s.Course);
            }

            if (courseID != null)
            {
                CourseID = courseID.Value;
                var selectedCourse = InstructorData.Courses
                    .Where(x => x.CourseID == courseID).Single();
                InstructorData.Enrollments = selectedCourse.Enrollments;
            }
        }
    }
}
```

The `OnGetAsync` method accepts optional route data for the ID of the selected instructor.

Examine the query in the *Pages/Instructors/Index.cshtml.cs* file:

```
InstructorData.Instructors = await _context.Instructors
    .Include(i => i.OfficeAssignment)
    .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
    .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
    .AsNoTracking()
    .OrderBy(i => i.LastName)
    .ToListAsync();
```

The code specifies eager loading for the following navigation properties:

- `Instructor.OfficeAssignment`
- `Instructor.CourseAssignments`
  - `CourseAssignments.Course`
    - `Course.Department`
    - `Course.Enrollments`
      - `Enrollment.Student`

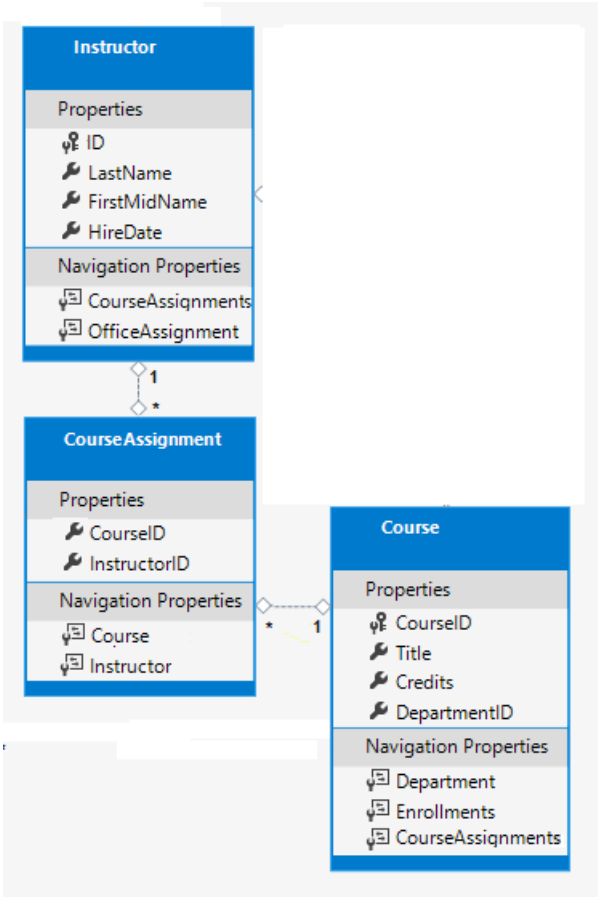
Notice the repetition of `Include` and `ThenInclude` methods for `CourseAssignments` and `Course`. This repetition is necessary to specify eager loading for two navigation properties of the `Course` entity.

The following code executes when an instructor is selected (`id != null`).

```
if (id != null)
{
    InstructorID = id.Value;
    Instructor instructor = InstructorData.Instructors
        .Where(i => i.ID == id.Value).Single();
    InstructorData.Courses = instructor.CourseAssignments.Select(s => s.Course);
}
```

The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is loaded with the `Course` entities from that instructor's `CourseAssignments` navigation property.

The `Where` method returns a collection. But in this case, the filter will select a single entity, so the `Single` method is called to convert the collection into a single `Instructor` entity. The `Instructor` entity provides access to the `CourseAssignments` property. `CourseAssignments` provides access to the related `Course` entities.



The `Single` method is used on a collection when the collection has only one item. The `Single` method throws an exception if the collection is empty or if there's more than one item. An alternative is `SingleOrDefault`, which returns a default value (null in this case) if the collection is empty.

The following code populates the view model's `Enrollments` property when a course is selected:

```
if (courseID != null)
{
    CourseID = courseID.Value;
    var selectedCourse = InstructorData.Courses
        .Where(x => x.CourseID == courseID).Single();
    InstructorData.Enrollments = selectedCourse.Enrollments;
}
```

Update the instructors Index page

Update *Pages/Instructors/Index.cshtml* with the following code.

```
@page "{id:int?}"
@model ContosoUniversity.Pages.Instructors.IndexModel

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
```

```
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.InstructorData.Instructors)
        {
            string selectedRow = "";
            if (item.ID == Model.InstructorID)
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @{
                        foreach (var course in item.CourseAssignments)
                        {
                            @course.Course.CourseID @:  @course.Course.Title <br />
                        }
                    }
                </td>
                <td>
                    <a asp-page="./Index" asp-route-id="@item.ID">Select</a> |
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@if (Model.InstructorData.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

        @foreach (var item in Model.InstructorData.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == Model.CourseID)
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
```

```
                    <a asp-page="./Index" asp-route-courseID="@item.CourseID">Select</a>
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}

@if (Model.InstructorData.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.InstructorData.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

The preceding code makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int?}"`. `"{id:int?}"` is a route template. The route template changes integer query strings in the URL to route data. For example, clicking on the **Select** link for an instructor with only the `@page` directive produces a URL like the following:

  `https://localhost:5001/Instructors?id=2`

  When the page directive is `@page "{id:int?}"`, the URL is:

  `https://localhost:5001/Instructors/2`

- Adds an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.

  ```
  @if (item.OfficeAssignment != null)
  {
      @item.OfficeAssignment.Location
  }
  ```

- Adds a **Courses** column that displays courses taught by each instructor. See Explicit line transition for more about this razor syntax.

- Adds code that dynamically adds `class="success"` to the `tr` element of the selected instructor and course. This sets a background color for the selected row using a Bootstrap class.

```
string selectedRow = "";
if (item.CourseID == Model.CourseID)
{
    selectedRow = "success";
}
<tr class="@selectedRow">
```

- Adds a new hyperlink labeled **Select**. This link sends the selected instructor's ID to the `Index` method and sets a background color.

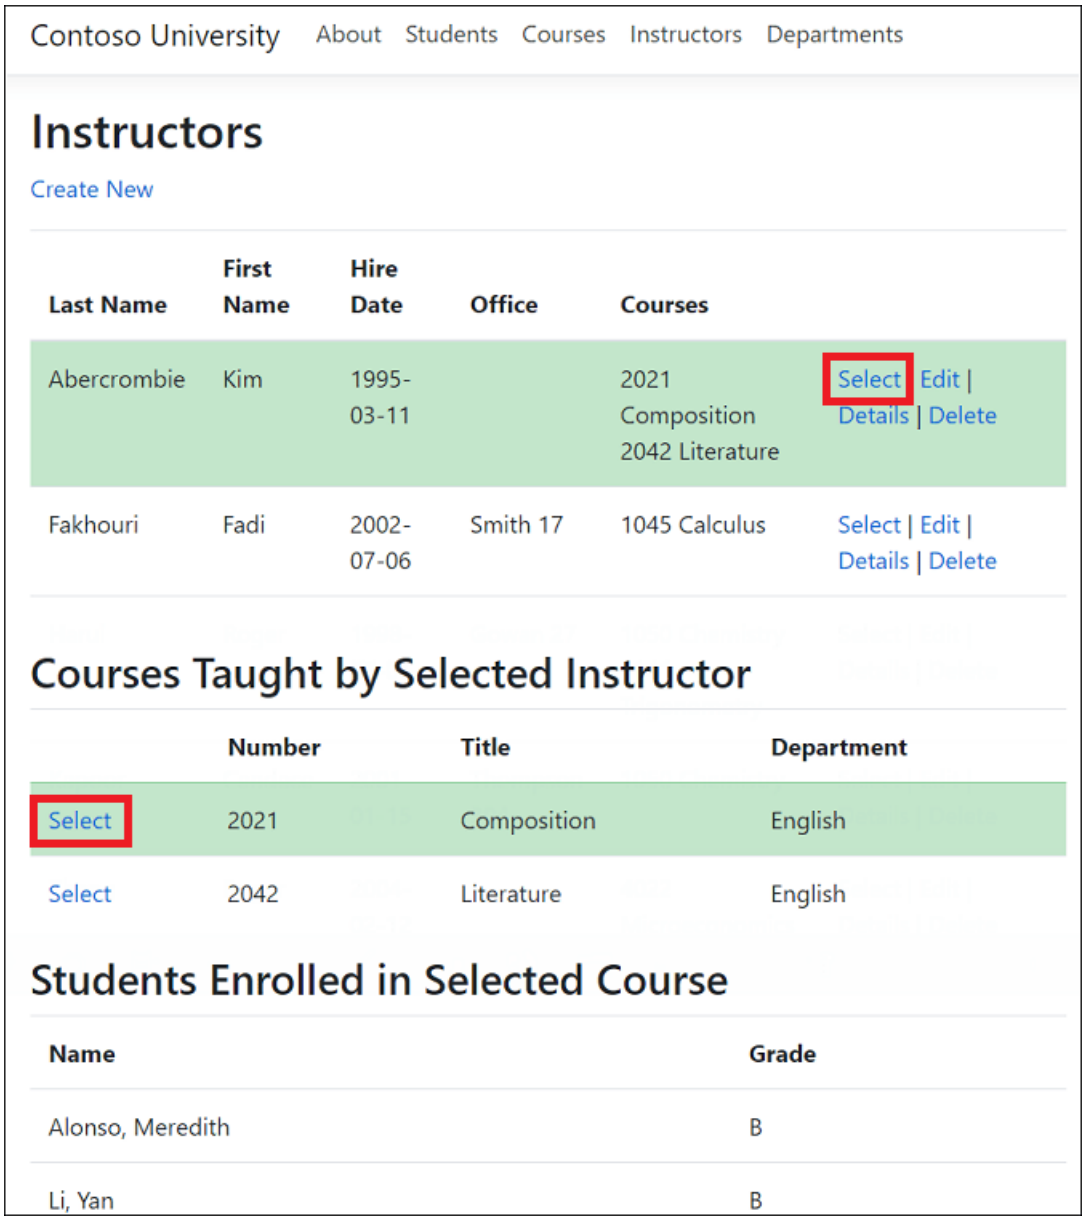
```
<a asp-action="Index" asp-route-id="@item.ID">Select</a> |
```

- Adds a table of courses for the selected Instructor.
- Adds a table of student enrollments for the selected course.

Run the app and select the **Instructors** tab. The page displays the `Location` (office) from the related `OfficeAssignment` entity. If `OfficeAssignment` is null, an empty table cell is displayed.

Click on the **Select** link for an instructor. The row style changes and courses assigned to that instructor are displayed.

Select a course to see the list of enrolled students and their grades.



Using Single

The `Single` method can pass in the `Where` condition instead of calling the `Where` method separately:

```
public async Task OnGetAsync(int? id, int? courseID)
{
    InstructorData = new InstructorIndexData();

    InstructorData.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
            .Include(i => i.CourseAssignments)
                .ThenInclude(i => i.Course)
                    .ThenInclude(i => i.Enrollments)
                        .ThenInclude(i => i.Student)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        InstructorID = id.Value;
        Instructor instructor = InstructorData.Instructors.Single(
            i => i.ID == id.Value);
        InstructorData.Courses = instructor.CourseAssignments.Select(
            s => s.Course);
    }

    if (courseID != null)
    {
        CourseID = courseID.Value;
        InstructorData.Enrollments = InstructorData.Courses.Single(
            x => x.CourseID == courseID).Enrollments;
    }
}
```

Use of `Single` with a Where condition is a matter of personal preference. It provides no benefits over using the `Where` method.

Explicit loading

The current code specifies eager loading for `Enrollments` and `Students`:

```
InstructorData.Instructors = await _context.Instructors
    .Include(i => i.OfficeAssignment)
    .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
    .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
    .AsNoTracking()
    .OrderBy(i => i.LastName)
    .ToListAsync();
```

Suppose users rarely want to see enrollments in a course. In that case, an optimization would be to only load the enrollment data if it's requested. In this section, the `OnGetAsync` is updated to use explicit loading of `Enrollments` and `Students`.

Update *Pages/Instructors/Index.cshtml.cs* with the following code.

```
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;  // Add VM
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public InstructorIndexData InstructorData { get; set; }
        public int InstructorID { get; set; }
        public int CourseID { get; set; }

        public async Task OnGetAsync(int? id, int? courseID)
        {
            InstructorData = new InstructorIndexData();
            InstructorData.Instructors = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                        .ThenInclude(i => i.Department)
                //.Include(i => i.CourseAssignments)
                //    .ThenInclude(i => i.Course)
                //        .ThenInclude(i => i.Enrollments)
                //            .ThenInclude(i => i.Student)
                //.AsNoTracking()
                .OrderBy(i => i.LastName)
                .ToListAsync();

            if (id != null)
            {
                InstructorID = id.Value;
                Instructor instructor = InstructorData.Instructors
                    .Where(i => i.ID == id.Value).Single();
                InstructorData.Courses = instructor.CourseAssignments.Select(s => s.Course);
            }

            if (courseID != null)
            {
                CourseID = courseID.Value;
                var selectedCourse = InstructorData.Courses
                    .Where(x => x.CourseID == courseID).Single();
                await _context.Entry(selectedCourse).Collection(x => x.Enrollments).LoadAsync();
                foreach (Enrollment enrollment in selectedCourse.Enrollments)
                {
                    await _context.Entry(enrollment).Reference(x => x.Student).LoadAsync();
                }
                InstructorData.Enrollments = selectedCourse.Enrollments;
            }
        }
    }
}
```

The preceding code drops the *ThenInclude* method calls for enrollment and student data. If a course is selected, the explicit loading code retrieves:

- The `Enrollment` entities for the selected course.

- The `Student` entities for each `Enrollment`.

Notice that the preceding code comments out `.AsNoTracking()`. Navigation properties can only be explicitly loaded for tracked entities.

Test the app. From a user's perspective, the app behaves identically to the previous version.

Next steps

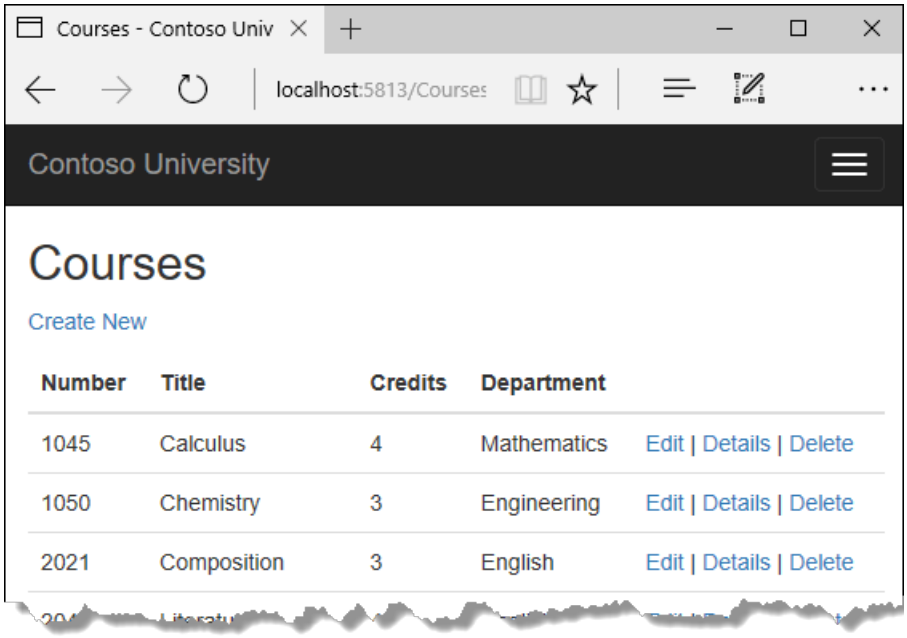
The next tutorial shows how to update related data.

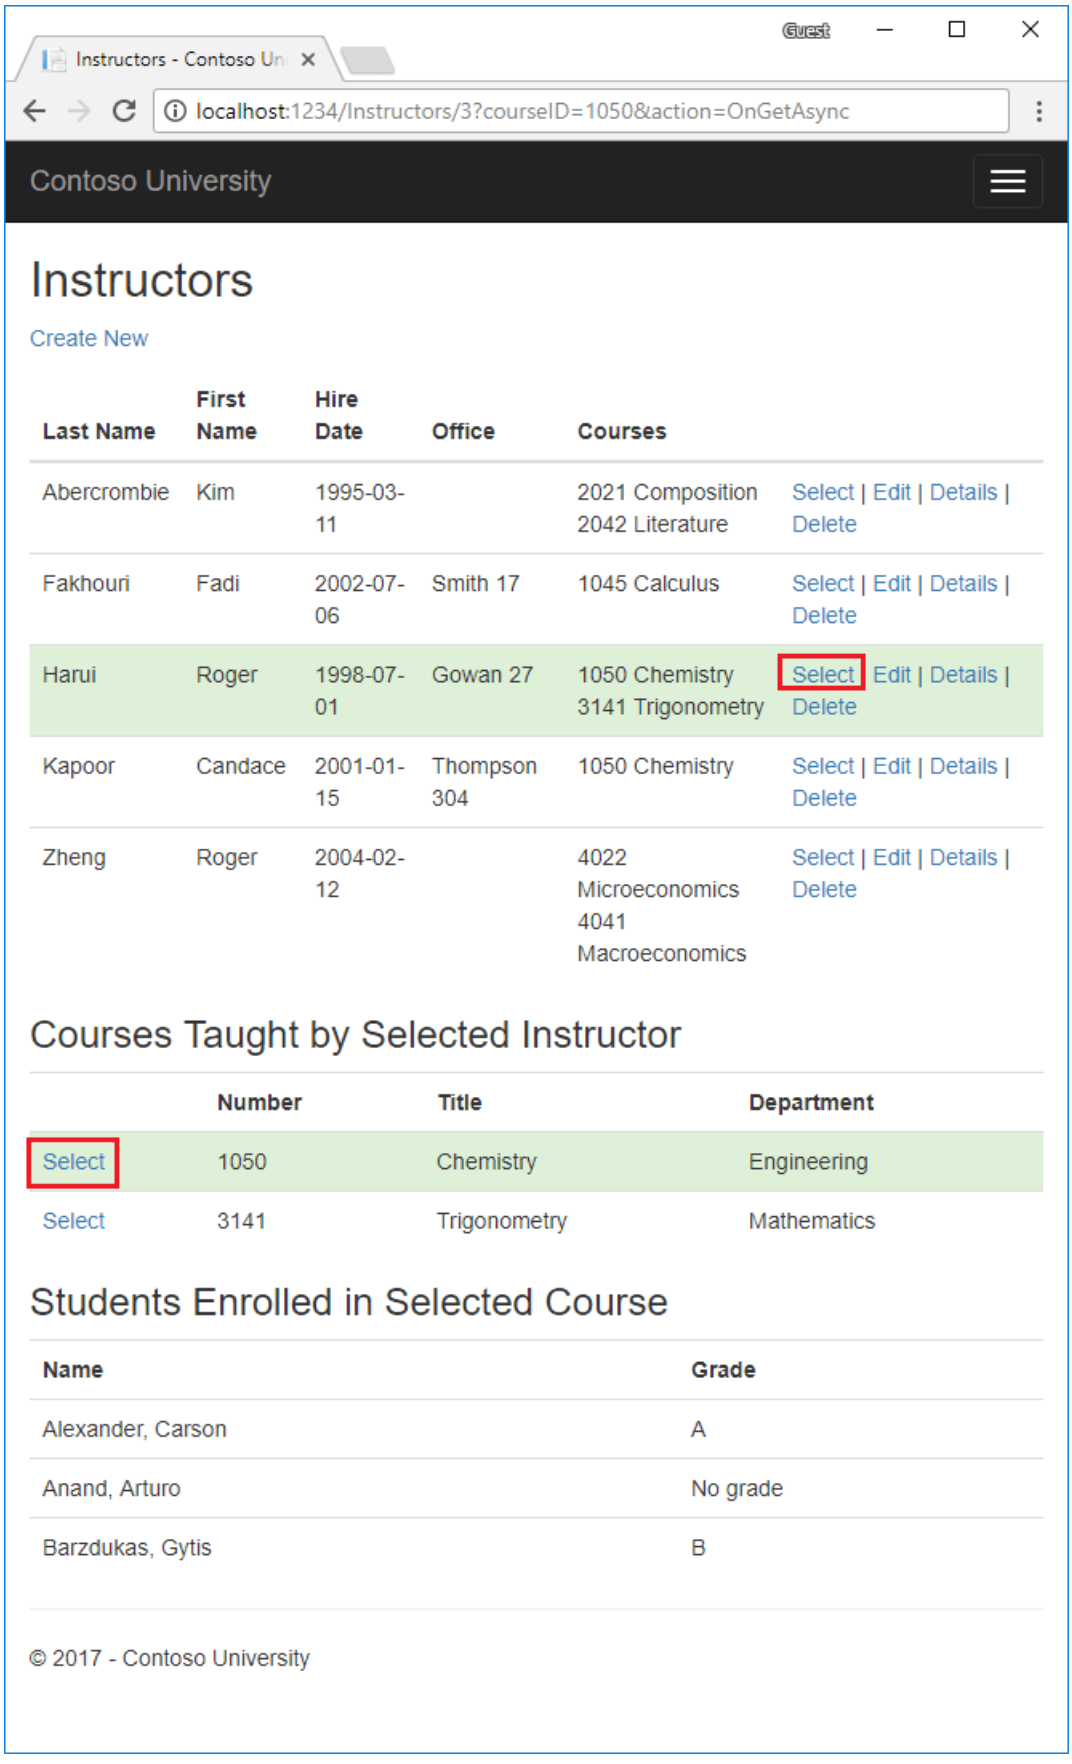
PREVIOUS TUTORIAL | NEXT TUTORIAL

In this tutorial, related data is read and displayed. Related data is data that EF Core loads into navigation properties.

If you run into problems you can't solve, download or view the completed app. Download instructions.

The following illustrations show the completed pages for this tutorial:





Eager, explicit, and lazy Loading of related data

There are several ways that EF Core can load related data into the navigation properties of an entity:

- Eager loading. Eager loading is when a query for one type of entity also loads related entities. When the entity is read, its related data is retrieved. This typically results in a single join query that retrieves all of the data that's needed. EF Core will issue multiple queries for some types of eager loading. Issuing multiple queries can be more efficient than was the case for some queries in EF6 where there was a single query.

Eager loading is specified with the `Include` and `ThenInclude` methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department entities and related Course entities

Eager loading sends multiple queries when a collection navigation is included:

- One query for the main query
- One query for each collection "edge" in the load tree.

- Separate queries with `Load`: The data can be retrieved in separate queries, and EF Core "fixes up" the navigation properties. "fixes up" means that EF Core automatically populates the navigation properties. Separate queries with `Load` is more like explicit loading than eager loading.

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Courses.Where(c => c.DepartmentID == d.DepartmentID).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

Note: EF Core automatically fixes up navigation properties to any other entities that were previously loaded into the context instance. Even if the data for a navigation property is *not* explicitly included, the property may still be populated if some or all of the related entities were previously loaded.

- Explicit loading. When the entity is first read, related data isn't retrieved. Code must be written to retrieve the related data when it's needed. Explicit loading with separate queries results in multiple queries sent to the DB. With explicit loading, the code specifies the navigation properties to be loaded. Use the `Load` method to do explicit loading. For example:

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Entry(d).Collection(p => p.Courses).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

- Lazy loading. Lazy loading was added to EF Core in version 2.1. When the entity is first read, related data isn't retrieved. The first time a navigation property is accessed, the data required for that navigation property is automatically retrieved. A query is sent to the DB each time a navigation property is accessed for the first time.

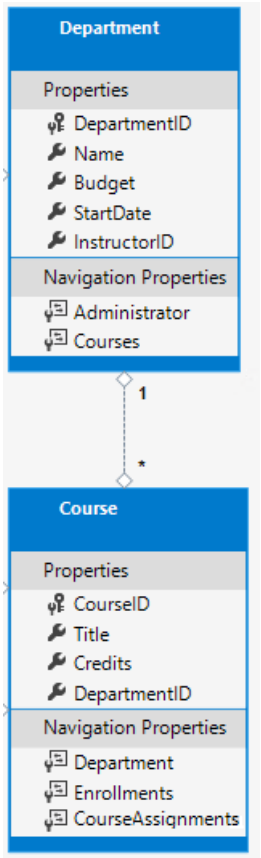
- The `Select` operator loads only the related data needed.

Create a Course page that displays department name

The Course entity includes a navigation property that contains the `Department` entity. The `Department` entity contains the department that the course is assigned to.

To display the name of the assigned department in a list of courses:

- Get the `Name` property from the `Department` entity.
- The `Department` entity comes from the `Course.Department` navigation property.



Scaffold the Course model

- Visual Studio
- Visual Studio Code

Follow the instructions in Scaffold the student model and use `Course` for the model class.

The preceding command scaffolds the `Course` model. Open the project in Visual Studio.

Open *Pages/Courses/Index.cshtml.cs* and examine the `OnGetAsync` method. The scaffolding engine specified eager loading for the `Department` navigation property. The `Include` method specifies eager loading.

Run the app and select the **Courses** link. The department column displays the `DepartmentID`, which isn't useful.

Update the `OnGetAsync` method with the following code:

```
public async Task OnGetAsync()
{
    Course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .ToListAsync();
}
```

The preceding code adds `AsNoTracking`. `AsNoTracking` improves performance because the entities returned are not tracked. The entities are not tracked because they're not updated in the current context.

Update *Pages/Courses/Index.cshtml* with the following highlighted markup:

```
@page
@model ContosoUniversity.Pages.Courses.IndexModel
@{
    ViewData["Title"] = "Courses";
}

<h2>Courses</h2>

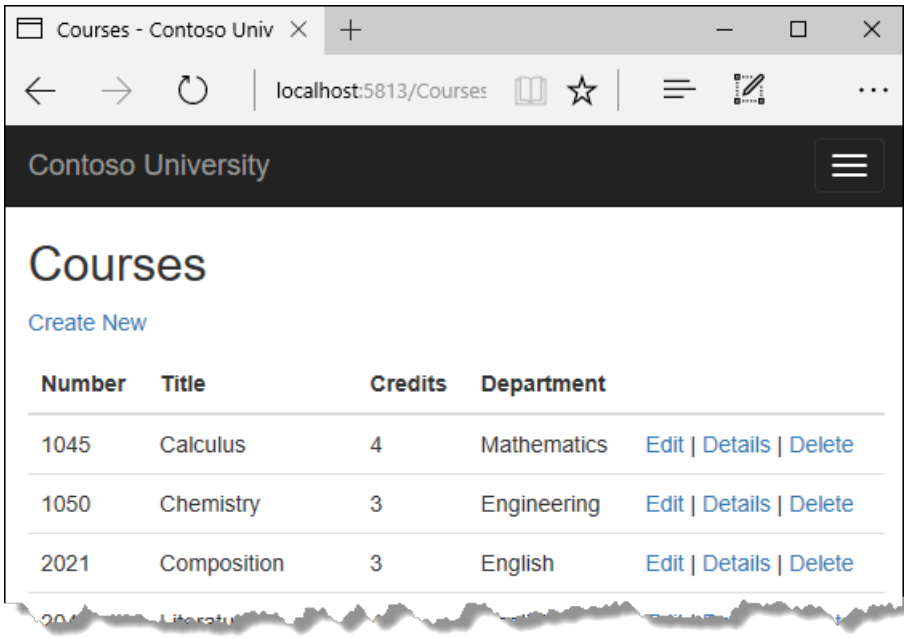
<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Course[0].CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Course[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Course[0].Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Course[0].Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Course)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.CourseID)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Credits)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Department.Name)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.CourseID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.CourseID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.CourseID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The following changes have been made to the scaffolded code:

- Changed the heading from Index to Courses.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful.
- Changed the **Department** column to display the department name. The code displays the `Name` property of the `Department` entity that's loaded into the `Department` navigation property:

```
@Html.DisplayFor(modelItem => item.Department.Name)
```

Run the app and select the **Courses** tab to see the list with department names.



Loading related data with Select

The `OnGetAsync` method loads related data with the `Include` method:

```
public async Task OnGetAsync()
{
    Course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .ToListAsync();
}
```

The `Select` operator loads only the related data needed. For single items, like the `Department.Name` it uses a SQL INNER JOIN. For collections, it uses another database access, but so does the `Include` operator on collections.

The following code loads related data with the `Select` method:

```
public IList<CourseViewModel> CourseVM { get; set; }

public async Task OnGetAsync()
{
    CourseVM = await _context.Courses
            .Select(p => new CourseViewModel
            {
                CourseID = p.CourseID,
                Title = p.Title,
                Credits = p.Credits,
                DepartmentName = p.Department.Name
            }).ToListAsync();
}
```

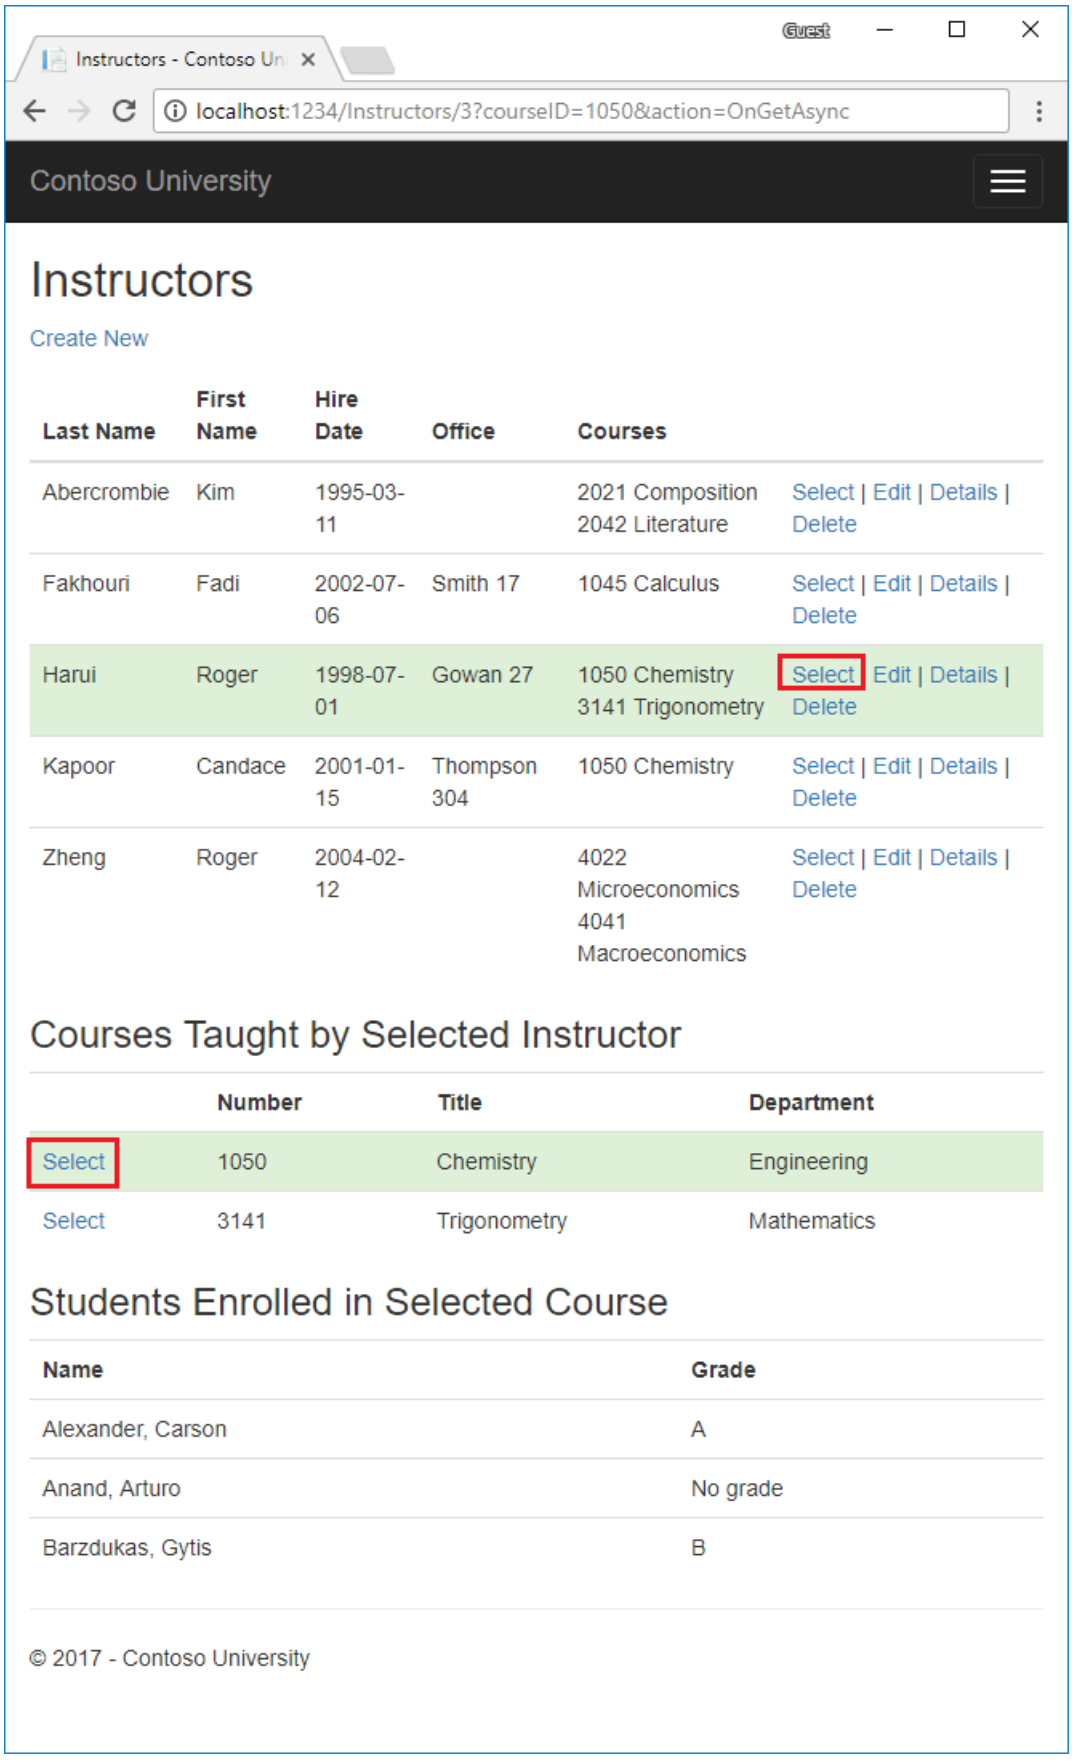
The `CourseViewModel`:

```
public class CourseViewModel
{
    public int CourseID { get; set; }
    public string Title { get; set; }
    public int Credits { get; set; }
    public string DepartmentName { get; set; }
}
```

See IndexSelect.cshtml and IndexSelect.cshtml.cs for a complete example.

Create an Instructors page that shows Courses and Enrollments

In this section, the Instructors page is created.



This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity (Office in the preceding image). The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. Eager loading is used for the `OfficeAssignment` entities. Eager loading is typically more efficient when the related data needs to be displayed. In this case, office assignments for the instructors are displayed.
- When the user selects an instructor (Harui in the preceding image), related `Course` entities are displayed. The

`Instructor` and `Course` entities are in a many-to-many relationship. Eager loading is used for the `Course` entities and their related `Department` entities. In this case, separate queries might be more efficient because only courses for the selected instructor are needed. This example shows how to use eager loading for navigation properties in entities that are in navigation properties.

- When the user selects a course (Chemistry in the preceding image), related data from the `Enrollments` entity is displayed. In the preceding image, student name and grade are displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship.

Create a view model for the Instructor Index view

The instructors page shows data from three different tables. A view model is created that includes the three entities representing the three tables.

In the *SchoolViewModels* folder, create *InstructorIndexData.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Scaffold the Instructor model

- Visual Studio
- Visual Studio Code

Follow the instructions in Scaffold the student model and use `Instructor` for the model class.

The preceding command scaffolds the `Instructor` model. Run the app and navigate to the instructors page.

Replace *Pages/Instructors/Index.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;  // Add VM
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public InstructorIndexData Instructor { get; set; }
        public int InstructorID { get; set; }

        public async Task OnGetAsync(int? id)
        {
            Instructor = new InstructorIndexData();
            Instructor.Instructors = await _context.Instructors
                  .Include(i => i.OfficeAssignment)
                  .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                  .AsNoTracking()
                  .OrderBy(i => i.LastName)
                  .ToListAsync();

            if (id != null)
            {
                InstructorID = id.Value;
            }
        }
    }
}
```

The `OnGetAsync` method accepts optional route data for the ID of the selected instructor.

Examine the query in the *Pages/Instructors/Index.cshtml.cs* file:

```
Instructor.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

The query has two includes:

- `OfficeAssignment`: Displayed in the instructors view.
- `CourseAssignments`: Which brings in the courses taught.

Update the instructors Index page

Update *Pages/Instructors/Index.cshtml* with the following markup:

```
@page "{id:int?}"
@model ContosoUniversity.Pages.Instructors.IndexModel

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Instructor.Instructors)
        {
            string selectedRow = "";
            if (item.ID == Model.InstructorID)
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @{
                        foreach (var course in item.CourseAssignments)
                        {
                            @course.Course.CourseID @:  @course.Course.Title <br />
                        }
                    }
                </td>
                <td>
                    <a asp-page="./Index" asp-route-id="@item.ID">Select</a> |
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding markup makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int?}"`. `"{id:int?}"` is a route template. The route template changes integer query strings in the URL to route data. For example, clicking on the **Select** link for an instructor with only the `@page` directive produces a URL like the following:

  `http://localhost:1234/Instructors?id=2`

  When the page directive is `@page "{id:int?}"`, the previous URL is:

  `http://localhost:1234/Instructors/2`

- Page title is **Instructors**.
- Added an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.

```
@if (item.OfficeAssignment != null)
{
    @item.OfficeAssignment.Location
}
```

- Added a **Courses** column that displays courses taught by each instructor. See Explicit line transition for more about this razor syntax.
- Added code that dynamically adds `class="success"` to the `tr` element of the selected instructor. This sets a background color for the selected row using a Bootstrap class.

```
string selectedRow = "";
if (item.CourseID == Model.CourseID)
{
    selectedRow = "success";
}
<tr class="@selectedRow">
```

- Added a new hyperlink labeled **Select**. This link sends the selected instructor's ID to the `Index` method and sets a background color.

```
<a asp-action="Index" asp-route-id="@item.ID">Select</a> |
```

Run the app and select the **Instructors** tab. The page displays the `Location` (office) from the related `OfficeAssignment` entity. If OfficeAssignment` is null, an empty table cell is displayed.

Click on the **Select** link. The row style changes.

Add courses taught by selected instructor

Update the `OnGetAsync` method in *Pages/Instructors/Index.cshtml.cs* with the following code:

```
public async Task OnGetAsync(int? id, int? courseID)
{
    Instructor = new InstructorIndexData();
    Instructor.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        InstructorID = id.Value;
        Instructor instructor = Instructor.Instructors.Where(
            i => i.ID == id.Value).Single();
        Instructor.Courses = instructor.CourseAssignments.Select(s => s.Course);
    }

    if (courseID != null)
    {
        CourseID = courseID.Value;
        Instructor.Enrollments = Instructor.Courses.Where(
            x => x.CourseID == courseID).Single().Enrollments;
    }
}
```

Add `public int CourseID { get; set; }`

```
public class IndexModel : PageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public IndexModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    public InstructorIndexData Instructor { get; set; }
    public int InstructorID { get; set; }
    public int CourseID { get; set; }

    public async Task OnGetAsync(int? id, int? courseID)
    {
        Instructor = new InstructorIndexData();
        Instructor.Instructors = await _context.Instructors
              .Include(i => i.OfficeAssignment)
              .Include(i => i.CourseAssignments)
                .ThenInclude(i => i.Course)
                    .ThenInclude(i => i.Department)
              .AsNoTracking()
              .OrderBy(i => i.LastName)
              .ToListAsync();

        if (id != null)
        {
            InstructorID = id.Value;
            Instructor instructor = Instructor.Instructors.Where(
                i => i.ID == id.Value).Single();
            Instructor.Courses = instructor.CourseAssignments.Select(s => s.Course);
        }

        if (courseID != null)
        {
            CourseID = courseID.Value;
            Instructor.Enrollments = Instructor.Courses.Where(
                x => x.CourseID == courseID).Single().Enrollments;
        }
    }
```

Examine the updated query:

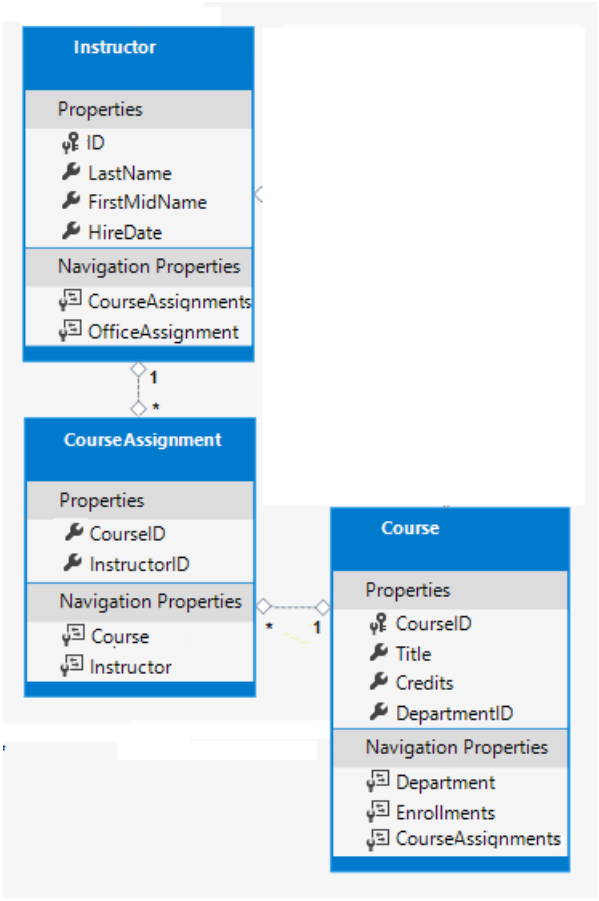
```
Instructor.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

The preceding query adds the `Department` entities.

The following code executes when an instructor is selected (`id != null`). The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is loaded with the `Course` entities from that instructor's `CourseAssignments` navigation property.

```
if (id != null)
{
    InstructorID = id.Value;
    Instructor instructor = Instructor.Instructors.Where(
        i => i.ID == id.Value).Single();
    Instructor.Courses = instructor.CourseAssignments.Select(s => s.Course);
}
```

The `Where` method returns a collection. In the preceding `Where` method, only a single `Instructor` entity is returned. The `Single` method converts the collection into a single `Instructor` entity. The `Instructor` entity provides access to the `CourseAssignments` property. `CourseAssignments` provides access to the related `Course` entities.



The `Single` method is used on a collection when the collection has only one item. The `Single` method throws an exception if the collection is empty or if there's more than one item. An alternative is `SingleOrDefault`, which returns a default value (null in this case) if the collection is empty. Using `SingleOrDefault` on an empty collection:

- Results in an exception (from trying to find a `Courses` property on a null reference).
- The exception message would less clearly indicate the cause of the problem.

The following code populates the view model's `Enrollments` property when a course is selected:

```
if (courseID != null)
{
    CourseID = courseID.Value;
    Instructor.Enrollments = Instructor.Courses.Where(
        x => x.CourseID == courseID).Single().Enrollments;
}
```

Add the following markup to the end of the *Pages/Instructors/Index.cshtml* Razor Page:

```
                    <a asp-page="./Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@if (Model.Instructor.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

        @foreach (var item in Model.Instructor.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == Model.CourseID)
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    <a asp-page="./Index" asp-route-courseID="@item.CourseID">Select</a>
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}
```

The preceding markup displays a list of courses related to an instructor when an instructor is selected.

Test the app. Click on a **Select** link on the instructors page.

Show student data

In this section, the app is updated to show the student data for a selected course.

Update the query in the `OnGetAsync` method in *Pages/Instructors/Index.cshtml.cs* with the following code:

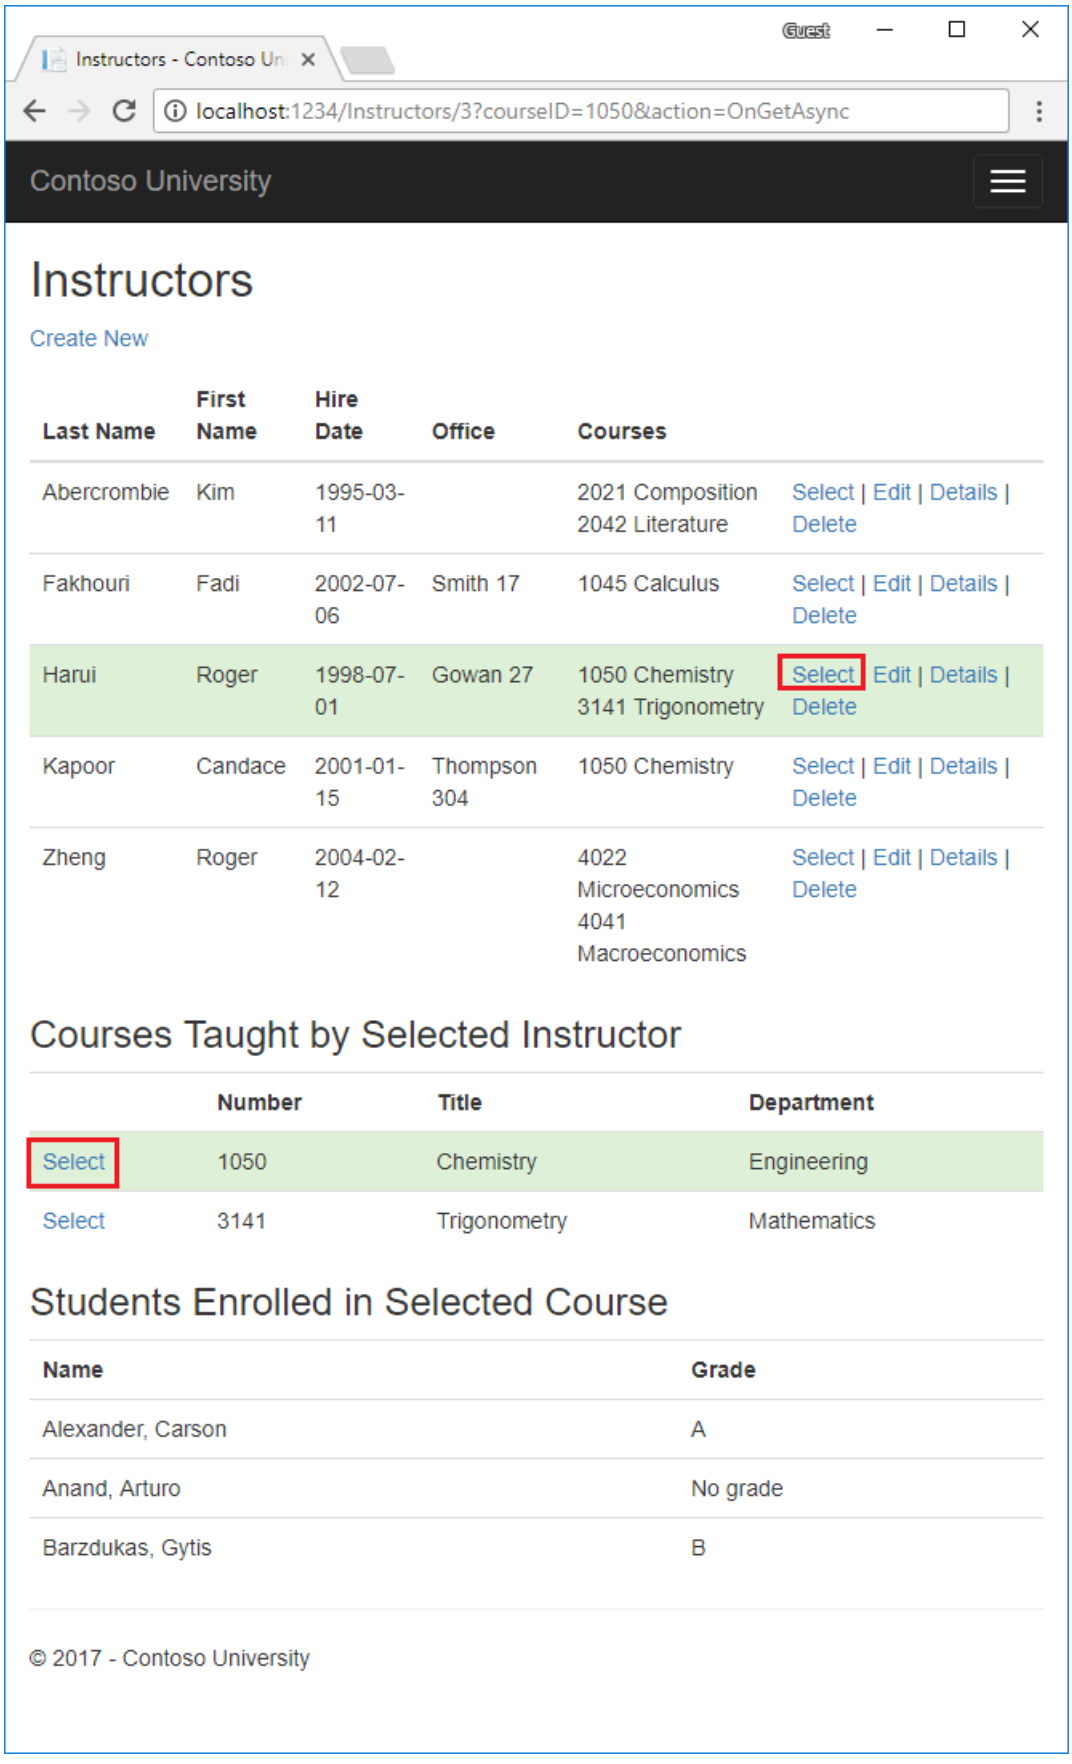
```
Instructor.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
        .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Enrollments)
                    .ThenInclude(i => i.Student)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

Update *Pages/Instructors/Index.cshtml*. Add the following markup to the end of the file:

```
@if (Model.Instructor.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Instructor.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

The preceding markup displays a list of the students who are enrolled in the selected course.

Refresh the page and select an instructor. Select a course to see the list of enrolled students and their grades.



Using Single

The `Single` method can pass in the `Where` condition instead of calling the `Where` method separately:

```
public async Task OnGetAsync(int? id, int? courseID)
{
    Instructor = new InstructorIndexData();

    Instructor.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
            .Include(i => i.CourseAssignments)
                .ThenInclude(i => i.Course)
                    .ThenInclude(i => i.Enrollments)
                        .ThenInclude(i => i.Student)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        InstructorID = id.Value;
        Instructor instructor = Instructor.Instructors.Single(
            i => i.ID == id.Value);
        Instructor.Courses = instructor.CourseAssignments.Select(
            s => s.Course);
    }

    if (courseID != null)
    {
        CourseID = courseID.Value;
        Instructor.Enrollments = Instructor.Courses.Single(
            x => x.CourseID == courseID).Enrollments;
    }
}
```

The preceding `Single` approach provides no benefits over using `Where`. Some developers prefer the `Single` approach style.

Explicit loading

The current code specifies eager loading for `Enrollments` and `Students`:

```
Instructor.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
        .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Enrollments)
                    .ThenInclude(i => i.Student)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

Suppose users rarely want to see enrollments in a course. In that case, an optimization would be to only load the enrollment data if it's requested. In this section, the `OnGetAsync` is updated to use explicit loading of `Enrollments` and `Students`.

Update the `OnGetAsync` with the following code:

```
public async Task OnGetAsync(int? id, int? courseID)
{
    Instructor = new InstructorIndexData();
    Instructor.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
            //.Include(i => i.CourseAssignments)
            //    .ThenInclude(i => i.Course)
            //        .ThenInclude(i => i.Enrollments)
            //            .ThenInclude(i => i.Student)
         // .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        InstructorID = id.Value;
        Instructor instructor = Instructor.Instructors.Where(
            i => i.ID == id.Value).Single();
        Instructor.Courses = instructor.CourseAssignments.Select(s => s.Course);
    }

    if (courseID != null)
    {
        CourseID = courseID.Value;
        var selectedCourse = Instructor.Courses.Where(x => x.CourseID == courseID).Single();
        await _context.Entry(selectedCourse).Collection(x => x.Enrollments).LoadAsync();
        foreach (Enrollment enrollment in selectedCourse.Enrollments)
        {
            await _context.Entry(enrollment).Reference(x => x.Student).LoadAsync();
        }
        Instructor.Enrollments = selectedCourse.Enrollments;
    }
}
```

The preceding code drops the *ThenInclude* method calls for enrollment and student data. If a course is selected, the highlighted code retrieves:

- The `Enrollment` entities for the selected course.
- The `Student` entities for each `Enrollment`.

Notice the preceding code comments out `.AsNoTracking()`. Navigation properties can only be explicitly loaded for tracked entities.

Test the app. From a users perspective, the app behaves identically to the previous version.

The next tutorial shows how to update related data.

Part 7, Razor Pages with EF Core in ASP.NET Core - Update Related Data

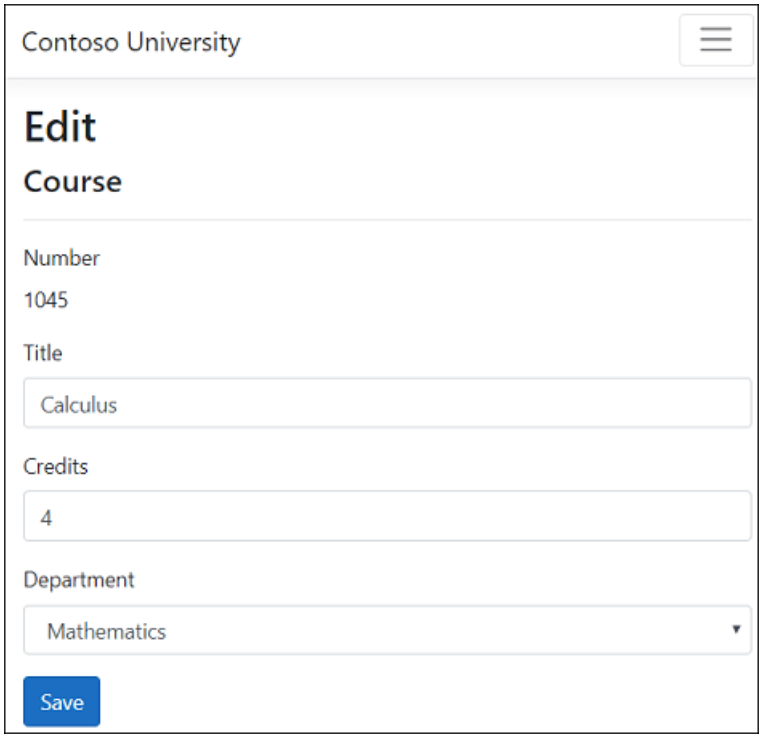
9/22/2020 • 32 minutes to read • Edit Online

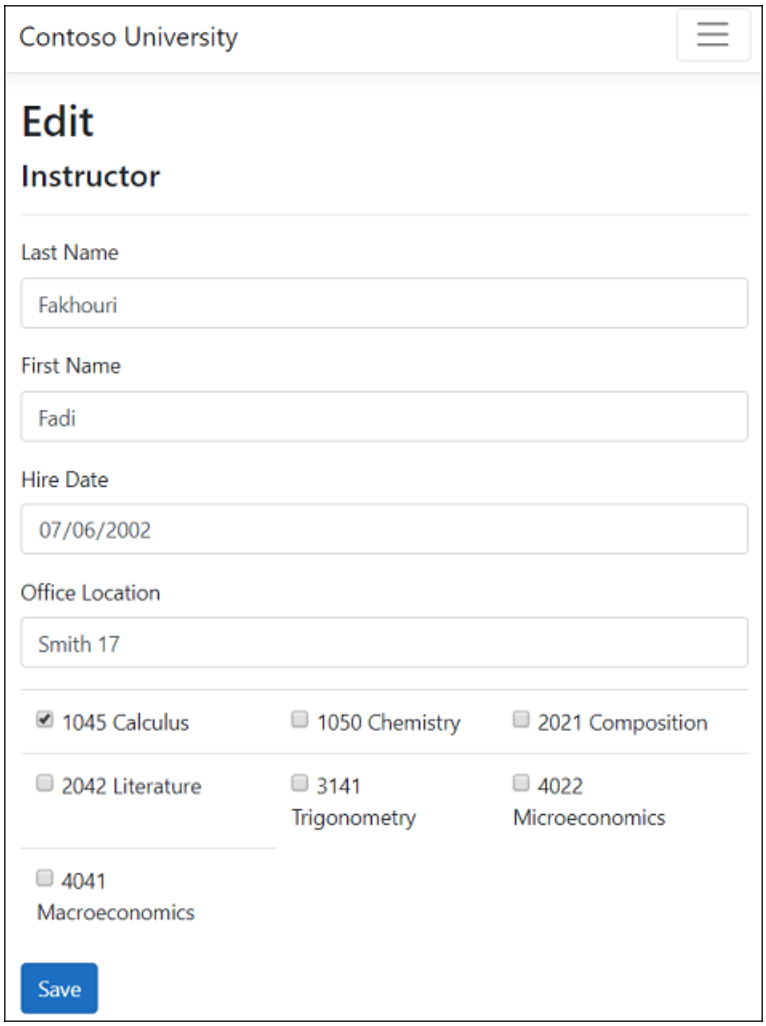
By Tom Dykstra, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to update related data. The following illustrations show some of the completed pages.





Update the Course Create and Edit pages

The scaffolded code for the Course Create and Edit pages has a Department drop-down list that shows Department ID (an integer). The drop-down should show the Department name, so both of these pages need a list of department names. To provide that list, use a base class for the Create and Edit pages.

Create a base class for Course Create and Edit

Create a *Pages/Courses/DepartmentNamePageModel.cs* file with the following code:

```
using ContosoUniversity.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;

namespace ContosoUniversity.Pages.Courses
{
    public class DepartmentNamePageModel : PageModel
    {
        public SelectList DepartmentNameSL { get; set; }

        public void PopulateDepartmentsDropDownList(SchoolContext _context,
            object selectedDepartment = null)
        {
            var departmentsQuery = from d in _context.Departments
                                   orderby d.Name // Sort by name.
                                   select d;

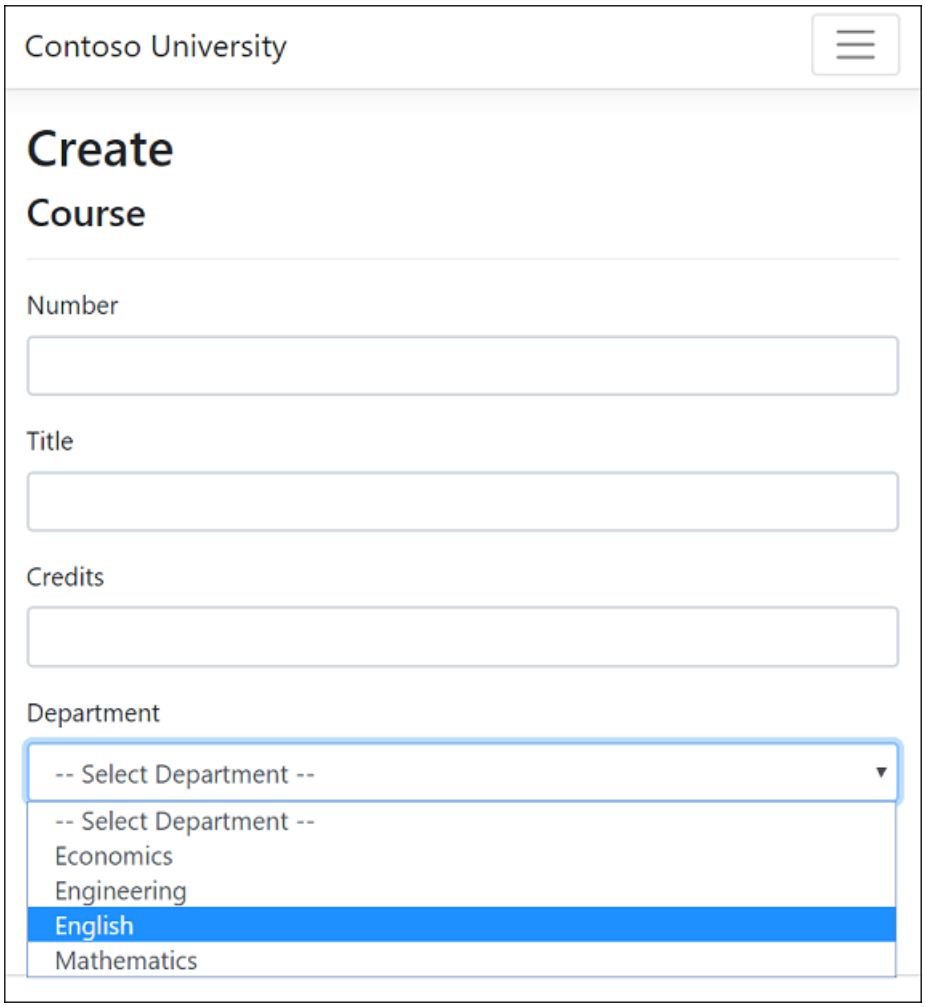
            DepartmentNameSL = new SelectList(departmentsQuery.AsNoTracking(),
                        "DepartmentID", "Name", selectedDepartment);
        }
    }
}
```

The preceding code creates a SelectList to contain the list of department names. If `selectedDepartment` is specified, that department is selected in the `SelectList`.

The Create and Edit page model classes will derive from `DepartmentNamePageModel`.

Update the Course Create page model

A Course is assigned to a Department. The base class for the Create and Edit pages provides a `SelectList` for selecting the department. The drop-down list that uses the `SelectList` sets the `Course.DepartmentID` foreign key (FK) property. EF Core uses the `Course.DepartmentID` FK to load the `Department` navigation property.



Update *Pages/Courses/Create.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class CreateModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            PopulateDepartmentsDropDownList(_context);
            return Page();
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            var emptyCourse = new Course();

            if (await TryUpdateModelAsync<Course>(
                 emptyCourse,
                 "course",   // Prefix for form value.
                 s => s.CourseID, s => s.DepartmentID, s => s.Title, s => s.Credits))
            {
                _context.Courses.Add(emptyCourse);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context, emptyCourse.DepartmentID);
            return Page();
        }
      }
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

The preceding code:

- Derives from `DepartmentNamePageModel`.
- Uses `TryUpdateModelAsync` to prevent overposting.
- Removes `ViewData["DepartmentID"]`. `DepartmentNameSL` from the base class is a strongly typed model and will be used by the Razor page. Strongly typed models are preferred over weakly typed. For more information, see Weakly typed data (ViewData and ViewBag).

Update the Course Create Razor page

Update *Pages/Courses/Create.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Courses.CreateModel
@{
    ViewData["Title"] = "Create Course";
}
<h2>Create</h2>
<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label"></label>
                <input asp-for="Course.CourseID" class="form-control" />
                <span asp-validation-for="Course.CourseID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label"></label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label"></label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL">
                    <option value="">-- Select Department --</option>
                </select>
                <span asp-validation-for="Course.DepartmentID" class="text-danger" />
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code makes the following changes:

- Changes the caption from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).
- Adds the "Select Department" option. This change renders "Select Department" in the drop-down when no department has been selected yet, rather than the first department.
- Adds a validation message when the department isn't selected.

The Razor Page uses the Select Tag Helper:

```
<div class="form-group">
    <label asp-for="Course.Department" class="control-label"></label>
    <select asp-for="Course.DepartmentID" class="form-control"
            asp-items="@Model.DepartmentNameSL">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="Course.DepartmentID" class="text-danger" />
</div>
```

Test the Create page. The Create page displays the department name rather than the department ID.

Update the Course Edit page model

Update *Pages/Courses/Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class EditModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                .Include(c => c.Department).FirstOrDefaultAsync(m => m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }

            // Select current DepartmentID.
            PopulateDepartmentsDropDownList(_context, Course.DepartmentID);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            var courseToUpdate = await _context.Courses.FindAsync(id);

            if (courseToUpdate == null)
            {
                return NotFound();
            }
```

```
            }

            if (await TryUpdateModelAsync<Course>(
                 courseToUpdate,
                 "course",   // Prefix for form value.
                   c => c.Credits, c => c.DepartmentID, c => c.Title))
            {
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context, courseToUpdate.DepartmentID);
            return Page();
        }
    }
}
```

The changes are similar to those made in the Create page model. In the preceding code, `PopulateDepartmentsDropDownList` passes in the department ID, which selects that department in the drop-down list.

Update the Course Edit Razor page

Update *Pages/Courses/Edit.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Courses.EditModel

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Course.CourseID" />
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label"></label>
                <div>@Html.DisplayFor(model => model.Course.CourseID)</div>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label"></label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label"></label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL"></select>
                <span asp-validation-for="Course.DepartmentID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code makes the following changes:

- Displays the course ID. Generally the Primary Key (PK) of an entity isn't displayed. PKs are usually meaningless to users. In this case, the PK is the course number.
- Changes the caption for the Department drop-down from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).

The page contains a hidden field (`<input type="hidden">`) for the course number. Adding a `<label>` tag helper with `asp-for="Course.CourseID"` doesn't eliminate the need for the hidden field. `<input type="hidden">` is required for the course number to be included in the posted data when the user clicks **Save**.

Update the Course Details and Delete pages

AsNoTracking can improve performance when tracking isn't required.

Update the Course page models

Update *Pages/Courses/Delete.cshtml.cs* with the following code to add `AsNoTracking`:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                .AsNoTracking()
                .Include(c => c.Department)
                .FirstOrDefaultAsync(m => m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses.FindAsync(id);

            if (Course != null)
            {
                _context.Courses.Remove(Course);
                await _context.SaveChangesAsync();
            }

            return RedirectToPage("./Index");
        }
    }
}
```

Make the same change in the *Pages/Courses/Details.cshtml.cs* file:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class DetailsModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DetailsModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                 .AsNoTracking()
                 .Include(c => c.Department)
                 .FirstOrDefaultAsync(m => m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }
            return Page();
        }
    }
}
```

Update the Course Razor pages

Update *Pages/Courses/Delete.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Courses.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Department.Name)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Course.CourseID" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Make the same changes to the Details page.

```
@page
@model ContosoUniversity.Pages.Courses.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h2>Details</h2>

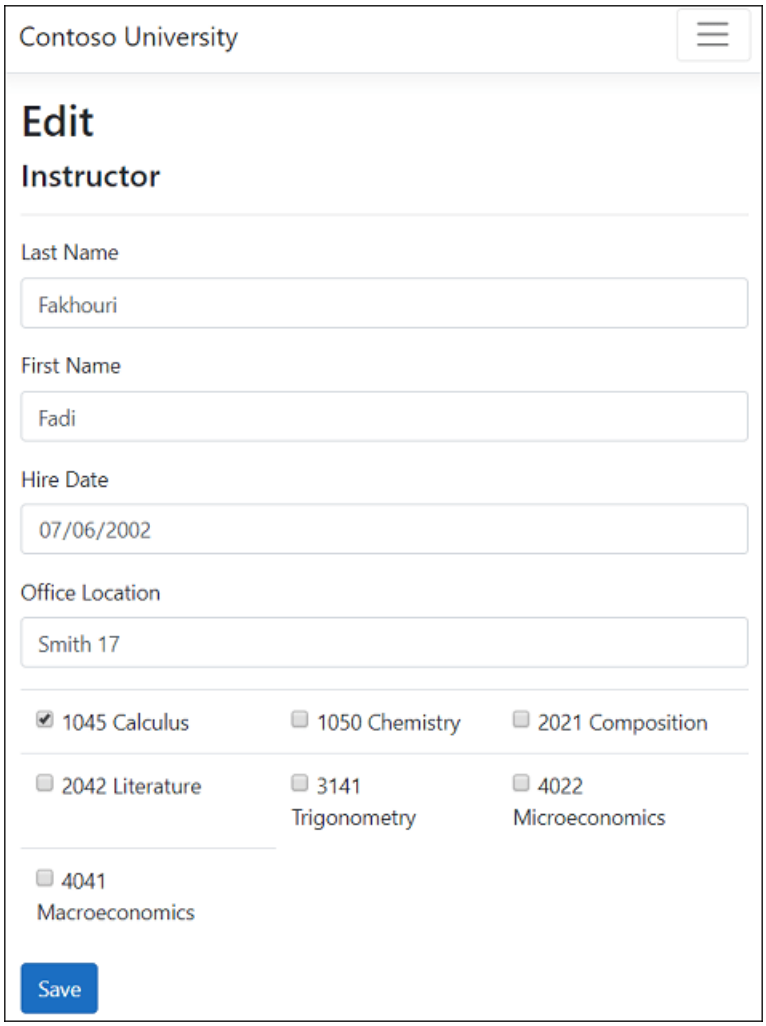
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Department.Name)
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Course.CourseID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

Test the Course pages

Test the create, edit, details, and delete pages.

Update the instructor Create and Edit pages

Instructors may teach any number of courses. The following image shows the instructor Edit page with an array of course checkboxes.



The checkboxes enable changes to courses an instructor is assigned to. A checkbox is displayed for every course in the database. Courses that the instructor is assigned to are selected. The user can select or clear checkboxes to change course assignments. If the number of courses were much greater, a different UI might work better. But the method of managing a many-to-many relationship shown here wouldn't change. To create or delete relationships, you manipulate a join entity.

Create a class for assigned courses data

Create *SchoolViewModels/AssignedCourseData.cs* with the following code:

```
namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

The `AssignedCourseData` class contains data to create the check boxes for courses assigned to an instructor.

Create an Instructor page model base class

Create the *Pages/Instructors/InstructorCoursesPageModel.cs* base class:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.AspNetCore.Mvc.RazorPages;
using System.Collections.Generic;
```

```
using System.Linq;

namespace ContosoUniversity.Pages.Instructors
{
    public class InstructorCoursesPageModel : PageModel
    {

        public List<AssignedCourseData> AssignedCourseDataList;

        public void PopulateAssignedCourseData(SchoolContext context,
                                               Instructor instructor)
        {
            var allCourses = context.Courses;
            var instructorCourses = new HashSet<int>(
                instructor.CourseAssignments.Select(c => c.CourseID));
            AssignedCourseDataList = new List<AssignedCourseData>();
            foreach (var course in allCourses)
            {
                AssignedCourseDataList.Add(new AssignedCourseData
                {
                    CourseID = course.CourseID,
                    Title = course.Title,
                    Assigned = instructorCourses.Contains(course.CourseID)
                });
            }
        }

        public void UpdateInstructorCourses(SchoolContext context,
            string[] selectedCourses, Instructor instructorToUpdate)
        {
            if (selectedCourses == null)
            {
                instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
                return;
            }

            var selectedCoursesHS = new HashSet<string>(selectedCourses);
            var instructorCourses = new HashSet<int>
                (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
            foreach (var course in context.Courses)
            {
                if (selectedCoursesHS.Contains(course.CourseID.ToString()))
                {
                    if (!instructorCourses.Contains(course.CourseID))
                    {
                        instructorToUpdate.CourseAssignments.Add(
                            new CourseAssignment
                            {
                                InstructorID = instructorToUpdate.ID,
                                CourseID = course.CourseID
                            });
                    }
                }
                else
                {
                    if (instructorCourses.Contains(course.CourseID))
                    {
                        CourseAssignment courseToRemove
                            = instructorToUpdate
                                .CourseAssignments
                                .SingleOrDefault(i => i.CourseID == course.CourseID);
                        context.Remove(courseToRemove);
                    }
                }
            }
        }
    }
}
```

The `InstructorCoursesPageModel` is the base class you will use for the Edit and Create page models. `PopulateAssignedCourseData` reads all `Course` entities to populate `AssignedCourseDataList`. For each course, the code sets the `CourseID`, title, and whether or not the instructor is assigned to the course. A HashSet is used for efficient lookups.

Since the Razor page doesn't have a collection of Course entities, the model binder can't automatically update the `CourseAssignments` navigation property. Instead of using the model binder to update the `CourseAssignments` navigation property, you do that in the new `UpdateInstructorCourses` method. Therefore you need to exclude the `CourseAssignments` property from model binding. This doesn't require any change to the code that calls `TryUpdateModel` because you're using the overload with declared properties and `CourseAssignments` isn't in the include list.

If no check boxes were selected, the code in `UpdateInstructorCourses` initializes the `CourseAssignments` navigation property with an empty collection and returns:

```
if (selectedCourses == null)
{
    instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
    return;
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the page. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the check box for a course was selected but the course isn't in the `Instructor.CourseAssignments` navigation property, the course is added to the collection in the navigation property.

```
if (selectedCoursesHS.Contains(course.CourseID.ToString()))
{
    if (!instructorCourses.Contains(course.CourseID))
    {
        instructorToUpdate.CourseAssignments.Add(
            new CourseAssignment
            {
                InstructorID = instructorToUpdate.ID,
                CourseID = course.CourseID
            });
    }
}
```

If the check box for a course wasn't selected, but the course is in the `Instructor.CourseAssignments` navigation property, the course is removed from the navigation property.

```
else
{
    if (instructorCourses.Contains(course.CourseID))
    {
        CourseAssignment courseToRemove
            = instructorToUpdate
                .CourseAssignments
                .SingleOrDefault(i => i.CourseID == course.CourseID);
        context.Remove(courseToRemove);
    }
}
```

Handle office location

Another relationship the edit page has to handle is the one-to-zero-or-one relationship that the Instructor entity has with the `OfficeAssignment` entity. The instructor edit code must handle the following scenarios:

- If the user clears the office assignment, delete the `OfficeAssignment` entity.
- If the user enters an office assignment and it was empty, create a new `OfficeAssignment` entity.
- If the user changes the office assignment, update the `OfficeAssignment` entity.

Update the Instructor Edit page model

Update *Pages/Instructors/Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class EditModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.CourseAssignments).ThenInclude(i => i.Course)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.ID == id);

            if (Instructor == null)
            {
                return NotFound();
            }
            PopulateAssignedCourseData(_context, Instructor);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id, string[] selectedCourses)
        {
            if (id == null)
            {
                return NotFound();
            }

            var instructorToUpdate = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.CourseAssignments)
                    .ThenInclude(i => i.Course)
                .FirstOrDefaultAsync(s => s.ID == id);

            if (instructorToUpdate == null)
            {
```

```
            {
                return NotFound();
            }

            if (await TryUpdateModelAsync<Instructor>(
                instructorToUpdate,
                "Instructor",
                i => i.FirstMidName, i => i.LastName,
                i => i.HireDate, i => i.OfficeAssignment))
            {
                if (String.IsNullOrWhiteSpace(
                    instructorToUpdate.OfficeAssignment?.Location))
                {
                    instructorToUpdate.OfficeAssignment = null;
                }
                UpdateInstructorCourses(_context, selectedCourses, instructorToUpdate);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            UpdateInstructorCourses(_context, selectedCourses, instructorToUpdate);
            PopulateAssignedCourseData(_context, instructorToUpdate);
            return Page();
        }
    }
}
```

The preceding code:

- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment`, `CourseAssignment`, and `CourseAssignment.Course` navigation properties.
- Updates the retrieved `Instructor` entity with values from the model binder. `TryUpdateModel` prevents overposting.
- If the office location is blank, sets `Instructor.OfficeAssignment` to null. When `Instructor.OfficeAssignment` is null, the related row in the `OfficeAssignment` table is deleted.
- Calls `PopulateAssignedCourseData` in `OnGetAsync` to provide information for the checkboxes using the `AssignedCourseData` view model class.
- Calls `UpdateInstructorCourses` in `OnPostAsync` to apply information from the checkboxes to the Instructor entity being edited.
- Calls `PopulateAssignedCourseData` and `UpdateInstructorCourses` in `OnPostAsync` if `TryUpdateModel` fails. These method calls restore the assigned course data entered on the page when it is redisplayed with an error message.

Update the Instructor Edit Razor page

Update *Pages/Instructors/Edit.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Instructors.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Instructor.ID" />
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
            </div>
```

```
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-control" />
                <span asp-validation-for="Instructor.FirstMidName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label"></label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location" class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location" class="form-control" />
                <span asp-validation-for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="table">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                               @course.CourseID @:  @course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code creates an HTML table that has three columns. Each column has a checkbox and a caption containing the course number and title. The checkboxes all have the same name ("selectedCourses"). Using the same name informs the model binder to treat them as a group. The value attribute of each checkbox is set to `CourseID`. When the page is posted, the model binder passes an array that consists of the `CourseID` values for only the checkboxes that are selected.

When the checkboxes are initially rendered, courses assigned to the instructor are selected.

Note: The approach taken here to edit instructor course data works well when there's a limited number of courses. For collections that are much larger, a different UI and a different updating method would be more useable and

efficient.

Run the app and test the updated Instructors Edit page. Change some course assignments. The changes are reflected on the Index page.

Update the Instructor Create page

Update the Instructor Create page model and Razor page with code similar to the Edit page:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class CreateModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            var instructor = new Instructor();
            instructor.CourseAssignments = new List<CourseAssignment>();

            // Provides an empty collection for the foreach loop
            // foreach (var course in Model.AssignedCourseDataList)
            // in the Create Razor page.
            PopulateAssignedCourseData(_context, instructor);
            return Page();
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnPostAsync(string[] selectedCourses)
        {
            var newInstructor = new Instructor();
            if (selectedCourses != null)
            {
                newInstructor.CourseAssignments = new List<CourseAssignment>();
                foreach (var course in selectedCourses)
                {
                    var courseToAdd = new CourseAssignment
                    {
                        CourseID = int.Parse(course)
                    };
                    newInstructor.CourseAssignments.Add(courseToAdd);
                }
            }

            if (await TryUpdateModelAsync<Instructor>(
                newInstructor,
                "Instructor",
                i => i.FirstMidName, i => i.LastName,
                i => i.HireDate, i => i.OfficeAssignment))
            {
                _context.Instructors.Add(newInstructor);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            PopulateAssignedCourseData(_context, newInstructor);
            return Page();
        }
    }
}
```

```
@page
@model ContosoUniversity.Pages.Instructors.CreateModel
```

```
@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
            </div>
            <div class="form-group">

            </div>
            <div class="form-group">
                <div class="table">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                               @course.CourseID @:  @course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>
```

```
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Test the instructor Create page.

Update the Instructor Delete page

Update *Pages/Instructors/Delete.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor = await _context.Instructors.FirstOrDefaultAsync(m => m.ID == id);

            if (Instructor == null)
            {
                return NotFound();
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor instructor = await _context.Instructors
                .Include(i => i.CourseAssignments)
                .SingleAsync(i => i.ID == id);

            if (instructor == null)
            {
                return RedirectToPage("./Index");
            }

            var departments = await _context.Departments
                .Where(d => d.InstructorID == id)
                .ToListAsync();
            departments.ForEach(d => d.InstructorID = null);

            _context.Instructors.Remove(instructor);

            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }
    }
}
```

The preceding code makes the following changes:

- Uses eager loading for the `CourseAssignments` navigation property. `CourseAssignments` must be included or they aren't deleted when the instructor is deleted. To avoid needing to read them, configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

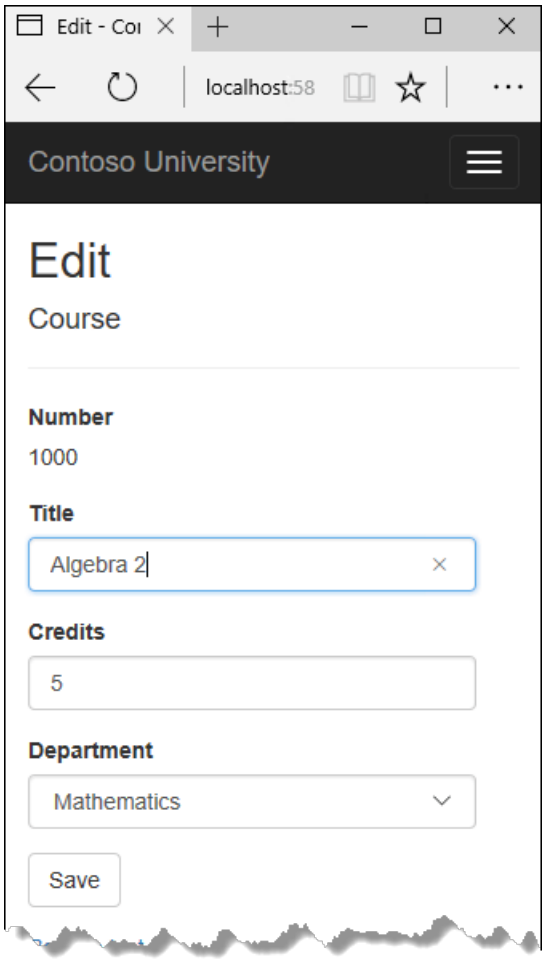
Run the app and test the Delete page.

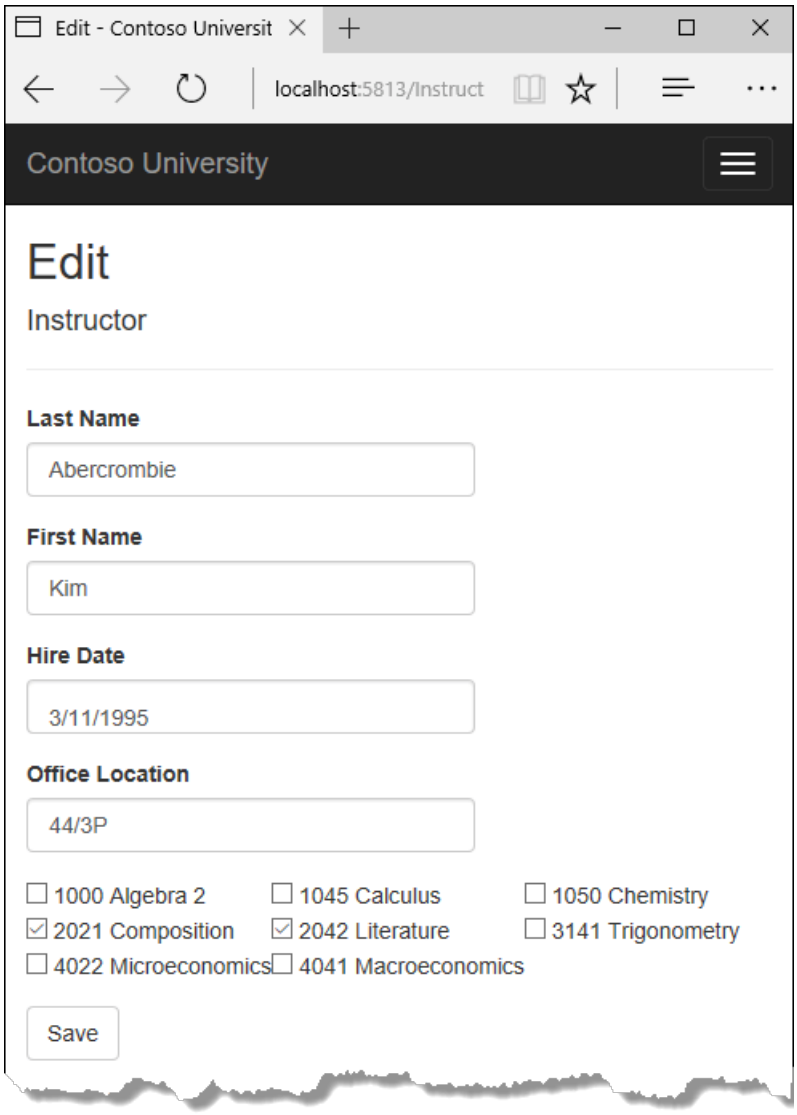
Next steps

PREVIOUS TUTORIAL NEXT TUTORIAL

This tutorial demonstrates updating related data. If you run into problems you can't solve, download or view the completed app. Download instructions.

The following illustrations shows some of the completed pages.





Examine and test the Create and Edit course pages. Create a new course. The department is selected by its primary key (an integer), not its name. Edit the new course. When you have finished testing, delete the new course.

Create a base class to share common code

The Courses/Create and Courses/Edit pages each need a list of department names. Create the *Pages/Courses/DepartmentNamePageModel.cshtml.cs* base class for the Create and Edit pages:

```
using ContosoUniversity.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;

namespace ContosoUniversity.Pages.Courses
{
    public class DepartmentNamePageModel : PageModel
    {
        public SelectList DepartmentNameSL { get; set; }

        public void PopulateDepartmentsDropDownList(SchoolContext _context,
            object selectedDepartment = null)
        {
            var departmentsQuery = from d in _context.Departments
                                   orderby d.Name // Sort by name.
                                   select d;

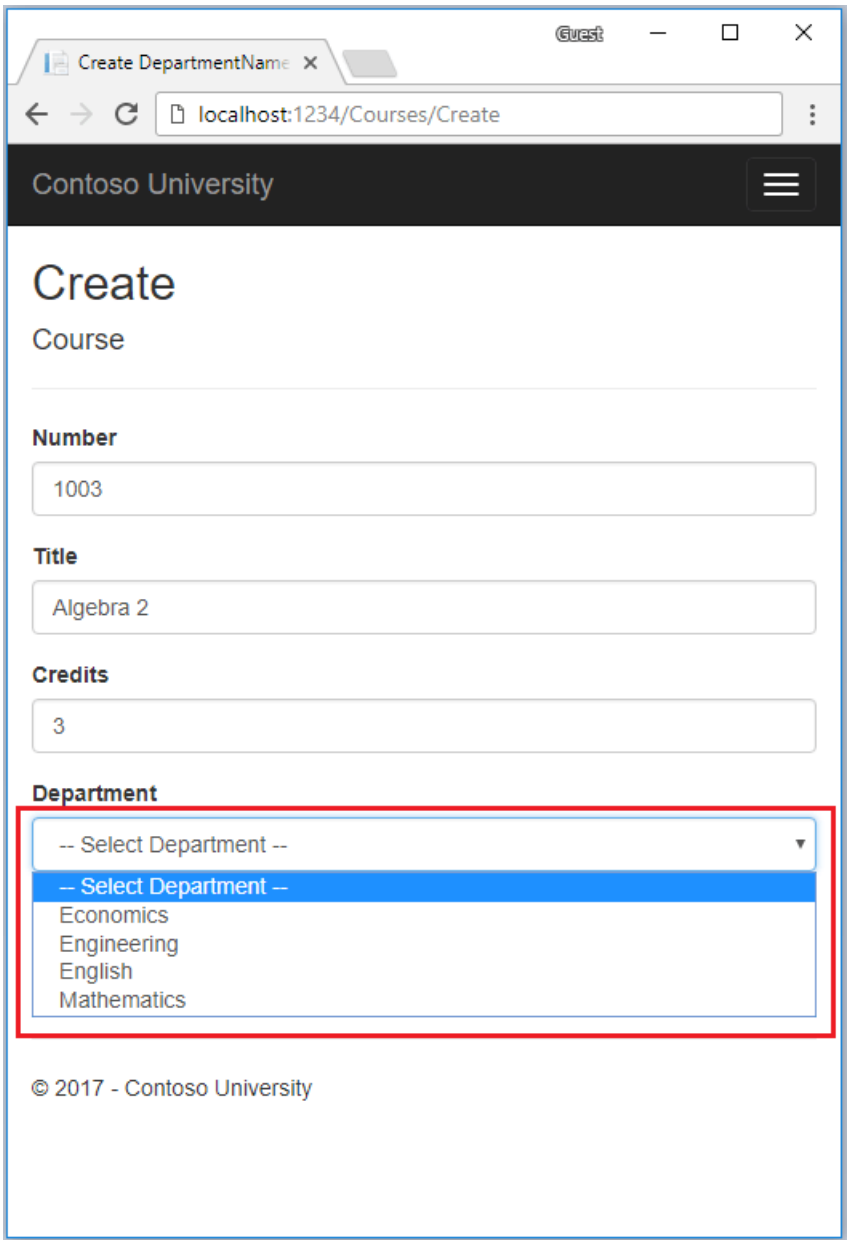
            DepartmentNameSL = new SelectList(departmentsQuery.AsNoTracking(),
                        "DepartmentID", "Name", selectedDepartment);
        }
    }
}
```

The preceding code creates a SelectList to contain the list of department names. If `selectedDepartment` is specified, that department is selected in the `SelectList`.

The Create and Edit page model classes will derive from `DepartmentNamePageModel`.

Customize the Courses Pages

When a new course entity is created, it must have a relationship to an existing department. To add a department while creating a course, the base class for Create and Edit contains a drop-down list for selecting the department. The drop-down list sets the `Course.DepartmentID` foreign key (FK) property. EF Core uses the `Course.DepartmentID` FK to load the `Department` navigation property.



Update the Create page model with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class CreateModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            PopulateDepartmentsDropDownList(_context);
            return Page();
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var emptyCourse = new Course();

            if (await TryUpdateModelAsync<Course>(
                 emptyCourse,
                 "course",   // Prefix for form value.
                 s => s.CourseID, s => s.DepartmentID, s => s.Title, s => s.Credits))
            {
                _context.Courses.Add(emptyCourse);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context, emptyCourse.DepartmentID);
            return Page();
        }
      }
}
```

The preceding code:

- Derives from `DepartmentNamePageModel`.
- Uses `TryUpdateModelAsync` to prevent overposting.
- Replaces `ViewData["DepartmentID"]` with `DepartmentNameSL` (from the base class).

`ViewData["DepartmentID"]` is replaced with the strongly typed `DepartmentNameSL`. Strongly typed models are preferred over weakly typed. For more information, see Weakly typed data (ViewData and ViewBag).

Update the Courses Create page

Update *Pages/Courses/Create.cshtml* with the following code:

```
@page
@model ContosoUniversity.Pages.Courses.CreateModel
@{
    ViewData["Title"] = "Create Course";
}
<h2>Create</h2>
<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label"></label>
                <input asp-for="Course.CourseID" class="form-control" />
                <span asp-validation-for="Course.CourseID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label"></label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label"></label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL">
                    <option value="">-- Select Department --</option>
                </select>
                <span asp-validation-for="Course.DepartmentID" class="text-danger" />
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding markup makes the following changes:

- Changes the caption from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).
- Adds the "Select Department" option. This change renders "Select Department" rather than the first department.
- Adds a validation message when the department isn't selected.

The Razor Page uses the Select Tag Helper:

```
<div class="form-group">
    <label asp-for="Course.Department" class="control-label"></label>
    <select asp-for="Course.DepartmentID" class="form-control"
            asp-items="@Model.DepartmentNameSL">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="Course.DepartmentID" class="text-danger" />
</div>
```

Test the Create page. The Create page displays the department name rather than the department ID.

Update the Courses Edit page.

Replace the code in *Pages/Courses/Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class EditModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                .Include(c => c.Department).FirstOrDefaultAsync(m => m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }

            // Select current DepartmentID.
            PopulateDepartmentsDropDownList(_context,Course.DepartmentID);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var courseToUpdate = await _context.Courses.FindAsync(id);

            if (await TryUpdateModelAsync<Course>(
                 courseToUpdate,
                 "course",   // Prefix for form value.
                   c => c.Credits, c => c.DepartmentID, c => c.Title))
            {
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context, courseToUpdate.DepartmentID);
            return Page();
        }
    }
}
```

The changes are similar to those made in the Create page model. In the preceding code, `PopulateDepartmentsDropDownList` passes in the department ID, which select the department specified in the drop-

down list.

Update *Pages/Courses/Edit.cshtml* with the following markup:

```
@page
@model ContosoUniversity.Pages.Courses.EditModel

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Course.CourseID" />
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label"></label>
                <div>@Html.DisplayFor(model => model.Course.CourseID)</div>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label"></label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label"></label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL"></select>
                <span asp-validation-for="Course.DepartmentID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding markup makes the following changes:

- Displays the course ID. Generally the Primary Key (PK) of an entity isn't displayed. PKs are usually meaningless to users. In this case, the PK is the course number.
- Changes the caption from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).

The page contains a hidden field (`<input type="hidden">`) for the course number. Adding a `<label>` tag helper with `asp-for="Course.CourseID"` doesn't eliminate the need for the hidden field. `<input type="hidden">` is required for

the course number to be included in the posted data when the user clicks **Save**.

Test the updated code. Create, edit, and delete a course.

Add AsNoTracking to the Details and Delete page models

AsNoTracking can improve performance when tracking isn't required. Add `AsNoTracking` to the Delete and Details page model. The following code shows the updated Delete page model:

```
public class DeleteModel : PageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public DeleteModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Course Course { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Course = await _context.Courses
            .AsNoTracking()
            .Include(c => c.Department)
            .FirstOrDefaultAsync(m => m.CourseID == id);

        if (Course == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Course = await _context.Courses
            .AsNoTracking()
            .FirstOrDefaultAsync(m => m.CourseID == id);

        if (Course != null)
        {
            _context.Courses.Remove(Course);
            await _context.SaveChangesAsync();
        }

        return RedirectToPage("./Index");
    }
}
```

Update the `OnGetAsync` method in the *Pages/Courses/Details.cshtml.cs* file:

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Course = await _context.Courses
         .AsNoTracking()
         .Include(c => c.Department)
         .FirstOrDefaultAsync(m => m.CourseID == id);

    if (Course == null)
    {
        return NotFound();
    }
    return Page();
}
```

Modify the Delete and Details pages

Update the Delete Razor page with the following markup:

```
@page
@model ContosoUniversity.Pages.Courses.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Course.Department.DepartmentID)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Course.CourseID" />
        <input type="submit" value="Delete" class="btn btn-default" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Make the same changes to the Details page.

Test the Course pages

Test create, edit, details, and delete.

Update the instructor pages

The following sections update the instructor pages.

Add office location

When editing an instructor record, you may want to update the instructor's office assignment. The `Instructor` entity has a one-to-zero-or-one relationship with the `OfficeAssignment` entity. The instructor code must handle:

- If the user clears the office assignment, delete the `OfficeAssignment` entity.
- If the user enters an office assignment and it was empty, create a new `OfficeAssignment` entity.

- If the user changes the office assignment, update the `OfficeAssignment` entity.

Update the instructors Edit page model with the following code:

```
public class EditModel : PageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public EditModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Instructor Instructor { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Instructor = await _context.Instructors
            .Include(i => i.OfficeAssignment)
            .AsNoTracking()
            .FirstOrDefaultAsync(m => m.ID == id);

        if (Instructor == null)
        {
            return NotFound();
        }
        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int? id)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        var instructorToUpdate = await _context.Instructors
            .Include(i => i.OfficeAssignment)
            .FirstOrDefaultAsync(s => s.ID == id);

        if (await TryUpdateModelAsync<Instructor>(
            instructorToUpdate,
            "Instructor",
            i => i.FirstMidName, i => i.LastName,
            i => i.HireDate, i => i.OfficeAssignment))
        {
            if (String.IsNullOrWhiteSpace(
                instructorToUpdate.OfficeAssignment?.Location))
            {
                instructorToUpdate.OfficeAssignment = null;
            }
            await _context.SaveChangesAsync();
        }
        return RedirectToPage("./Index");

    }
}
```

The preceding code:

- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment` navigation property.
- Updates the retrieved `Instructor` entity with values from the model binder. `TryUpdateModel` prevents overposting.
- If the office location is blank, sets `Instructor.OfficeAssignment` to null. When `Instructor.OfficeAssignment` is null, the related row in the `OfficeAssignment` table is deleted.

Update the instructor Edit page

Update *Pages/Instructors/Edit.cshtml* with the office location:

```
@page
@model ContosoUniversity.Pages.Instructors.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Instructor.ID" />
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-control" />
                <span asp-validation-for="Instructor.FirstMidName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label"></label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location" class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location" class="form-control" />
                <span asp-validation-for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

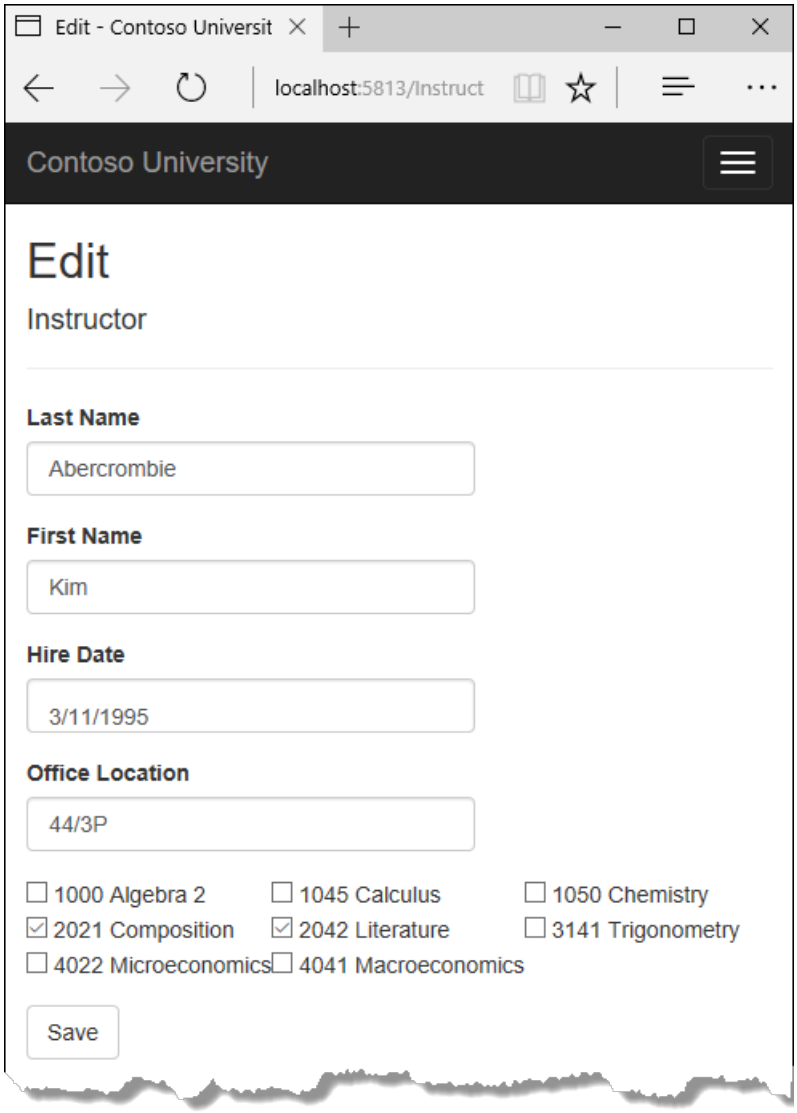
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Verify you can change an instructors office location.

Add Course assignments to the instructor Edit page

Instructors may teach any number of courses. In this section, you add the ability to change course assignments. The

following image shows the updated instructor Edit page:



`Course` and `Instructor` has a many-to-many relationship. To add and remove relationships, you add and remove entities from the `CourseAssignments` join entity set.

Check boxes enable changes to courses an instructor is assigned to. A check box is displayed for every course in the database. Courses that the instructor is assigned to are checked. The user can select or clear check boxes to change course assignments. If the number of courses were much greater:

- You'd probably use a different user interface to display the courses.
- The method of manipulating a join entity to create or delete relationships wouldn't change.

Add classes to support Create and Edit instructor pages

Create *SchoolViewModels/AssignedCourseData.cs* with the following code:

```
namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

The `AssignedCourseData` class contains data to create the check boxes for assigned courses by an instructor.

Create the *Pages/Instructors/InstructorCoursesPageModel.cshtml.cs* base class:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.AspNetCore.Mvc.RazorPages;
using System.Collections.Generic;
using System.Linq;

namespace ContosoUniversity.Pages.Instructors
{
    public class InstructorCoursesPageModel : PageModel
    {

        public List<AssignedCourseData> AssignedCourseDataList;

        public void PopulateAssignedCourseData(SchoolContext context,
                                               Instructor instructor)
        {
            var allCourses = context.Courses;
            var instructorCourses = new HashSet<int>(
                instructor.CourseAssignments.Select(c => c.CourseID));
            AssignedCourseDataList = new List<AssignedCourseData>();
            foreach (var course in allCourses)
            {
                AssignedCourseDataList.Add(new AssignedCourseData
                {
                    CourseID = course.CourseID,
                    Title = course.Title,
                    Assigned = instructorCourses.Contains(course.CourseID)
                });
            }
        }

        public void UpdateInstructorCourses(SchoolContext context,
            string[] selectedCourses, Instructor instructorToUpdate)
        {
            if (selectedCourses == null)
            {
                instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
                return;
            }

            var selectedCoursesHS = new HashSet<string>(selectedCourses);
            var instructorCourses = new HashSet<int>
                (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
            foreach (var course in context.Courses)
            {
                if (selectedCoursesHS.Contains(course.CourseID.ToString()))
                {
                    if (!instructorCourses.Contains(course.CourseID))
                    {
                        instructorToUpdate.CourseAssignments.Add(
                            new CourseAssignment
                            {
                                InstructorID = instructorToUpdate.ID,
                                CourseID = course.CourseID
                            });
                    }
                }
                else
                {
                    if (instructorCourses.Contains(course.CourseID))
                    {
                        CourseAssignment courseToRemove
                            = instructorToUpdate
                                .CourseAssignments
                                .SingleOrDefault(i => i.CourseID == course.CourseID);
```

```
                        context.Remove(courseToRemove);
                    }
                }
            }
        }
    }
}
```

The `InstructorCoursesPageModel` is the base class you will use for the Edit and Create page models. `PopulateAssignedCourseData` reads all `Course` entities to populate `AssignedCourseDataList`. For each course, the code sets the `CourseID`, title, and whether or not the instructor is assigned to the course. A HashSet is used to create efficient lookups.

Instructors Edit page model

Update the instructor Edit page model with the following code:

```
public class EditModel : InstructorCoursesPageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public EditModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Instructor Instructor { get; set; }

    public async Task<IActionResult> OnGetAsync(int? id)
    {
        if (id == null)
        {
            return NotFound();
        }

        Instructor = await _context.Instructors
            .Include(i => i.OfficeAssignment)
            .Include(i => i.CourseAssignments).ThenInclude(i => i.Course)
            .AsNoTracking()
            .FirstOrDefaultAsync(m => m.ID == id);

        if (Instructor == null)
        {
            return NotFound();
        }
        PopulateAssignedCourseData(_context, Instructor);
        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int? id, string[] selectedCourses)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        var instructorToUpdate = await _context.Instructors
            .Include(i => i.OfficeAssignment)
            .Include(i => i.CourseAssignments)
                .ThenInclude(i => i.Course)
            .FirstOrDefaultAsync(s => s.ID == id);

        if (await TryUpdateModelAsync<Instructor>(
            instructorToUpdate,
            "Instructor",
            i => i.FirstMidName, i => i.LastName,
            i => i.HireDate, i => i.OfficeAssignment))
        {
            if (String.IsNullOrWhiteSpace(
                instructorToUpdate.OfficeAssignment?.Location))
            {
                instructorToUpdate.OfficeAssignment = null;
            }
            UpdateInstructorCourses(_context, selectedCourses, instructorToUpdate);
            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }
        UpdateInstructorCourses(_context, selectedCourses, instructorToUpdate);
        PopulateAssignedCourseData(_context, instructorToUpdate);
        return Page();
    }
}
```

The preceding code handles office assignment changes.

Update the instructor Razor View:

```
@page
@model ContosoUniversity.Pages.Instructors.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Instructor.ID" />
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-control" />
                <span asp-validation-for="Instructor.FirstMidName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label"></label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location" class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location" class="form-control" />
                <span asp-validation-for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="col-md-offset-2 col-md-10">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                               @course.CourseID @:  @course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
```

```
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

> **NOTE**
>
> When you paste the code in Visual Studio, line breaks are changed in a way that breaks the code. Press Ctrl+Z one time to undo the automatic formatting. Ctrl+Z fixes the line breaks so that they look like what you see here. The indentation doesn't have to be perfect, but the `@:</tr><tr>`, `@:<td>`, `@:</td>`, and `@:</tr>` lines must each be on a single line as shown. With the block of new code selected, press Tab three times to line up the new code with the existing code. Vote on or review the status of this bug with this link.

The preceding code creates an HTML table that has three columns. Each column has a check box and a caption containing the course number and title. The check boxes all have the same name ("selectedCourses"). Using the same name informs the model binder to treat them as a group. The value attribute of each check box is set to `CourseID`. When the page is posted, the model binder passes an array that consists of the `CourseID` values for only the check boxes that are selected.

When the check boxes are initially rendered, courses assigned to the instructor have checked attributes.

Run the app and test the updated instructors Edit page. Change some course assignments. The changes are reflected on the Index page.

Note: The approach taken here to edit instructor course data works well when there's a limited number of courses. For collections that are much larger, a different UI and a different updating method would be more useable and efficient.

Update the instructors Create page

Update the instructor Create page model with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class CreateModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
        {
            var instructor = new Instructor();
            instructor.CourseAssignments = new List<CourseAssignment>();

            // Provides an empty collection for the foreach loop
            // foreach (var course in Model.AssignedCourseDataList)
            // in the Create Razor page.
            PopulateAssignedCourseData( context, instructor);
```

```
            return Page();
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnPostAsync(string[] selectedCourses)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var newInstructor = new Instructor();
            if (selectedCourses != null)
            {
                newInstructor.CourseAssignments = new List<CourseAssignment>();
                foreach (var course in selectedCourses)
                {
                    var courseToAdd = new CourseAssignment
                    {
                        CourseID = int.Parse(course)
                    };
                    newInstructor.CourseAssignments.Add(courseToAdd);
                }
            }

            if (await TryUpdateModelAsync<Instructor>(
                newInstructor,
                "Instructor",
                i => i.FirstMidName, i => i.LastName,
                i => i.HireDate, i => i.OfficeAssignment))
            {
                _context.Instructors.Add(newInstructor);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            PopulateAssignedCourseData(_context, newInstructor);
            return Page();
        }
    }
}
```

The preceding code is similar to the *Pages/Instructors/Edit.cshtml.cs* code.

Update the instructor Create Razor page with the following markup:

```
@page
@model ContosoUniversity.Pages.Instructors.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label"></label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-danger"></span>
            </div>
```

```
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-control" />
                <span asp-validation-for="Instructor.FirstMidName" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label"></label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-danger"></span>
            </div>

            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location" class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location" class="form-control" />
                <span asp-validation-for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="col-md-offset-2 col-md-10">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                               @course.CourseID @:  @course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Test the instructor Create page.

Update the Delete page

Update the Delete page model with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor = await _context.Instructors.SingleAsync(m => m.ID == id);

            if (Instructor == null)
            {
                return NotFound();
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            Instructor instructor = await _context.Instructors
                .Include(i => i.CourseAssignments)
                .SingleAsync(i => i.ID == id);

            var departments = await _context.Departments
                .Where(d => d.InstructorID == id)
                .ToListAsync();
            departments.ForEach(d => d.InstructorID = null);

            _context.Instructors.Remove(instructor);

            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }
    }
}
```

The preceding code makes the following changes:

- Uses eager loading for the `CourseAssignments` navigation property. `CourseAssignments` must be included or they aren't deleted when the instructor is deleted. To avoid needing to read them, configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

Part 8, Razor Pages with EF Core in ASP.NET Core - Concurrency

9/22/2020 • 36 minutes to read • Edit Online

By Rick Anderson, Tom Dykstra, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to handle conflicts when multiple users update an entity concurrently (at the same time).

Concurrency conflicts

A concurrency conflict occurs when:

- A user navigates to the edit page for an entity.
- Another user updates the same entity before the first user's change is written to the database.

If concurrency detection isn't enabled, whoever updates the database last overwrites the other user's changes. If this risk is acceptable, the cost of programming for concurrency might outweigh the benefit.

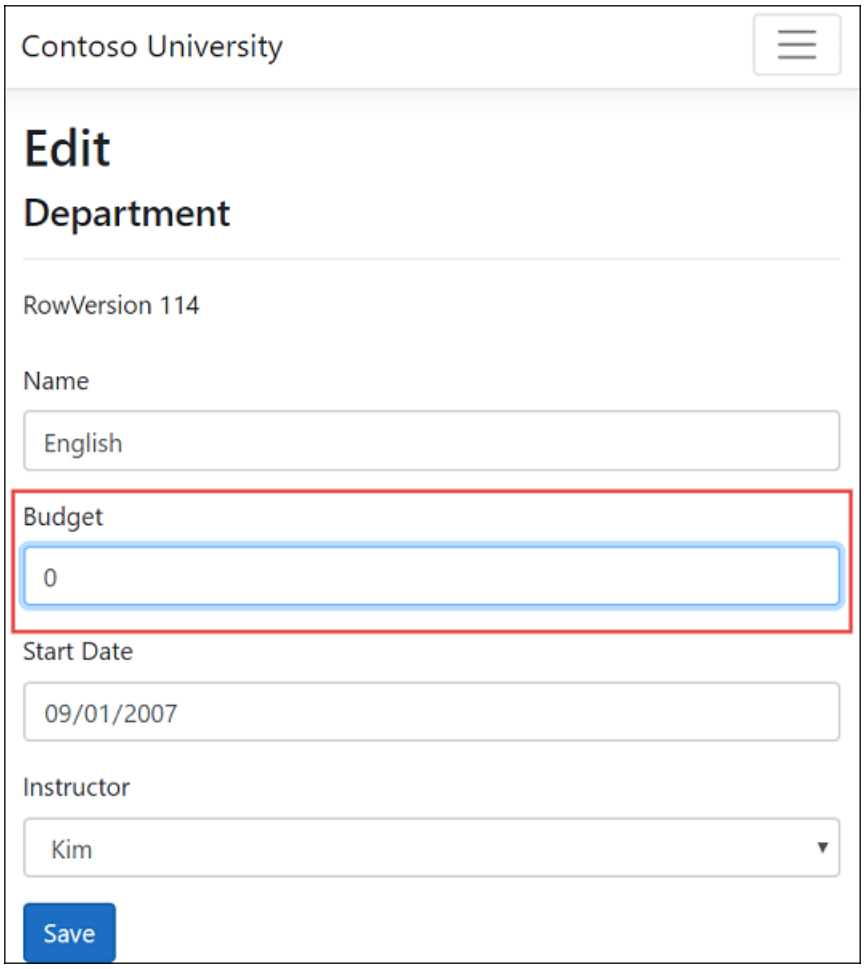
Pessimistic concurrency (locking)

One way to prevent concurrency conflicts is to use database locks. This is called pessimistic concurrency. Before the app reads a database row that it intends to update, it requests a lock. Once a row is locked for update access, no other users are allowed to lock the row until the first lock is released.

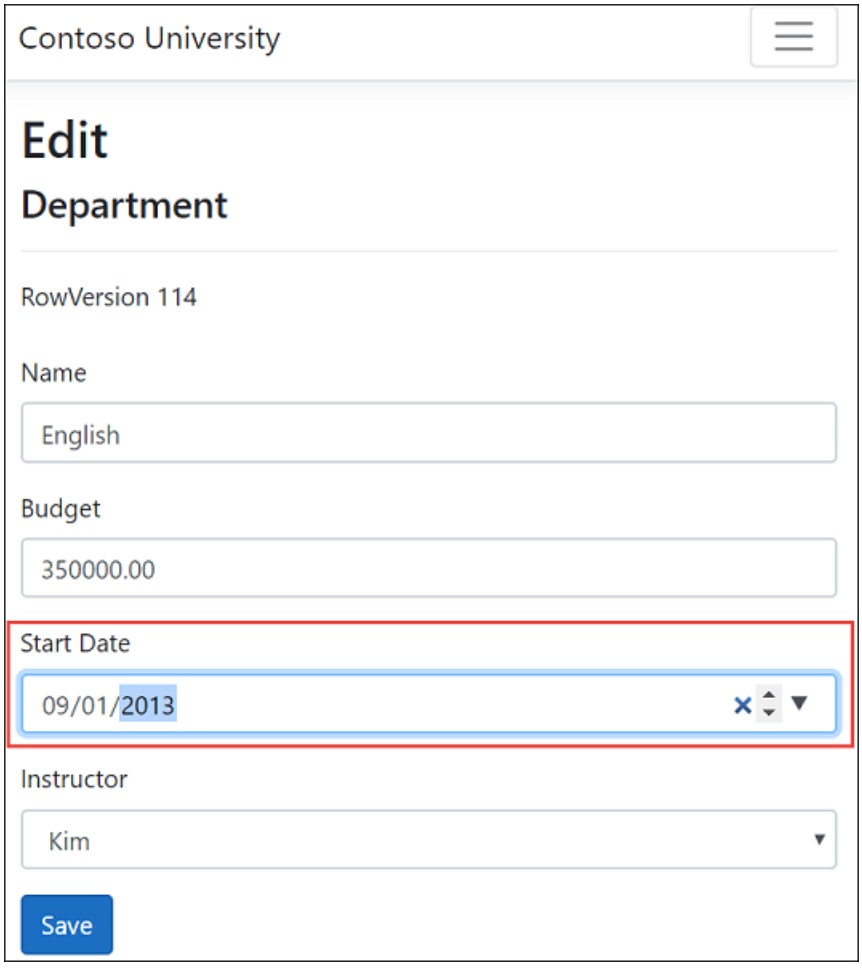
Managing locks has disadvantages. It can be complex to program and can cause performance problems as the number of users increases. Entity Framework Core provides no built-in support for it, and this tutorial doesn't show how to implement it.

Optimistic concurrency

Optimistic concurrency allows concurrency conflicts to happen, and then reacts appropriately when they do. For example, Jane visits the Department edit page and changes the budget for the English department from $350,000.00 to $0.00.



Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.



Jane clicks **Save** first and sees her change take effect, since the browser displays the Index page with zero as the

Budget amount.

John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts:

- You can keep track of which property a user has modified and update only the corresponding columns in the database.

  In the scenario, no data would be lost. Different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes. This method of updating can reduce the number of conflicts that could result in data loss. This approach has some disadvantages:

  - Can't avoid data loss if competing changes are made to the same property.
  - Is generally not practical in a web app. It requires maintaining significant state in order to keep track of all fetched values and new values. Maintaining large amounts of state can affect app performance.
  - Can increase app complexity compared to concurrency detection on an entity.
- You can let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the fetched $350,000.00 value. This approach is called a *Client Wins* or *Last in Wins* scenario. (All values from the client take precedence over what's in the data store.) If you don't do any coding for concurrency handling, Client Wins happens automatically.
- You can prevent John's change from being updated in the database. Typically, the app would:

  - Display an error message.
  - Show the current state of the data.
  - Allow the user to reapply the changes.

  This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You implement the Store Wins scenario in this tutorial. This method ensures that no changes are overwritten without a user being alerted.

Conflict detection in EF Core

EF Core throws `DbConcurrencyException` exceptions when it detects conflicts. The data model has to be configured to enable conflict detection. Options for enabling conflict detection include the following:

- Configure EF Core to include the original values of columns configured as concurrency tokens in the Where clause of Update and Delete commands.

  When `SaveChanges` is called, the Where clause looks for the original values of any properties annotated with the ConcurrencyCheckAttribute attribute. The update statement won't find a row to update if any of the concurrency token properties changed since the row was first read. EF Core interprets that as a concurrency conflict. For database tables that have many columns, this approach can result in very large Where clauses, and can require large amounts of state. Therefore this approach is generally not recommended, and it isn't the method used in this tutorial.
- In the database table, include a tracking column that can be used to determine when a row has been changed.

  In a SQL Server database, the data type of the tracking column is `rowversion`. The `rowversion` value is a sequential number that's incremented each time the row is updated. In an Update or Delete command, the Where clause includes the original value of the tracking column (the original row version number). If the row being updated has been changed by another user, the value in the `rowversion` column is different than the original value. In that case, the Update or Delete statement can't find the row to update because of the Where

clause. EF Core throws a concurrency exception when no rows are affected by an Update or Delete command.

Add a tracking property

In *Models/Department.cs*, add a tracking property named RowVersion:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
        public byte[] RowVersion { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The TimestampAttribute attribute is what identifies the column as a concurrency tracking column. The fluent API is an alternative way to specify the tracking property:

```
modelBuilder.Entity<Department>()
  .Property<byte[]>("RowVersion")
  .IsRowVersion();
```

- Visual Studio
- Visual Studio Code

For a SQL Server database, the `[Timestamp]` attribute on an entity property defined as byte array:

- Causes the column to be included in DELETE and UPDATE WHERE clauses.
- Sets the column type in the database to rowversion.

The database generates a sequential row version number that's incremented each time the row is updated. In an `Update` or `Delete` command, the `Where` clause includes the fetched row version value. If the row being updated has changed since it was fetched:

- The current row version value doesn't match the fetched value.

- The `Update` or `Delete` commands don't find a row because the `Where` clause looks for the fetched row version value.
- A `DbUpdateConcurrencyException` is thrown.

The following code shows a portion of the T-SQL generated by EF Core when the Department name is updated:

```
SET NOCOUNT ON;
UPDATE [Department] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [RowVersion] = @p2;
SELECT [RowVersion]
FROM [Department]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

The preceding highlighted code shows the `WHERE` clause containing `RowVersion`. If the database `RowVersion` doesn't equal the `RowVersion` parameter (`@p2`), no rows are updated.

The following highlighted code shows the T-SQL that verifies exactly one row was updated:

```
SET NOCOUNT ON;
UPDATE [Department] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [RowVersion] = @p2;
SELECT [RowVersion]
FROM [Department]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

@@ROWCOUNT returns the number of rows affected by the last statement. If no rows are updated, EF Core throws a `DbUpdateConcurrencyException`.

Update the database

Adding the `RowVersion` property changes the data model, which requires a migration.

Build the project.

- Visual Studio
- Visual Studio Code

- Run the following command in the PMC:

  ```
  Add-Migration RowVersion
  ```

This command:

- Creates the *Migrations/{time stamp}_RowVersion.cs* migration file.
- Updates the *Migrations/SchoolContextModelSnapshot.cs* file. The update adds the following highlighted code to the `BuildModel` method:

```
modelBuilder.Entity("ContosoUniversity.Models.Department", b =>
    {
        b.Property<int>("DepartmentID")
            .ValueGeneratedOnAdd()
            .HasAnnotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn);

        b.Property<decimal>("Budget")
            .HasColumnType("money");

        b.Property<int?>("InstructorID");

        b.Property<string>("Name")
            .HasMaxLength(50);

        b.Property<byte[]>("RowVersion")
            .IsConcurrencyToken()
            .ValueGeneratedOnAddOrUpdate();

        b.Property<DateTime>("StartDate");

        b.HasKey("DepartmentID");

        b.HasIndex("InstructorID");

        b.ToTable("Department");
    });
```

- Visual Studio
- Visual Studio Code
- Run the following command in the PMC:

```
Update-Database
```

Scaffold Department pages

- Visual Studio
- Visual Studio Code
- Follow the instructions in Scaffold Student pages with the following exceptions:
- Create a *Pages/Departments* folder.
- Use `Department` for the model class.
  - Use the existing context class instead of creating a new one.

Build the project.

Update the Index page

The scaffolding tool created a `RowVersion` column for the Index page, but that field wouldn't be displayed in a production app. In this tutorial, the last byte of the `RowVersion` is displayed to help show how concurrency handling works. The last byte isn't guaranteed to be unique by itself.

Update *Pages\Departments\Index.cshtml* page:

- Replace Index with Departments.

- Change the code containing `RowVersion` to show just the last byte of the byte array.
- Replace FirstMidName with FullName.

The following code shows the updated page:

```
@page
@model ContosoUniversity.Pages.Departments.IndexModel

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].Name)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].Budget)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].StartDate)
                </th>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].Administrator)
            </th>
            <th>
                RowVersion
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Department)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Name)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Budget)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.StartDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Administrator.FullName)
                </td>
                <td>
                    @item.RowVersion[7]
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.DepartmentID">Edit</a> |
                    <a asp-page="./Details" asp-route-id="@item.DepartmentID">Details</a> |
                    <a asp-page="./Delete" asp-route-id="@item.DepartmentID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

Update the Edit page model

Update *Pages\Departments\Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class EditModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        // Replace ViewData["InstructorID"]
        public SelectList InstructorNameSL { get; set; }

        public async Task<IActionResult> OnGetAsync(int id)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)  // eager loading
                .AsNoTracking()                 // tracking not required
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                return NotFound();
            }

            // Use strongly typed data rather than ViewData.
            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FirstMidName");

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var departmentToUpdate = await _context.Departments
                .Include(i => i.Administrator)
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (departmentToUpdate == null)
            {
                return HandleDeletedDepartment();
            }

            _context.Entry(departmentToUpdate)
                .Property("RowVersion").OriginalValue = Department.RowVersion;

            if (
```

```
            if (await TryUpdateModelAsync<Department>(
                departmentToUpdate,
                "Department",
                s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
            {
                try
                {
                    await _context.SaveChangesAsync();
                    return RedirectToPage("./Index");
                }
                catch (DbUpdateConcurrencyException ex)
                {
                    var exceptionEntry = ex.Entries.Single();
                    var clientValues = (Department)exceptionEntry.Entity;
                    var databaseEntry = exceptionEntry.GetDatabaseValues();
                    if (databaseEntry == null)
                    {
                        ModelState.AddModelError(string.Empty, "Unable to save. " +
                            "The department was deleted by another user.");
                        return Page();
                    }

                    var dbValues = (Department)databaseEntry.ToObject();
                    await setDbErrorMessage(dbValues, clientValues, _context);

                    // Save the current RowVersion so next postback
                    // matches unless an new concurrency issue happens.
                    Department.RowVersion = (byte[])dbValues.RowVersion;
                    // Clear the model error for the next postback.
                    ModelState.Remove("Department.RowVersion");
                }
            }

            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FullName", departmentToUpdate.InstructorID);

            return Page();
        }

        private IActionResult HandleDeletedDepartment()
        {
            var deletedDepartment = new Department();
            // ModelState contains the posted data because of the deletion error
            // and will overide the Department instance values when displaying Page().
            ModelState.AddModelError(string.Empty,
                "Unable to save. The department was deleted by another user.");
            InstructorNameSL = new SelectList(_context.Instructors, "ID", "FullName", Department.InstructorID);
            return Page();
        }

        private async Task setDbErrorMessage(Department dbValues,
                Department clientValues, SchoolContext context)
        {

            if (dbValues.Name != clientValues.Name)
            {
                ModelState.AddModelError("Department.Name",
                    $"Current value: {dbValues.Name}");
            }
            if (dbValues.Budget != clientValues.Budget)
            {
                ModelState.AddModelError("Department.Budget",
                    $"Current value: {dbValues.Budget:c}");
            }
            if (dbValues.StartDate != clientValues.StartDate)
            {
                ModelState.AddModelError("Department.StartDate",
                    $"Current value: {dbValues.StartDate:d}");
            }
```

```
            if (dbValues.InstructorID != clientValues.InstructorID)
            {
                Instructor dbInstructor = await _context.Instructors
                   .FindAsync(dbValues.InstructorID);
                ModelState.AddModelError("Department.InstructorID",
                    $"Current value: {dbInstructor?.FullName}");
            }

            ModelState.AddModelError(string.Empty,
                "The record you attempted to edit "
              + "was modified by another user after you. The "
              + "edit operation was canceled and the current values in the database "
              + "have been displayed. If you still want to edit this record, click "
              + "the Save button again.");
        }
    }
}
```

The OriginalValue is updated with the `rowVersion` value from the entity when it was fetched in the `OnGet` method. EF Core generates a SQL UPDATE command with a WHERE clause containing the original `RowVersion` value. If no rows are affected by the UPDATE command (no rows have the original `RowVersion` value), a `DbUpdateConcurrencyException` exception is thrown.

```
public async Task<IActionResult> OnPostAsync(int id)
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var departmentToUpdate = await _context.Departments
        .Include(i => i.Administrator)
        .FirstOrDefaultAsync(m => m.DepartmentID == id);

    if (departmentToUpdate == null)
    {
        return HandleDeletedDepartment();
    }

    _context.Entry(departmentToUpdate)
        .Property("RowVersion").OriginalValue = Department.RowVersion;
```

In the preceding highlighted code:

- The value in `Department.RowVersion` is what was in the entity when it was originally fetched in the Get request for the Edit page. The value is provided to the `OnPost` method by a hidden field in the Razor page that displays the entity to be edited. The hidden field value is copied to `Department.RowVersion` by the model binder.
- `OriginalValue` is what EF Core will use in the Where clause. Before the highlighted line of code executes, `OriginalValue` has the value that was in the database when `FirstOrDefaultAsync` was called in this method, which might be different from what was displayed on the Edit page.
- The highlighted code makes sure that EF Core uses the original `RowVersion` value from the displayed `Department` entity in the SQL UPDATE statement's Where clause.

When a concurrency error happens, the following highlighted code gets the client values (the values posted to this method) and the database values.

```
if (await TryUpdateModelAsync<Department>(
    departmentToUpdate,
    "Department",
    s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
{
    try
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateConcurrencyException ex)
    {
        var exceptionEntry = ex.Entries.Single();
        var clientValues = (Department)exceptionEntry.Entity;
        var databaseEntry = exceptionEntry.GetDatabaseValues();
        if (databaseEntry == null)
        {
            ModelState.AddModelError(string.Empty, "Unable to save. " +
                "The department was deleted by another user.");
            return Page();
        }

        var dbValues = (Department)databaseEntry.ToObject();
        await setDbErrorMessage(dbValues, clientValues, _context);

        // Save the current RowVersion so next postback
        // matches unless an new concurrency issue happens.
        Department.RowVersion = (byte[])dbValues.RowVersion;
        // Clear the model error for the next postback.
        ModelState.Remove("Department.RowVersion");
    }
```

The following code adds a custom error message for each column that has database values different from what was posted to `OnPostAsync`:

```
private async Task setDbErrorMessage(Department dbValues,
        Department clientValues, SchoolContext context)
{

    if (dbValues.Name != clientValues.Name)
    {
        ModelState.AddModelError("Department.Name",
            $"Current value: {dbValues.Name}");
    }
    if (dbValues.Budget != clientValues.Budget)
    {
        ModelState.AddModelError("Department.Budget",
            $"Current value: {dbValues.Budget:c}");
    }
    if (dbValues.StartDate != clientValues.StartDate)
    {
        ModelState.AddModelError("Department.StartDate",
            $"Current value: {dbValues.StartDate:d}");
    }
    if (dbValues.InstructorID != clientValues.InstructorID)
    {
        Instructor dbInstructor = await _context.Instructors
           .FindAsync(dbValues.InstructorID);
        ModelState.AddModelError("Department.InstructorID",
            $"Current value: {dbInstructor?.FullName}");
    }

    ModelState.AddModelError(string.Empty,
        "The record you attempted to edit "
      + "was modified by another user after you. The "
      + "edit operation was canceled and the current values in the database "
      + "have been displayed. If you still want to edit this record, click "
      + "the Save button again.");
}
```

The following highlighted code sets the `RowVersion` value to the new value retrieved from the database. The next time the user clicks **Save**, only concurrency errors that happen since the last display of the Edit page will be caught.

```
if (await TryUpdateModelAsync<Department>(
    departmentToUpdate,
    "Department",
    s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
{
    try
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateConcurrencyException ex)
    {
        var exceptionEntry = ex.Entries.Single();
        var clientValues = (Department)exceptionEntry.Entity;
        var databaseEntry = exceptionEntry.GetDatabaseValues();
        if (databaseEntry == null)
        {
            ModelState.AddModelError(string.Empty, "Unable to save. " +
                "The department was deleted by another user.");
            return Page();
        }

        var dbValues = (Department)databaseEntry.ToObject();
        await setDbErrorMessage(dbValues, clientValues, _context);

        // Save the current RowVersion so next postback
        // matches unless an new concurrency issue happens.
        Department.RowVersion = (byte[])dbValues.RowVersion;
        // Clear the model error for the next postback.
        ModelState.Remove("Department.RowVersion");
    }
```

The `ModelState.Remove` statement is required because `ModelState` has the old `RowVersion` value. In the Razor Page, the `ModelState` value for a field takes precedence over the model property values when both are present.

Update the Edit page

Update *Pages/Departments/Edit.cshtml* with the following code:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Department.DepartmentID" />
            <input type="hidden" asp-for="Department.RowVersion" />
            <div class="form-group">
                <label>RowVersion</label>
                @Model.Department.RowVersion[7]
            </div>
            <div class="form-group">
                <label asp-for="Department.Name" class="control-label"></label>
                <input asp-for="Department.Name" class="form-control" />
                <span asp-validation-for="Department.Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.Budget" class="control-label"></label>
                <input asp-for="Department.Budget" class="form-control" />
                <span asp-validation-for="Department.Budget" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.StartDate" class="control-label"></label>
                <input asp-for="Department.StartDate" class="form-control" />
                <span asp-validation-for="Department.StartDate" class="text-danger">
                </span>
            </div>
            <div class="form-group">
                <label class="control-label">Instructor</label>
                <select asp-for="Department.InstructorID" class="form-control"
                        asp-items="@Model.InstructorNameSL"></select>
                <span asp-validation-for="Department.InstructorID" class="text-danger">
                </span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="./Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds a hidden row version. `RowVersion` must be added so postback binds the value.
- Displays the last byte of `RowVersion` for debugging purposes.
- Replaces `ViewData` with the strongly-typed `InstructorNameSL`.

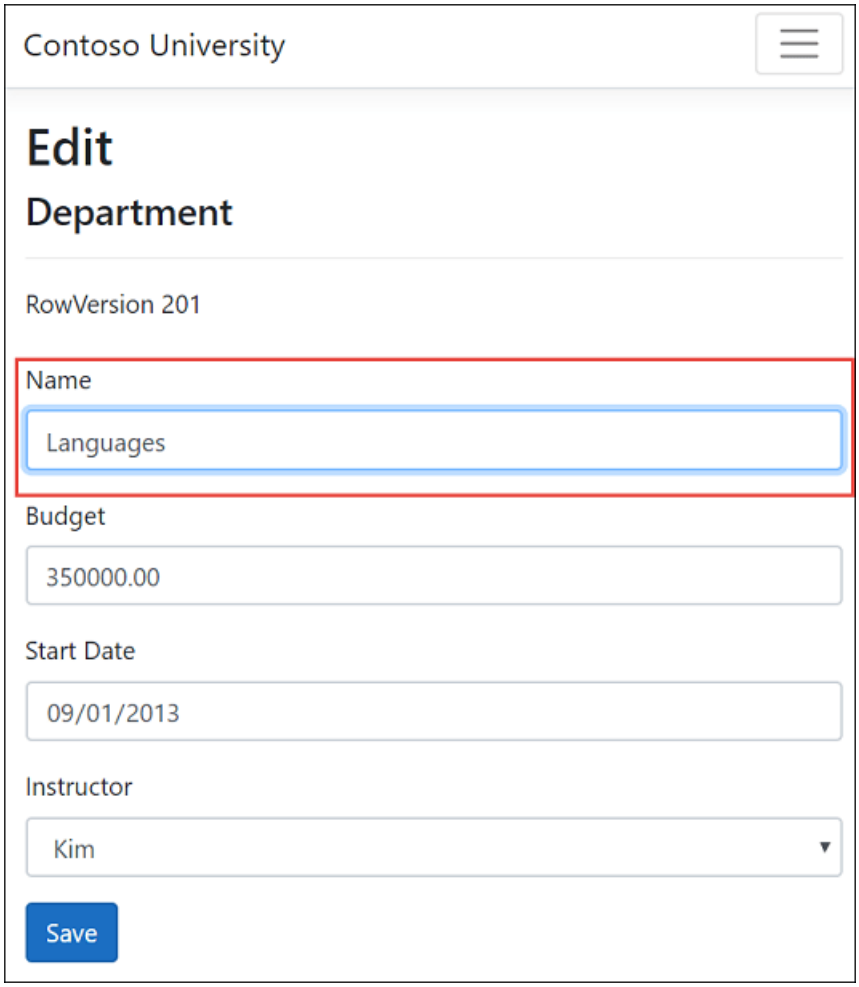
Test concurrency conflicts with the Edit page

Open two browsers instances of Edit on the English department:

- Run the app and select Departments.
- Right-click the **Edit** hyperlink for the English department and select **Open in new tab**.
- In the first tab, click the **Edit** hyperlink for the English department.

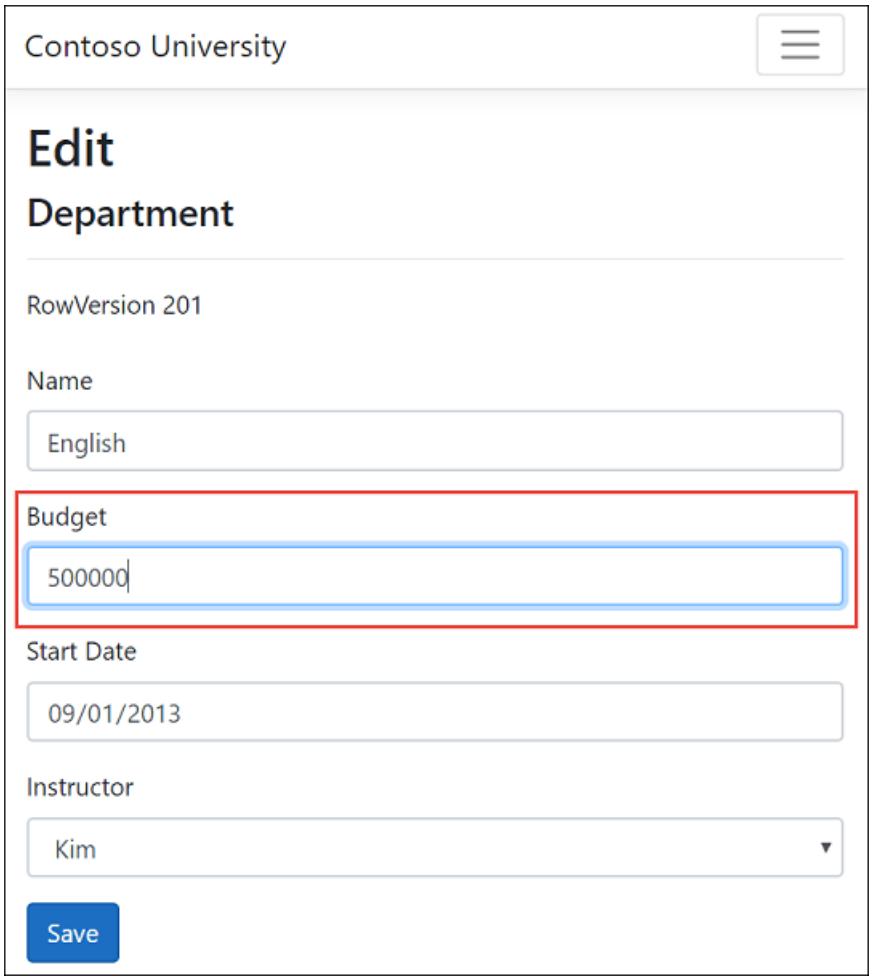
The two browser tabs display the same information.

Change the name in the first browser tab and click **Save**.

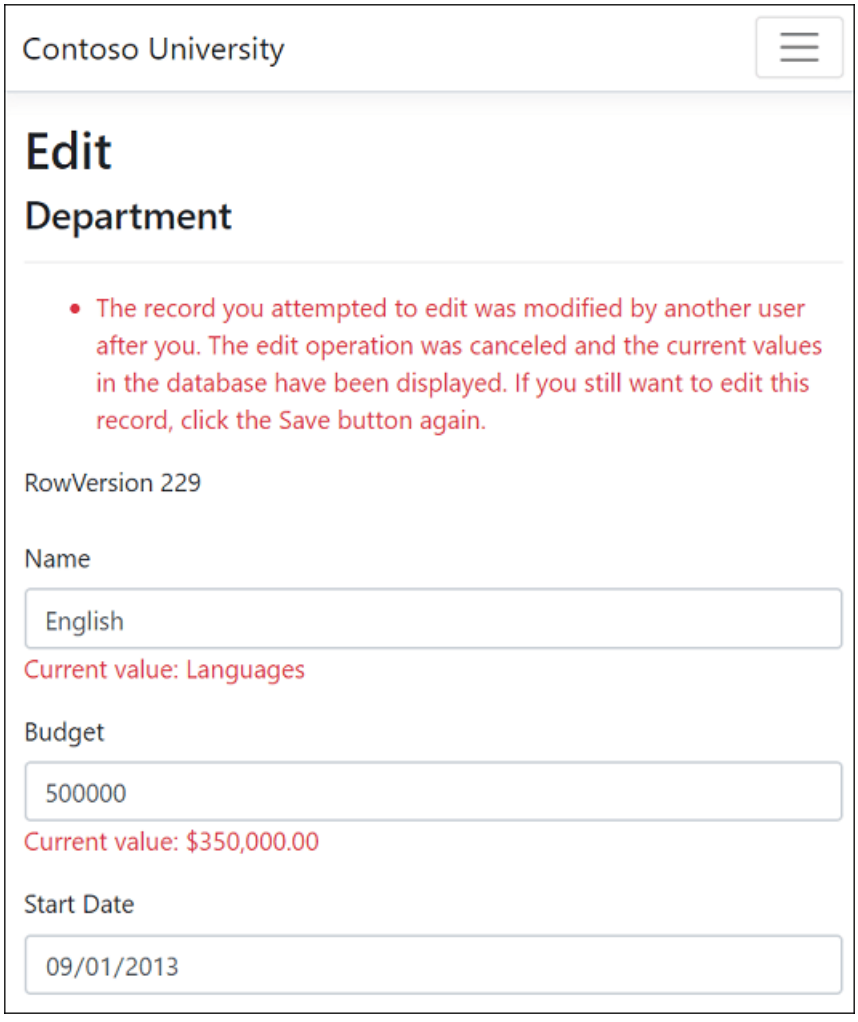


The browser shows the Index page with the changed value and updated rowVersion indicator. Note the updated rowVersion indicator, it's displayed on the second postback in the other tab.

Change a different field in the second browser tab.



Click **Save**. You see error messages for all fields that don't match the database values:



This browser window didn't intend to change the Name field. Copy and paste the current value (Languages) into the Name field. Tab out. Client-side validation removes the error message.

Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values in the Index page.

Update the Delete page model

Update *Pages/Departments/Delete.cshtml.cs* with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        public string ConcurrencyErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int id, bool? concurrencyError)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                 return NotFound();
            }

            if (concurrencyError.GetValueOrDefault())
            {
                ConcurrencyErrorMessage = "The record you attempted to delete "
                  + "was modified by another user after you selected delete. "
                  + "The delete operation was canceled and the current values in the "
                  + "database have been displayed. If you still want to delete this "
                  + "record, click the Delete button again.";
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            try
            {
                if (await _context.Departments.AnyAsync(
                    m => m.DepartmentID == id))
                {
                    // Department.rowVersion value is from when the entity
                    // was fetched. If it doesn't match the DB, a
                    // DbUpdateConcurrencyException exception is thrown.
                    _context.Departments.Remove(Department);
                    await _context.SaveChangesAsync();
```

```
                }
                return RedirectToPage("./Index");
            }
            catch (DbUpdateConcurrencyException)
            {
                return RedirectToPage("./Delete",
                    new { concurrencyError = true, id = id });
            }
        }
    }
}
```

The Delete page detects concurrency conflicts when the entity has changed after it was fetched. `Department.RowVersion` is the row version when the entity was fetched. When EF Core creates the SQL DELETE command, it includes a WHERE clause with `RowVersion`. If the SQL DELETE command results in zero rows affected:

- The `RowVersion` in the SQL DELETE command doesn't match `RowVersion` in the database.
- A DbUpdateConcurrencyException exception is thrown.
- `OnGetAsync` is called with the `concurrencyError`.

Update the Delete page

Update *Pages/Departments/Delete.cshtml* with the following code:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<p class="text-danger">@Model.ConcurrencyErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Department.Name)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.Budget)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Budget)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.StartDate)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.StartDate)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.RowVersion)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.RowVersion[7])
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.Administrator)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Administrator.FullName)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Department.DepartmentID" />
        <input type="hidden" asp-for="Department.RowVersion" />
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-danger" /> |
            <a asp-page="./Index">Back to List</a>
        </div>
</form>
</div>
```

The preceding code makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds an error message.
- Replaces FirstMidName with FullName in the **Administrator** field.
- Changes `RowVersion` to display the last byte.

- Adds a hidden row version. `RowVersion` must be added so postback binds the value.

Test concurrency conflicts

Create a test department.

Open two browsers instances of Delete on the test department:

- Run the app and select Departments.
- Right-click the **Delete** hyperlink for the test department and select **Open in new tab**.
- Click the **Edit** hyperlink for the test department.

The two browser tabs display the same information.

Change the budget in the first browser tab and click **Save**.

The browser shows the Index page with the changed value and updated rowVersion indicator. Note the updated rowVersion indicator, it's displayed on the second postback in the other tab.

Delete the test department from the second tab. A concurrency error is display with the current values from the database. Clicking **Delete** deletes the entity, unless `RowVersion` has been updated.

Next steps

This is the last tutorial in the series. Additional topics are covered in the MVC version of this tutorial series.

PREVIOUS TUTORIAL

This tutorial shows how to handle conflicts when multiple users update an entity concurrently (at the same time). If you run into problems you can't solve, download or view the completed app. Download instructions.

Concurrency conflicts

A concurrency conflict occurs when:

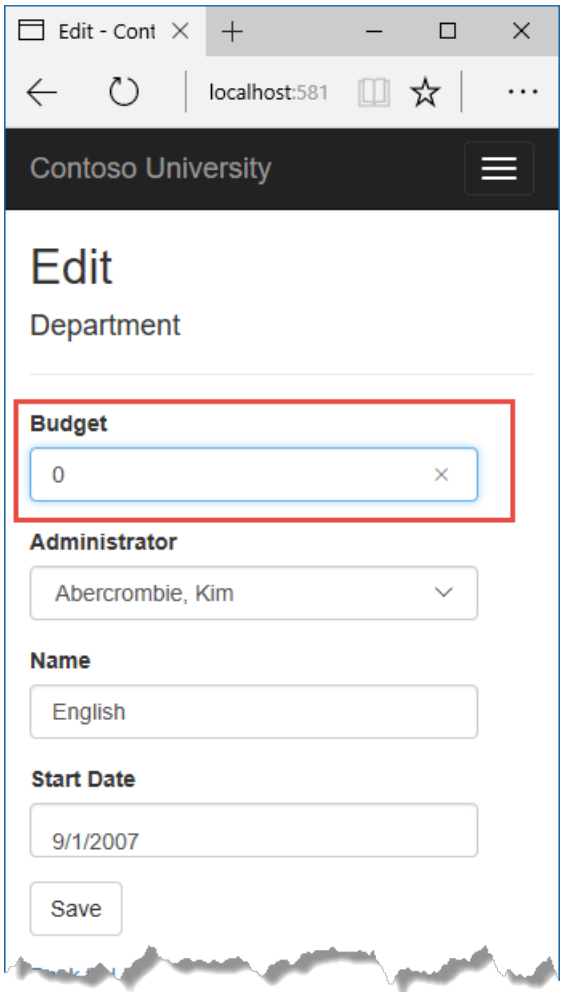
- A user navigates to the edit page for an entity.
- Another user updates the same entity before the first user's change is written to the DB.

If concurrency detection isn't enabled, when concurrent updates occur:

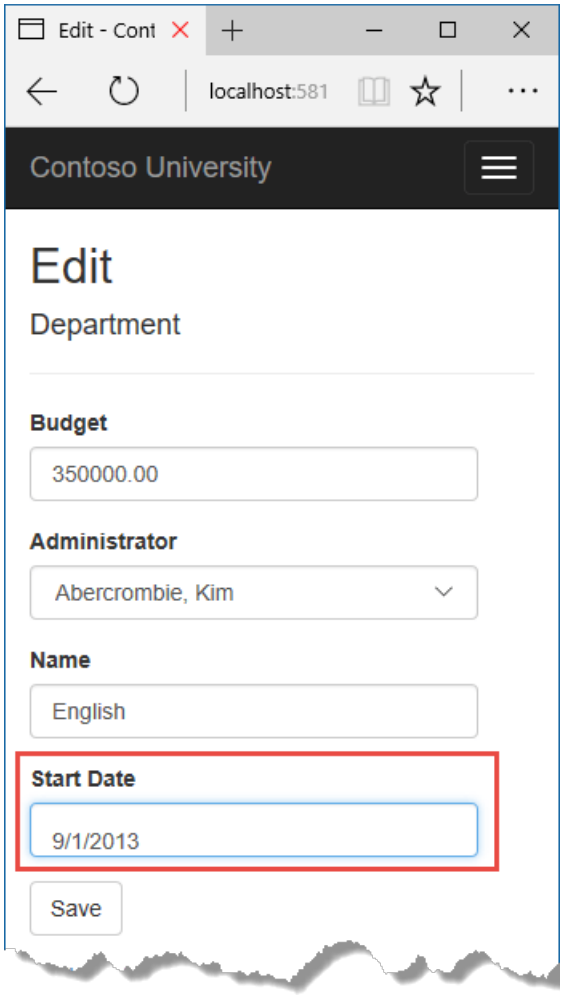
- The last update wins. That is, the last update values are saved to the DB.
- The first of the current updates are lost.

Optimistic concurrency

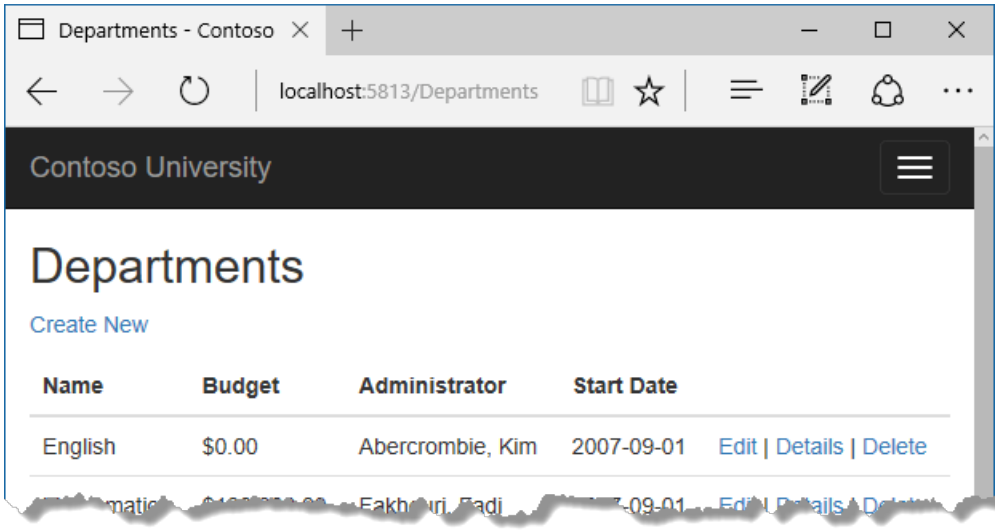
Optimistic concurrency allows concurrency conflicts to happen, and then reacts appropriately when they do. For example, Jane visits the Department edit page and changes the budget for the English department from $350,000.00 to $0.00.



Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.



Jane clicks **Save** first and sees her change when the browser displays the Index page.



John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts.

Optimistic concurrency includes the following options:

- You can keep track of which property a user has modified and update only the corresponding columns in the DB.

  In the scenario, no data would be lost. Different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes. This method of updating can reduce the number of conflicts that could result in data loss. This approach:

  - Can't avoid data loss if competing changes are made to the same property.
  - Is generally not practical in a web app. It requires maintaining significant state in order to keep track of all fetched values and new values. Maintaining large amounts of state can affect app performance.
  - Can increase app complexity compared to concurrency detection on an entity.
- You can let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the fetched $350,000.00 value. This approach is called a *Client Wins* or *Last in Wins* scenario. (All values from the client take precedence over what's in the data store.) If you don't do any coding for concurrency handling, Client Wins happens automatically.
- You can prevent John's change from being updated in the DB. Typically, the app would:

  - Display an error message.
  - Show the current state of the data.
  - Allow the user to reapply the changes.

  This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You implement the Store Wins scenario in this tutorial. This method ensures that no changes are overwritten without a user being alerted.

Handling concurrency

When a property is configured as a concurrency token:

- EF Core verifies that property has not been modified after it was fetched. The check occurs when SaveChanges or SaveChangesAsync is called.
- If the property has been changed after it was fetched, a DbUpdateConcurrencyException is thrown.

The DB and data model must be configured to support throwing `DbUpdateConcurrencyException`.

Detecting concurrency conflicts on a property

Concurrency conflicts can be detected at the property level with the ConcurrencyCheck attribute. The attribute can be applied to multiple properties on the model. For more information, see Data Annotations-ConcurrencyCheck.

The `[ConcurrencyCheck]` attribute isn't used in this tutorial.

Detecting concurrency conflicts on a row

To detect concurrency conflicts, a rowversion tracking column is added to the model. `rowversion`:

- Is SQL Server specific. Other databases may not provide a similar feature.
- Is used to determine that an entity has not been changed since it was fetched from the DB.

The DB generates a sequential `rowversion` number that's incremented each time the row is updated. In an `Update` or `Delete` command, the `Where` clause includes the fetched value of `rowversion`. If the row being updated has changed:

- `rowversion` doesn't match the fetched value.
- The `Update` or `Delete` commands don't find a row because the `Where` clause includes the fetched `rowversion`.
- A `DbUpdateConcurrencyException` is thrown.

In EF Core, when no rows have been updated by an `Update` or `Delete` command, a concurrency exception is thrown.

Add a tracking property to the Department entity

In *Models/Department.cs*, add a tracking property named RowVersion:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
        public byte[] RowVersion { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Timestamp attribute specifies that this column is included in the `Where` clause of `Update` and `Delete` commands. The attribute is called `Timestamp` because previous versions of SQL Server used a SQL `timestamp` data type before the SQL `rowversion` type replaced it.

The fluent API can also specify the tracking property:

```
modelBuilder.Entity<Department>()
  .Property<byte[]>("RowVersion")
  .IsRowVersion();
```

The following code shows a portion of the T-SQL generated by EF Core when the Department name is updated:

```
SET NOCOUNT ON;
UPDATE [Department] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [RowVersion] = @p2;
SELECT [RowVersion]
FROM [Department]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

The preceding highlighted code shows the `WHERE` clause containing `RowVersion`. If the DB `RowVersion` doesn't equal the `RowVersion` parameter (`@p2`), no rows are updated.

The following highlighted code shows the T-SQL that verifies exactly one row was updated:

```
SET NOCOUNT ON;
UPDATE [Department] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [RowVersion] = @p2;
SELECT [RowVersion]
FROM [Department]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

@@ROWCOUNT returns the number of rows affected by the last statement. In no rows are updated, EF Core throws a `DbUpdateConcurrencyException`.

You can see the T-SQL EF Core generates in the output window of Visual Studio.

Update the DB

Adding the `RowVersion` property changes the DB model, which requires a migration.

Build the project. Enter the following in a command window:

```
dotnet ef migrations add RowVersion
dotnet ef database update
```

The preceding commands:

- Adds the *Migrations/{time stamp}_RowVersion.cs* migration file.
- Updates the *Migrations/SchoolContextModelSnapshot.cs* file. The update adds the following highlighted code to the `BuildModel` method:

  ```
  ```

- Runs migrations to update the DB.

Scaffold the Departments model

- Visual Studio
- Visual Studio Code

Follow the instructions in Scaffold the student model and use `Department` for the model class.

The preceding command scaffolds the `Department` model. Open the project in Visual Studio.

Build the project.

Update the Departments Index page

The scaffolding engine created a `RowVersion` column for the Index page, but that field shouldn't be displayed. In this tutorial, the last byte of the `RowVersion` is displayed to help understand concurrency. The last byte isn't guaranteed to be unique. A real app wouldn't display `RowVersion` or the last byte of `RowVersion`.

Update the Index page:

- Replace Index with Departments.
- Replace the markup containing `RowVersion` with the last byte of `RowVersion`.
- Replace FirstMidName with FullName.

The following markup shows the updated page:

```
@page
@model ContosoUniversity.Pages.Departments.IndexModel

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].Name)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].Budget)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.Department[0].StartDate)
                </th>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].Administrator)
            </th>
            <th>
                RowVersion
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Department) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Name)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Budget)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.StartDate)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Administrator.FullName)
            </td>
            <td>
                @item.RowVersion[7]
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.DepartmentID">Edit</a> |
                <a asp-page="./Details" asp-route-id="@item.DepartmentID">Details</a> |
                <a asp-page="./Delete" asp-route-id="@item.DepartmentID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Update the Edit page model

Update *Pages\Departments\Edit.cshtml.cs* with the following code:

```
using ContosoUniversity.Data;
```

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class EditModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        // Replace ViewData["InstructorID"]
        public SelectList InstructorNameSL { get; set; }

        public async Task<IActionResult> OnGetAsync(int id)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)  // eager loading
                .AsNoTracking()                 // tracking not required
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                return NotFound();
            }

            // Use strongly typed data rather than ViewData.
            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FirstMidName");

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            var departmentToUpdate = await _context.Departments
                .Include(i => i.Administrator)
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            // null means Department was deleted by another user.
            if (departmentToUpdate == null)
            {
                return HandleDeletedDepartment();
            }

            // Update the RowVersion to the value when this entity was
            // fetched. If the entity has been updated after it was
            // fetched, RowVersion won't match the DB RowVersion and
            // a DbUpdateConcurrencyException is thrown.
            // A second postback will make them match, unless a new
            // concurrency issue happens.
            _context.Entry(departmentToUpdate)
                .Property("RowVersion").OriginalValue = Department.RowVersion;
```

```
            if (await TryUpdateModelAsync<Department>(
                departmentToUpdate,
                "Department",
                s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
            {
                try
                {
                    await _context.SaveChangesAsync();
                    return RedirectToPage("./Index");
                }
                catch (DbUpdateConcurrencyException ex)
                {
                    var exceptionEntry = ex.Entries.Single();
                    var clientValues = (Department)exceptionEntry.Entity;
                    var databaseEntry = exceptionEntry.GetDatabaseValues();
                    if (databaseEntry == null)
                    {
                        ModelState.AddModelError(string.Empty, "Unable to save. " +
                            "The department was deleted by another user.");
                        return Page();
                    }

                    var dbValues = (Department)databaseEntry.ToObject();
                    await setDbErrorMessage(dbValues, clientValues, _context);

                    // Save the current RowVersion so next postback
                    // matches unless an new concurrency issue happens.
                    Department.RowVersion = (byte[])dbValues.RowVersion;
                    // Must clear the model error for the next postback.
                    ModelState.Remove("Department.RowVersion");
                }
            }

            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FullName", departmentToUpdate.InstructorID);

            return Page();
        }

        private IActionResult HandleDeletedDepartment()
        {
            var deletedDepartment = new Department();
            // ModelState contains the posted data because of the deletion error and will overide the
Department instance values when displaying Page().
            ModelState.AddModelError(string.Empty,
                "Unable to save. The department was deleted by another user.");
            InstructorNameSL = new SelectList(_context.Instructors, "ID", "FullName", Department.InstructorID);
            return Page();
        }

        private async Task setDbErrorMessage(Department dbValues,
                Department clientValues, SchoolContext context)
        {

            if (dbValues.Name != clientValues.Name)
            {
                ModelState.AddModelError("Department.Name",
                    $"Current value: {dbValues.Name}");
            }
            if (dbValues.Budget != clientValues.Budget)
            {
                ModelState.AddModelError("Department.Budget",
                    $"Current value: {dbValues.Budget:c}");
            }
            if (dbValues.StartDate != clientValues.StartDate)
            {
                ModelState.AddModelError("Department.StartDate",
                    $"Current value: {dbValues.StartDate:d}");
            }
```

```
            if (dbValues.InstructorID != clientValues.InstructorID)
            {
                Instructor dbInstructor = await _context.Instructors
                   .FindAsync(dbValues.InstructorID);
                ModelState.AddModelError("Department.InstructorID",
                    $"Current value: {dbInstructor?.FullName}");
            }

            ModelState.AddModelError(string.Empty,
                "The record you attempted to edit "
              + "was modified by another user after you. The "
              + "edit operation was canceled and the current values in the database "
              + "have been displayed. If you still want to edit this record, click "
              + "the Save button again.");
        }
    }
}
```

To detect a concurrency issue, the OriginalValue is updated with the `rowVersion` value from the entity it was fetched. EF Core generates a SQL UPDATE command with a WHERE clause containing the original `RowVersion` value. If no rows are affected by the UPDATE command (no rows have the original `RowVersion` value), a `DbUpdateConcurrencyException` exception is thrown.

```
public async Task<IActionResult> OnPostAsync(int id)
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var departmentToUpdate = await _context.Departments
        .Include(i => i.Administrator)
        .FirstOrDefaultAsync(m => m.DepartmentID == id);

    // null means Department was deleted by another user.
    if (departmentToUpdate == null)
    {
        return HandleDeletedDepartment();
    }

    // Update the RowVersion to the value when this entity was
    // fetched. If the entity has been updated after it was
    // fetched, RowVersion won't match the DB RowVersion and
    // a DbUpdateConcurrencyException is thrown.
    // A second postback will make them match, unless a new
    // concurrency issue happens.
    _context.Entry(departmentToUpdate)
        .Property("RowVersion").OriginalValue = Department.RowVersion;
```

In the preceding code, `Department.RowVersion` is the value when the entity was fetched. `OriginalValue` is the value in the DB when `FirstOrDefaultAsync` was called in this method.

The following code gets the client values (the values posted to this method) and the DB values:

```
try
{
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
catch (DbUpdateConcurrencyException ex)
{
    var exceptionEntry = ex.Entries.Single();
    var clientValues = (Department)exceptionEntry.Entity;
    var databaseEntry = exceptionEntry.GetDatabaseValues();
    if (databaseEntry == null)
    {
        ModelState.AddModelError(string.Empty, "Unable to save. " +
            "The department was deleted by another user.");
        return Page();
    }

    var dbValues = (Department)databaseEntry.ToObject();
    await setDbErrorMessage(dbValues, clientValues, _context);

    // Save the current RowVersion so next postback
    // matches unless an new concurrency issue happens.
    Department.RowVersion = (byte[])dbValues.RowVersion;
    // Must clear the model error for the next postback.
    ModelState.Remove("Department.RowVersion");
}
```

The following code adds a custom error message for each column that has DB values different from what was posted to `OnPostAsync`:

```
private async Task setDbErrorMessage(Department dbValues,
        Department clientValues, SchoolContext context)
{

    if (dbValues.Name != clientValues.Name)
    {
        ModelState.AddModelError("Department.Name",
            $"Current value: {dbValues.Name}");
    }
    if (dbValues.Budget != clientValues.Budget)
    {
        ModelState.AddModelError("Department.Budget",
            $"Current value: {dbValues.Budget:c}");
    }
    if (dbValues.StartDate != clientValues.StartDate)
    {
        ModelState.AddModelError("Department.StartDate",
            $"Current value: {dbValues.StartDate:d}");
    }
    if (dbValues.InstructorID != clientValues.InstructorID)
    {
        Instructor dbInstructor = await _context.Instructors
           .FindAsync(dbValues.InstructorID);
        ModelState.AddModelError("Department.InstructorID",
            $"Current value: {dbInstructor?.FullName}");
    }

    ModelState.AddModelError(string.Empty,
        "The record you attempted to edit "
      + "was modified by another user after you. The "
      + "edit operation was canceled and the current values in the database "
      + "have been displayed. If you still want to edit this record, click "
      + "the Save button again.");
}
```

The following highlighted code sets the `RowVersion` value to the new value retrieved from the DB. The next time the user clicks **Save**, only concurrency errors that happen since the last display of the Edit page will be caught.

```
try
{
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
catch (DbUpdateConcurrencyException ex)
{
    var exceptionEntry = ex.Entries.Single();
    var clientValues = (Department)exceptionEntry.Entity;
    var databaseEntry = exceptionEntry.GetDatabaseValues();
    if (databaseEntry == null)
    {
        ModelState.AddModelError(string.Empty, "Unable to save. " +
            "The department was deleted by another user.");
        return Page();
    }

    var dbValues = (Department)databaseEntry.ToObject();
    await setDbErrorMessage(dbValues, clientValues, _context);

    // Save the current RowVersion so next postback
    // matches unless an new concurrency issue happens.
    Department.RowVersion = (byte[])dbValues.RowVersion;
    // Must clear the model error for the next postback.
    ModelState.Remove("Department.RowVersion");
}
```

The `ModelState.Remove` statement is required because `ModelState` has the old `RowVersion` value. In the Razor Page, the `ModelState` value for a field takes precedence over the model property values when both are present.

Update the Edit page

Update *Pages/Departments/Edit.cshtml* with the following markup:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="Department.DepartmentID" />
            <input type="hidden" asp-for="Department.RowVersion" />
            <div class="form-group">
                <label>RowVersion</label>
                @Model.Department.RowVersion[7]
            </div>
            <div class="form-group">
                <label asp-for="Department.Name" class="control-label"></label>
                <input asp-for="Department.Name" class="form-control" />
                <span asp-validation-for="Department.Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.Budget" class="control-label"></label>
                <input asp-for="Department.Budget" class="form-control" />
                <span asp-validation-for="Department.Budget" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Department.StartDate" class="control-label"></label>
                <input asp-for="Department.StartDate" class="form-control" />
                <span asp-validation-for="Department.StartDate" class="text-danger">
                </span>
            </div>
            <div class="form-group">
                <label class="control-label">Instructor</label>
                <select asp-for="Department.InstructorID" class="form-control"
                        asp-items="@Model.InstructorNameSL"></select>
                <span asp-validation-for="Department.InstructorID" class="text-danger">
                </span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="./Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding markup:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds a hidden row version. `RowVersion` must be added so post back binds the value.
- Displays the last byte of `RowVersion` for debugging purposes.
- Replaces `ViewData` with the strongly-typed `InstructorNameSL`.

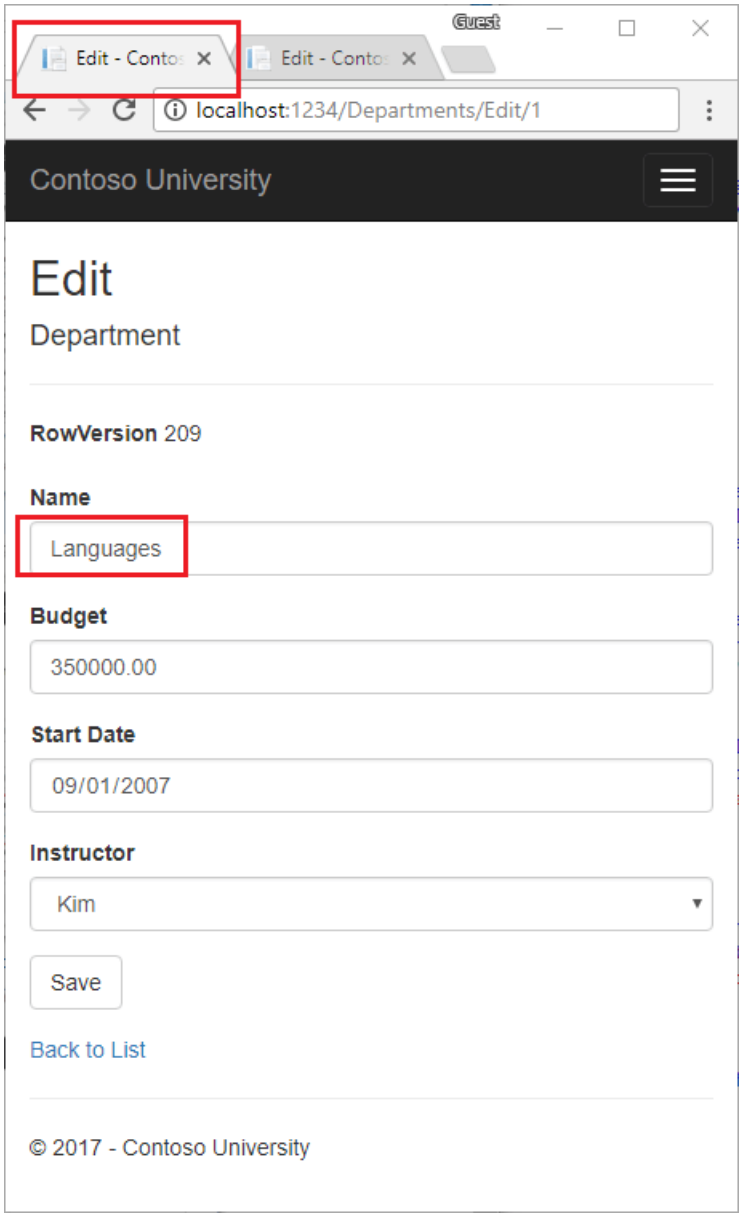
Test concurrency conflicts with the Edit page

Open two browsers instances of Edit on the English department:

- Run the app and select Departments.
- Right-click the **Edit** hyperlink for the English department and select **Open in new tab**.
- In the first tab, click the **Edit** hyperlink for the English department.

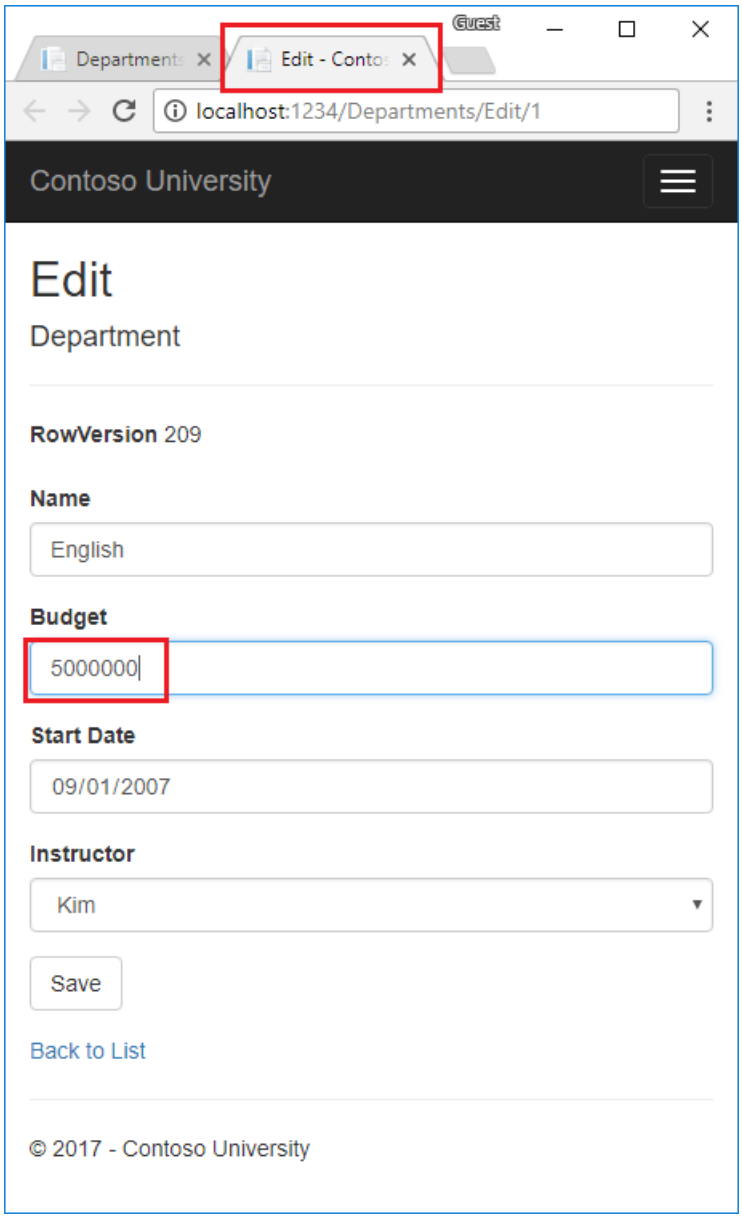
The two browser tabs display the same information.

Change the name in the first browser tab and click **Save**.

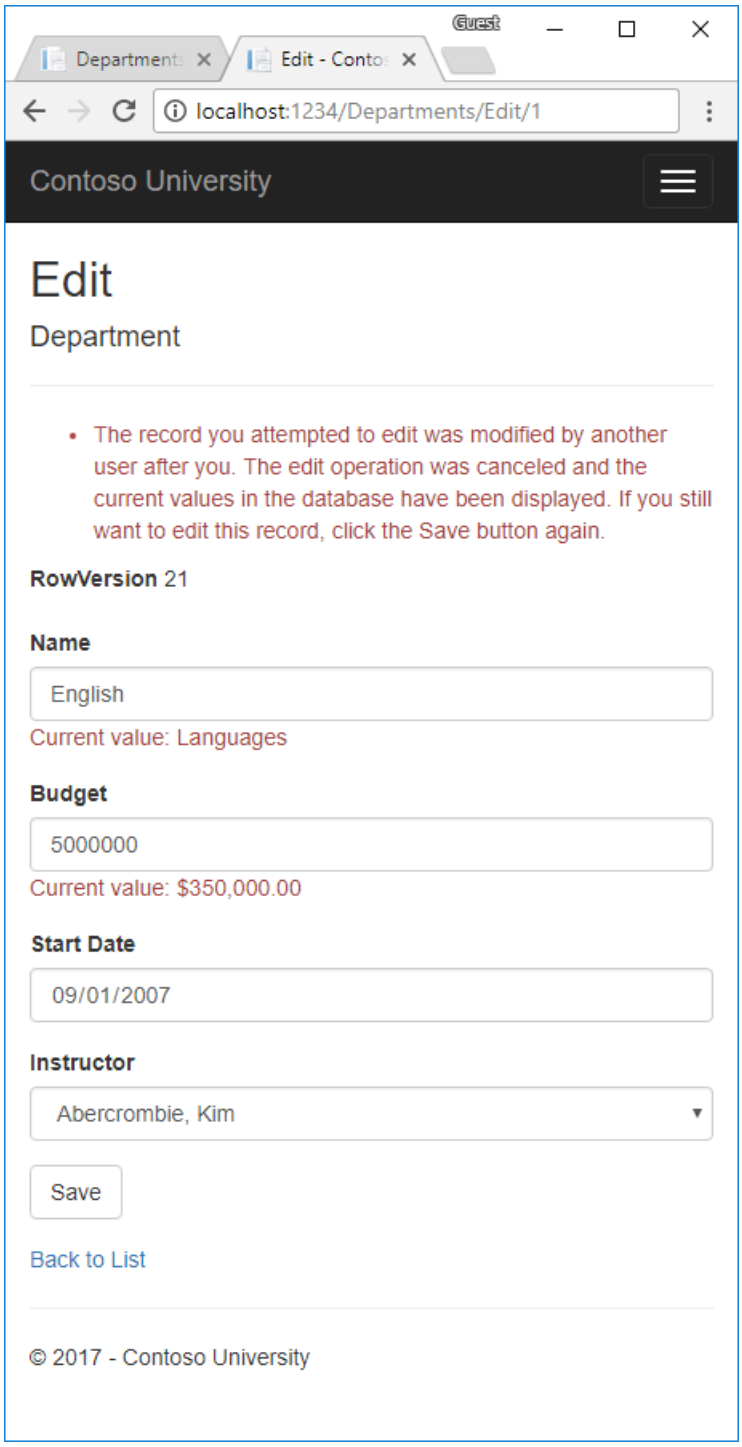


The browser shows the Index page with the changed value and updated rowVersion indicator. Note the updated rowVersion indicator, it's displayed on the second postback in the other tab.

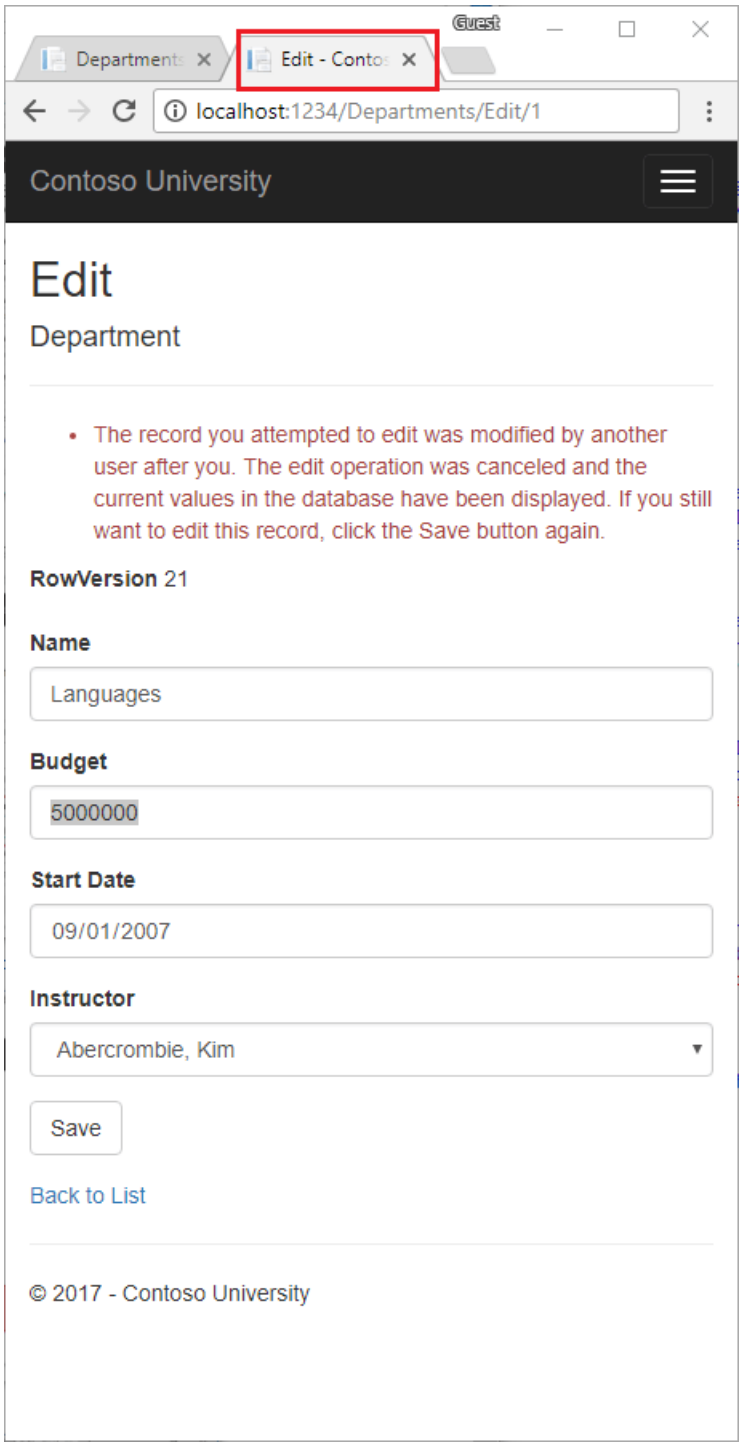
Change a different field in the second browser tab.



Click **Save**. You see error messages for all fields that don't match the DB values:



This browser window didn't intend to change the Name field. Copy and paste the current value (Languages) into the Name field. Tab out. Client-side validation removes the error message.



Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values in the Index page.

Update the Delete page

Update the Delete page model with the following code:

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;
```

```
        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        public string ConcurrencyErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int id, bool? concurrencyError)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                 return NotFound();
            }

            if (concurrencyError.GetValueOrDefault())
            {
                ConcurrencyErrorMessage = "The record you attempted to delete "
                  + "was modified by another user after you selected delete. "
                  + "The delete operation was canceled and the current values in the "
                  + "database have been displayed. If you still want to delete this "
                  + "record, click the Delete button again.";
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            try
            {
                if (await _context.Departments.AnyAsync(
                    m => m.DepartmentID == id))
                {
                    // Department.rowVersion value is from when the entity
                    // was fetched. If it doesn't match the DB, a
                    // DbUpdateConcurrencyException exception is thrown.
                    _context.Departments.Remove(Department);
                    await _context.SaveChangesAsync();
                }
                return RedirectToPage("./Index");
            }
            catch (DbUpdateConcurrencyException)
            {
                return RedirectToPage("./Delete",
                    new { concurrencyError = true, id = id });
            }
        }
    }
}
```

The Delete page detects concurrency conflicts when the entity has changed after it was fetched. `Department.RowVersion` is the row version when the entity was fetched. When EF Core creates the SQL DELETE command, it includes a WHERE clause with `RowVersion`. If the SQL DELETE command results in zero rows affected:

- The `RowVersion` in the SQL DELETE command doesn't match `RowVersion` in the DB.
- A DbUpdateConcurrencyException exception is thrown.
- `OnGetAsync` is called with the `concurrencyError`.

Update the Delete page

Update *Pages/Departments/Delete.cshtml* with the following code:

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<p class="text-danger">@Model.ConcurrencyErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Department.Name)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.Budget)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Budget)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.StartDate)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.StartDate)
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.RowVersion)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.RowVersion[7])
        </dd>
        <dt>
            @Html.DisplayNameFor(model => model.Department.Administrator)
        </dt>
        <dd>
            @Html.DisplayFor(model => model.Department.Administrator.FullName)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Department.DepartmentID" />
        <input type="hidden" asp-for="Department.RowVersion" />
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-page="./Index">Back to List</a>
        </div>
</form>
</div>
```

The preceding code makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds an error message.
- Replaces FirstMidName with FullName in the **Administrator** field.

- Changes `RowVersion` to display the last byte.
- Adds a hidden row version. `RowVersion` must be added so post back binds the value.

Test concurrency conflicts with the Delete page

Create a test department.

Open two browsers instances of Delete on the test department:

- Run the app and select Departments.
- Right-click the **Delete** hyperlink for the test department and select **Open in new tab**.
- Click the **Edit** hyperlink for the test department.

The two browser tabs display the same information.

Change the budget in the first browser tab and click **Save**.

The browser shows the Index page with the changed value and updated rowVersion indicator. Note the updated rowVersion indicator, it's displayed on the second postback in the other tab.

Delete the test department from the second tab. A concurrency error is display with the current values from the DB. Clicking **Delete** deletes the entity, unless `RowVersion` has been updated.

See Inheritance on how to inherit a data model.

ASP.NET Core MVC with EF Core - tutorial series

9/22/2020 • 2 minutes to read • Edit Online

This tutorial has **not** been updated to ASP.NET Core 3.0. The Razor Pages version has been updated. For information on when this might be updated, see this GitHub issue.

This tutorial teaches ASP.NET Core MVC and Entity Framework Core with controllers and views. Razor Pages is an alternative programming model that was introduced in ASP.NET Core 2.0. For new development, we recommend Razor Pages over MVC with controllers and views. There is a Razor Pages version of this tutorial. Each tutorial covers some material the other doesn't:

Some things this MVC tutorial has that the Razor Pages tutorial doesn't:

- Implement inheritance in the data model
- Perform raw SQL queries
- Use dynamic LINQ to simplify code

Some things the Razor Pages tutorial has that this one doesn't:

- Use Select method to load related data
- A version available for ASP.NET Core 3.0

1. Get started
2. Create, Read, Update, and Delete operations
3. Sorting, filtering, paging, and grouping
4. Migrations
5. Create a complex data model
6. Reading related data
7. Updating related data
8. Handle concurrency conflicts
9. Inheritance
10. Advanced topics

Tutorial: Get started with EF Core in an ASP.NET MVC web app

9/22/2020 • 21 minutes to read • Edit Online

This tutorial has **not** been updated to ASP.NET Core 3.0. The Razor Pages version has been updated. Most of the code changes for the ASP.NET Core 3.0 and later version of this tutorial:

- Are in the *Startup.cs* and *Program.cs* files.
- Can be found in the Razor Pages version.

For information on when this might be updated, see this GitHub issue.

This tutorial teaches ASP.NET Core MVC and Entity Framework Core with controllers and views. Razor Pages is an alternative programming model that was introduced in ASP.NET Core 2.0. For new development, we recommend Razor Pages over MVC with controllers and views. There is a Razor Pages version of this tutorial. Each tutorial covers some material the other doesn't:

Some things this MVC tutorial has that the Razor Pages tutorial doesn't:

- Implement inheritance in the data model
- Perform raw SQL queries
- Use dynamic LINQ to simplify code

Some things the Razor Pages tutorial has that this one doesn't:

- Use Select method to load related data
- A version available for ASP.NET Core 3.0

The Contoso University sample web application demonstrates how to create ASP.NET Core 2.2 MVC web applications using Entity Framework (EF) Core 2.2 and Visual Studio 2017 or 2019.

The sample application is a web site for a fictional Contoso University. It includes functionality such as student admission, course creation, and instructor assignments. This is the first in a series of tutorials that explain how to build the Contoso University sample application from scratch.

In this tutorial, you:

- Create an ASP.NET Core MVC web app
- Set up the site style
- Learn about EF Core NuGet packages
- Create the data model
- Create the database context
- Register the context for dependency injection
- Initialize the database with test data
- Create a controller and views
- View the database

Prerequisites

- .NET Core SDK 2.2
- Visual Studio 2019 with the following workloads:

- **ASP.NET and web development** workload
- **.NET Core cross-platform development** workload

Troubleshooting

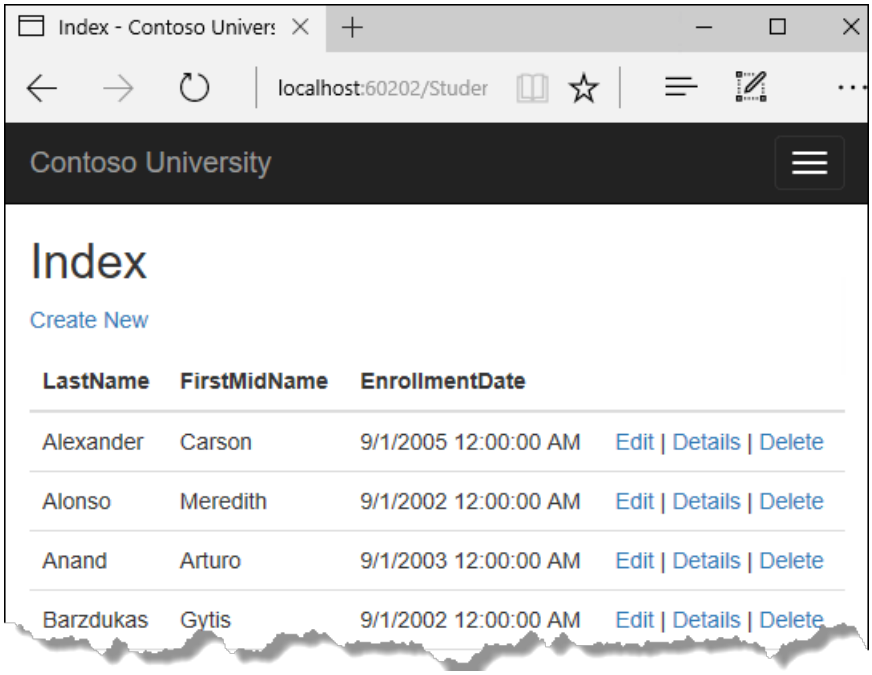
If you run into a problem you can't resolve, you can generally find the solution by comparing your code to the completed project. For a list of common errors and how to solve them, see the Troubleshooting section of the last tutorial in the series. If you don't find what you need there, you can post a question to StackOverflow.com for ASP.NET Core or EF Core.

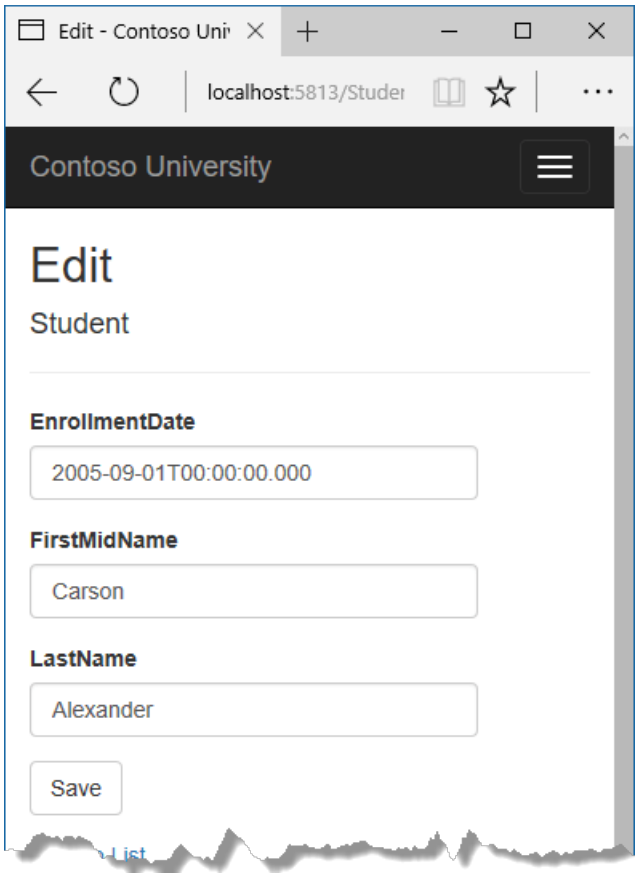
> **TIP**
> This is a series of 10 tutorials, each of which builds on what is done in earlier tutorials. Consider saving a copy of the project after each successful tutorial completion. Then if you run into problems, you can start over from the previous tutorial instead of going back to the beginning of the whole series.

Contoso University web app

The application you'll be building in these tutorials is a simple university web site.

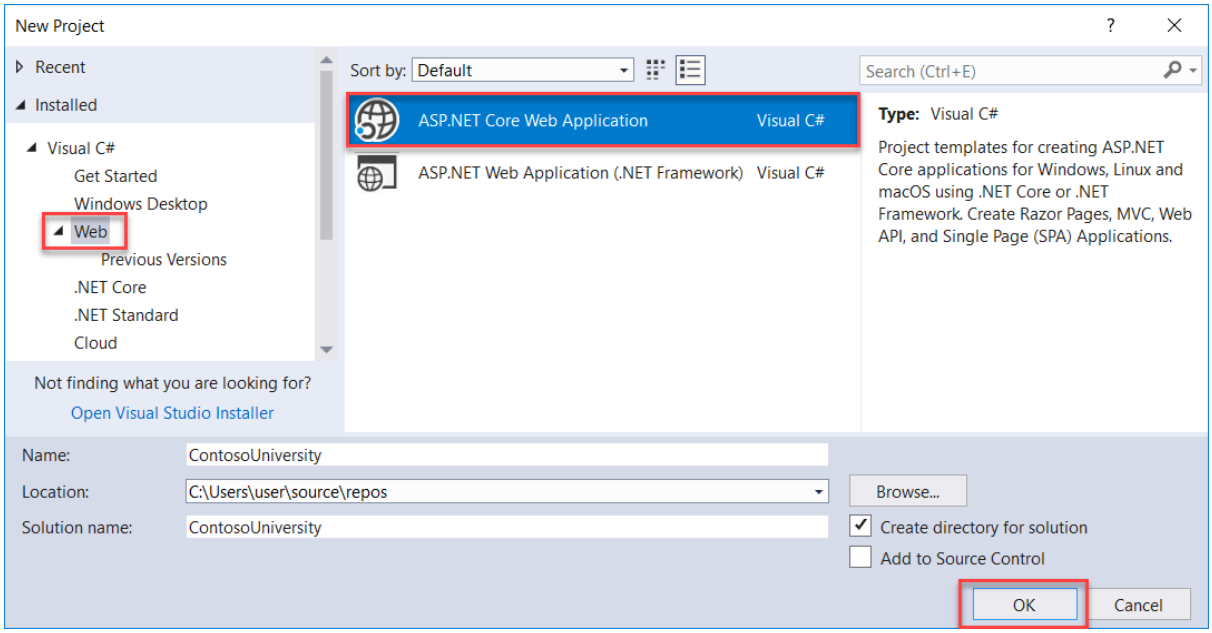
Users can view and update student, course, and instructor information. Here are a few of the screens you'll create.





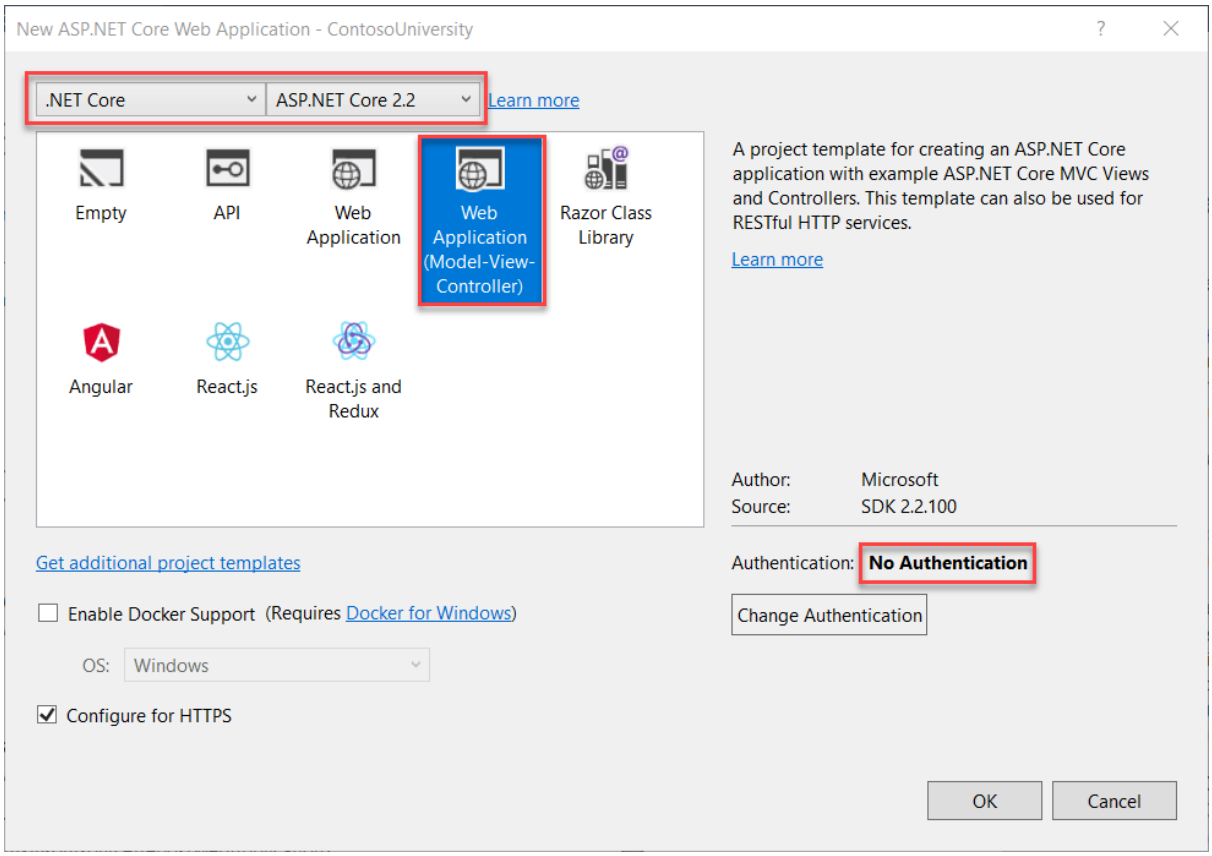
Create web app

- Open Visual Studio.
- From the **File** menu, select **New** > **Project**.
- From the left pane, select **Installed** > **Visual C#** > **Web**.
- Select the **ASP.NET Core Web Application** project template.
- Enter **ContosoUniversity** as the name and click **OK**.



- Wait for the **New ASP.NET Core Web Application** dialog to appear.
- Select **.NET Core**, **ASP.NET Core 2.2** and the **Web Application (Model-View-Controller)** template.

- Make sure **Authentication** is set to **No Authentication**.
- Select **OK**



Set up the site style

A few simple changes will set up the site menu, layout, and home page.

Open *Views/Shared/_Layout.cshtml* and make the following changes:

- Change each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- Add menu entries for **About**, **Students**, **Courses**, **Instructors**, and **Departments**, and delete the **Privacy** menu entry.

The changes are highlighted.

```

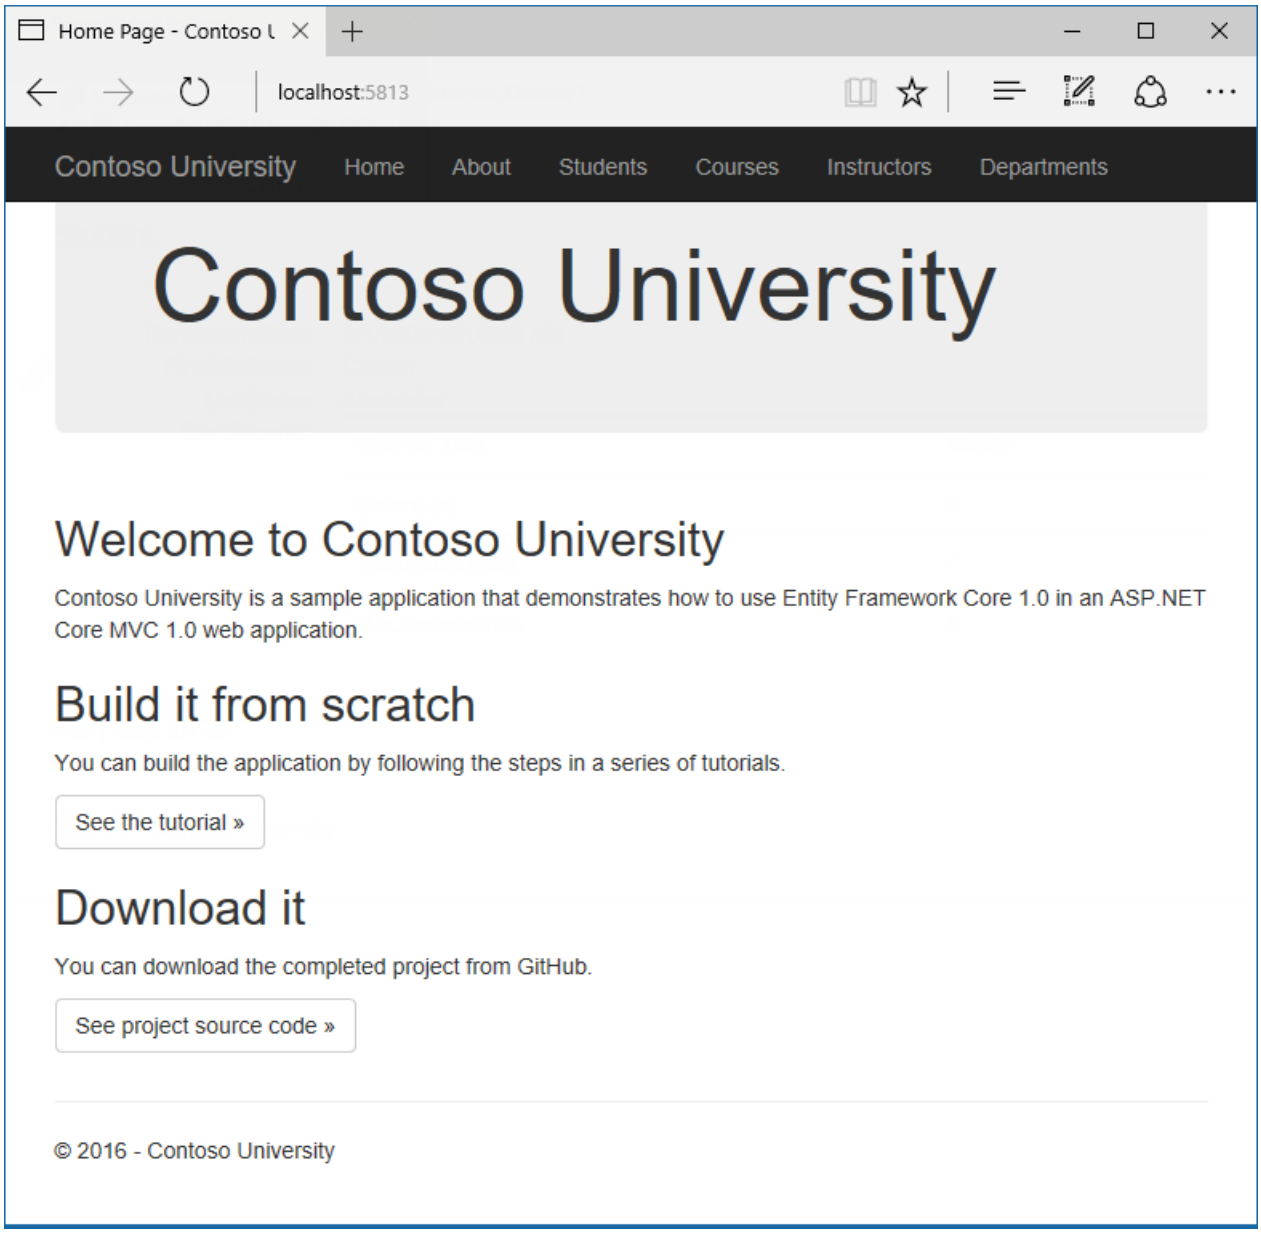
In *Views/Home/Index.cshtml*, replace the contents of the file with the following code to replace the text about ASP.NET and MVC with text about this application:

```
@{
    ViewData["Title"] = "Home Page";
}

<div class="jumbotron">
    <h1>Contoso University</h1>
</div>
<div class="row">
    <div class="col-md-4">
        <h2>Welcome to Contoso University</h2>
        <p>
            Contoso University is a sample application that
            demonstrates how to use Entity Framework Core in an
            ASP.NET Core MVC web application.
        </p>
    </div>
    <div class="col-md-4">
        <h2>Build it from scratch</h2>
        <p>You can build the application by following the steps in a series of tutorials.</p>
        <p><a class="btn btn-default" href="https://docs.asp.net/en/latest/data/ef-mvc/intro.html">See the
tutorial &raquo;</a></p>
    </div>
    <div class="col-md-4">
        <h2>Download it</h2>
        <p>You can download the completed project from GitHub.</p>
        <p><a class="btn btn-default"
href="https://github.com/dotnet/AspNetCore.Docs/tree/master/aspnetcore/data/ef-mvc/intro/samples/cu-final">See
project source code &raquo;</a></p>
    </div>
</div>
```

Press CTRL+F5 to run the project or choose **Debug > Start Without Debugging** from the menu. You see the home page with tabs for the pages you'll create in these tutorials.



About EF Core NuGet packages

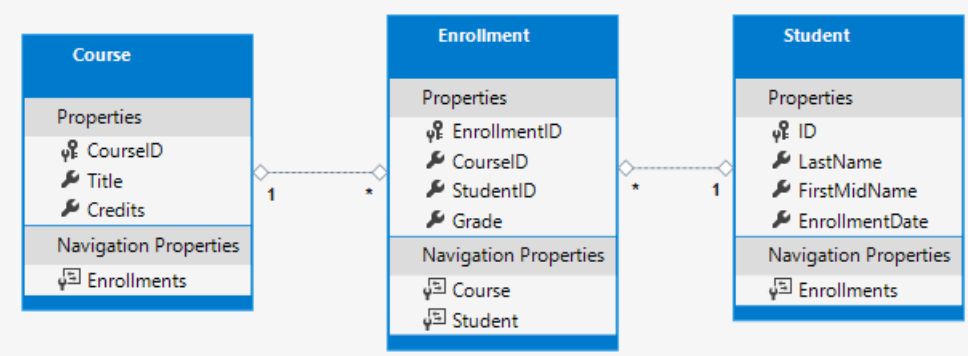
To add EF Core support to a project, install the database provider that you want to target. This tutorial uses SQL Server, and the provider package is Microsoft.EntityFrameworkCore.SqlServer. This package is included in the Microsoft.AspNetCore.App metapackage, so you don't need to reference the package.

The EF SQL Server package and its dependencies (`Microsoft.EntityFrameworkCore` and `Microsoft.EntityFrameworkCore.Relational`) provide runtime support for EF. You'll add a tooling package later, in the Migrations tutorial.

For information about other database providers that are available for Entity Framework Core, see Database providers.

Create the data model

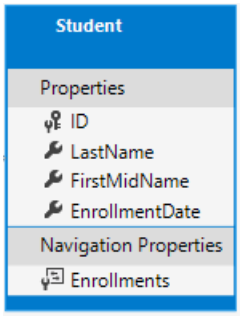
Next you'll create entity classes for the Contoso University application. You'll start with the following three entities.



There's a one-to-many relationship between `Student` and `Enrollment` entities, and there's a one-to-many relationship between `Course` and `Enrollment` entities. In other words, a student can be enrolled in any number of courses, and a course can have any number of students enrolled in it.

In the following sections you'll create a class for each one of these entities.

The Student entity



In the *Models* folder, create a class file named *Student.cs* and replace the template code with the following code.

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

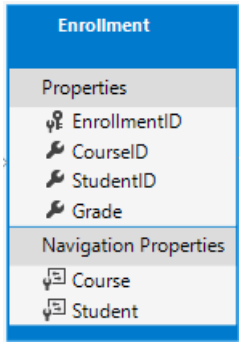
        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `ID` property will become the primary key column of the database table that corresponds to this class. By default, the Entity Framework interprets a property that's named `ID` or `classnameID` as the primary key.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student entity` will hold all of the `Enrollment` entities that are related to that `Student` entity. In other words, if a given Student row in the database has two related Enrollment rows (rows that contain that student's primary key value in their StudentID foreign key column), that `Student` entity's `Enrollments` navigation property will contain those two `Enrollment` entities.

If a navigation property can hold multiple entities (as in many-to-many or one-to-many relationships), its type must be a list in which entries can be added, deleted, and updated, such as `ICollection<T>`. You can specify `ICollection<T>` or a type such as `List<T>` or `HashSet<T>`. If you specify `ICollection<T>`, EF creates a `HashSet<T>` collection by default.

The Enrollment entity



In the *Models* folder, create *Enrollment.cs* and replace the existing code with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property will be the primary key; this entity uses the `classnameID` pattern instead of `ID` by itself as you saw in the `Student` entity. Ordinarily you would choose one pattern and use it throughout your data model. Here, the variation illustrates that you can use either pattern. In a later tutorial, you'll see how using ID without classname makes it easier to implement inheritance in the data model.

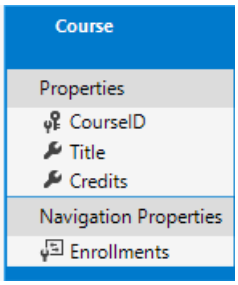
The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade -- null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property can only hold a single `Student` entity (unlike the `Student.Enrollments` navigation property you saw earlier, which can hold multiple `Enrollment` entities).

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

Entity Framework interprets a property as a foreign key property if it's named `<navigation property name><primary key property name>` (for example, `StudentID` for the `Student` navigation property since the `Student` entity's primary key is `ID`). Foreign key properties can also be named simply `<primary key property name>` (for example, `CourseID` since the `Course` entity's primary key is `CourseID`).

The Course entity



In the *Models* folder, create *Course.cs* and replace the existing code with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

We'll say more about the `DatabaseGenerated` attribute in a later tutorial in this series. Basically, this attribute lets you enter the primary key for the course rather than having the database generate it.

Create the database context

The main class that coordinates Entity Framework functionality for a given data model is the database context class. You create this class by deriving from the `Microsoft.EntityFrameworkCore.DbContext` class. In your code you specify which entities are included in the data model. You can also customize certain Entity Framework behavior. In this project, the class is named `SchoolContext`.

In the project folder, create a folder named *Data*.

In the *Data* folder create a new class file named *SchoolContext.cs*, and replace the template code with the following code:

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
    }
}
```

This code creates a `DbSet` property for each entity set. In Entity Framework terminology, an entity set typically corresponds to a database table, and an entity corresponds to a row in the table.

You could've omitted the `DbSet<Enrollment>` and `DbSet<Course>` statements and it would work the same. The Entity Framework would include them implicitly because the `Student` entity references the `Enrollment` entity and the `Enrollment` entity references the `Course` entity.

When the database is created, EF creates tables that have names the same as the `DbSet` property names. Property names for collections are typically plural (Students rather than Student), but developers disagree about whether table names should be pluralized or not. For these tutorials you'll override the default behavior by specifying singular table names in the DbContext. To do that, add the following highlighted code after the last DbSet property.

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

Register the SchoolContext

ASP.NET Core implements dependency injection by default. Services (such as the EF database context) are registered with dependency injection during application startup. Components that require these services (such as MVC controllers) are provided these services via constructor parameters. You'll see the controller constructor code that gets a context instance later in this tutorial.

To register `SchoolContext` as a service, open *Startup.cs*, and add the highlighted lines to the `ConfigureServices` method.

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddDbContext<SchoolContext>(options =>
        options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection")));

    services.AddMvc();
}
```

The name of the connection string is passed in to the context by calling a method on a `DbContextOptionsBuilder` object. For local development, the ASP.NET Core configuration system reads the connection string from the *appsettings.json* file.

Add `using` statements for `ContosoUniversity.Data` and `Microsoft.EntityFrameworkCore` namespaces, and then build the project.

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
using Microsoft.AspNetCore.Http;
```

Open the *appsettings.json* file and add a connection string as shown in the following example.

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity1;Trusted_Connection=True;MultipleActiveResultSets=true"
  },
  "Logging": {
    "IncludeScopes": false,
    "LogLevel": {
      "Default": "Warning"
    }
  }
}
```

SQL Server Express LocalDB

The connection string specifies a SQL Server LocalDB database. LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for application development, not production use. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB creates *.mdf* database files in the `C:/Users/<user>` directory.

Initialize DB with test data

The Entity Framework will create an empty database for you. In this section, you write a method that's called after the database is created in order to populate it with test data.

Here you'll use the `EnsureCreated` method to automatically create the database. In a later tutorial you'll see how to handle model changes by using Code First Migrations to change the database schema instead of dropping and re-creating the database.

In the *Data* folder, create a new class file named *DbInitializer.cs* and replace the template code with the following code, which causes a database to be created when needed and loads test data into the new database.

```
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
            new Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.Parse("2005-09-
01")},
            new Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse("2003-09-01")},
            new Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Parse("2001-09-01")},
            new Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse("2003-09-01")},
            new Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Parse("2005-09-01")}
            };
            foreach (Student s in students)
            {
                context.Students.Add(s);
            }
            context.SaveChanges();

            var courses = new Course[]
            {
            new Course{CourseID=1050,Title="Chemistry",Credits=3},
            new Course{CourseID=4022,Title="Microeconomics",Credits=3},
            new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
            new Course{CourseID=1045,Title="Calculus",Credits=4},
            new Course{CourseID=3141,Title="Trigonometry",Credits=4},
            new Course{CourseID=2021,Title="Composition",Credits=3},
            new Course{CourseID=2042,Title="Literature",Credits=4}
            };
            foreach (Course c in courses)
            {
                context.Courses.Add(c);
            }
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
            new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
            new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
            new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
            new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
            new Enrollment{StudentID=3,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
            new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
            new Enrollment{StudentID=6,CourseID=1045},
```

```
            new Enrollment{StudentID=6,CourseID=1045},
            new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };
            foreach (Enrollment e in enrollments)
            {
                context.Enrollments.Add(e);
            }
            context.SaveChanges();
        }
    }
}
```

The code checks if there are any students in the database, and if not, it assumes the database is new and needs to be seeded with test data. It loads test data into arrays rather than `List<T>` collections to optimize performance.

In *Program.cs*, modify the `Main` method to do the following on application startup:

- Get a database context instance from the dependency injection container.
- Call the seed method, passing to it the context.
- Dispose the context when the seed method is done.

```
public static void Main(string[] args)
{
     var host = CreateWebHostBuilder(args).Build();

    using (var scope = host.Services.CreateScope())
    {
        var services = scope.ServiceProvider;
        try
        {
            var context = services.GetRequiredService<SchoolContext>();
            DbInitializer.Initialize(context);
        }
        catch (Exception ex)
        {
            var logger = services.GetRequiredService<ILogger<Program>>();
            logger.LogError(ex, "An error occurred while seeding the database.");
        }
    }

    host.Run();
}
```

Add `using` statements:

```
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Data;
```

In older tutorials, you may see similar code in the `Configure` method in *Startup.cs*. We recommend that you use the `Configure` method only to set up the request pipeline. Application startup code belongs in the `Main` method.

Now the first time you run the application, the database will be created and seeded with test data. Whenever you change your data model, you can delete the database, update your seed method, and start afresh with a new database the same way. In later tutorials, you'll see how to modify the database when the data model changes, without deleting and re-creating it.

Create controller and views

Next, you'll use the scaffolding engine in Visual Studio to add an MVC controller and views that will use EF to query and save data.

The automatic creation of CRUD action methods and views is known as scaffolding. Scaffolding differs from code generation in that the scaffolded code is a starting point that you can modify to suit your own requirements, whereas you typically don't modify generated code. When you need to customize generated code, you use partial classes or you regenerate the code when things change.

- Right-click the **Controllers** folder in **Solution Explorer** and select **Add > New Scaffolded Item**.
- In the **Add Scaffold** dialog box:
  - Select **MVC controller with views, using Entity Framework**.
  - Click **Add**. The **Add MVC Controller with views, using Entity Framework** dialog box appears.

  - In **Model class** select **Student**.
  - In **Data context class** select **SchoolContext**.
  - Accept the default **StudentsController** as the name.
  - Click **Add**.

  When you click **Add**, the Visual Studio scaffolding engine creates a *StudentsController.cs* file and a set of views (*.cshtml* files) that work with the controller.

(The scaffolding engine can also create the database context for you if you don't create it manually first as you did earlier for this tutorial. You can specify a new context class in the **Add Controller** box by clicking the plus sign to the right of **Data context class**. Visual Studio will then create your `DbContext` class as well as the controller and views.)

You'll notice that the controller takes a `SchoolContext` as a constructor parameter.

```
namespace ContosoUniversity.Controllers
{
    public class StudentsController : Controller
    {
        private readonly SchoolContext _context;

        public StudentsController(SchoolContext context)
        {
            _context = context;
        }
```

ASP.NET Core dependency injection takes care of passing an instance of `SchoolContext` into the controller. You configured that in the *Startup.cs* file earlier.

The controller contains an `Index` action method, which displays all students in the database. The method gets a list of students from the Students entity set by reading the `Students` property of the database context instance:

```
public async Task<IActionResult> Index()
{
    return View(await _context.Students.ToListAsync());
}
```

You'll learn about the asynchronous programming elements in this code later in the tutorial.

The *Views/Students/Index.cshtml* view displays this list in a table:

```
@model IEnumerable<ContosoUniversity.Models.Student>

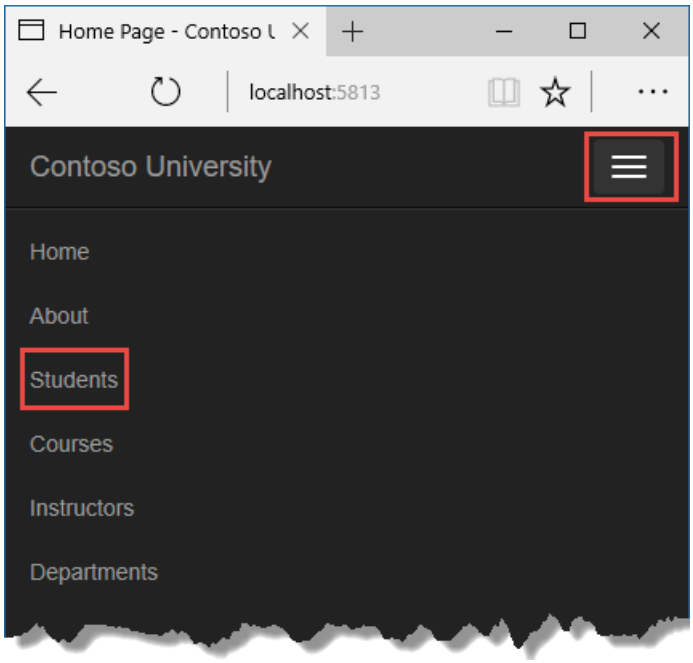
@{
    ViewData["Title"] = "Index";
}

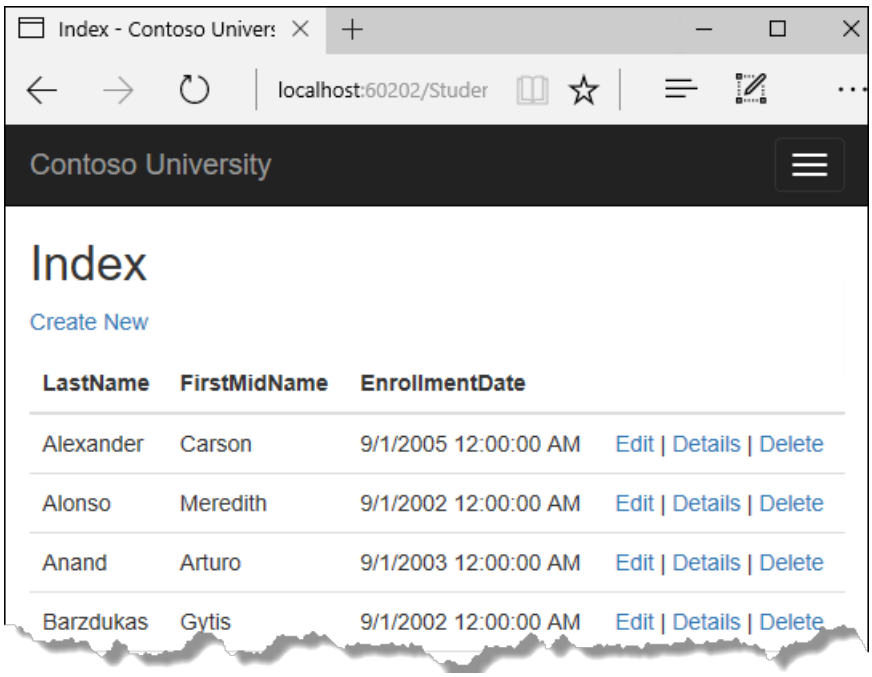
<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    @Html.DisplayNameFor(model => model.LastName)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.FirstMidName)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.EnrollmentDate)
                </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.LastName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.FirstMidName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
                <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Press CTRL+F5 to run the project or choose **Debug > Start Without Debugging** from the menu.

Click the Students tab to see the test data that the `DbInitializer.Initialize` method inserted. Depending on how narrow your browser window is, you'll see the `Students` tab link at the top of the page or you'll have to click the navigation icon in the upper right corner to see the link.





View the database

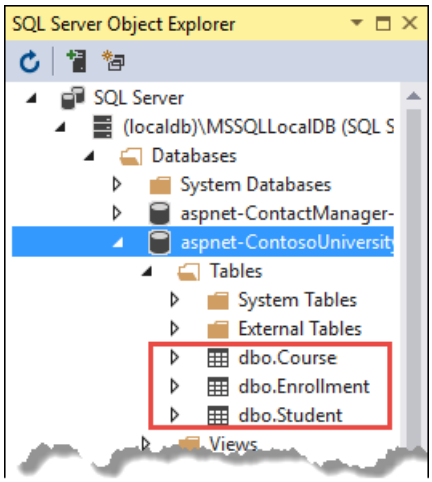
When you started the application, the `DbInitializer.Initialize` method calls `EnsureCreated`. EF saw that there was no database and so it created one, then the remainder of the `Initialize` method code populated the database with data. You can use **SQL Server Object Explorer** (SSOX) to view the database in Visual Studio.

Close the browser.

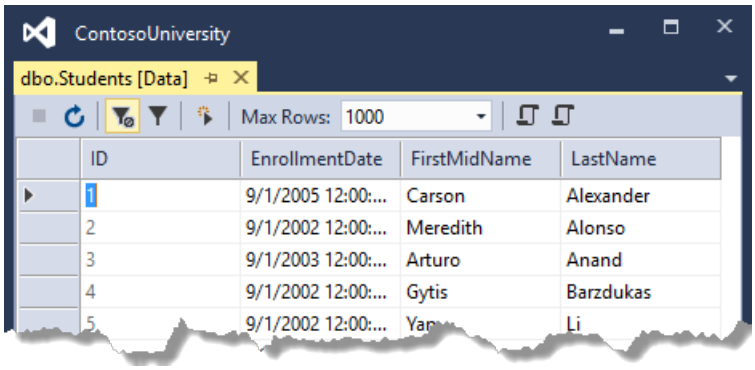
If the SSOX window isn't already open, select it from the **View** menu in Visual Studio.

In SSOX, click **(localdb)\MSSQLLocalDB > Databases**, and then click the entry for the database name that's in the connection string in your *appsettings.json* file.

Expand the **Tables** node to see the tables in your database.



Right-click the **Student** table and click **View Data** to see the columns that were created and the rows that were inserted into the table.



The *.mdf* and *.ldf* database files are in the *C:\Users\<yourusername>* folder.

Because you're calling `EnsureCreated` in the initializer method that runs on app start, you could now make a change to the `Student` class, delete the database, run the application again, and the database would automatically be re-created to match your change. For example, if you add an `EmailAddress` property to the `Student` class, you'll see a new `EmailAddress` column in the re-created table.

Conventions

The amount of code you had to write in order for the Entity Framework to be able to create a complete database for you is minimal because of the use of conventions, or assumptions that the Entity Framework makes.

- The names of `DbSet` properties are used as table names. For entities not referenced by a `DbSet` property, entity class names are used as table names.
- Entity property names are used for column names.
- Entity properties that are named ID or classnameID are recognized as primary key properties.
- A property is interpreted as a foreign key property if it's named *<navigation property name><primary key property name>* (for example, `StudentID` for the `Student` navigation property since the `Student` entity's primary key is `ID`). Foreign key properties can also be named simply *<primary key property name>* (for example, `EnrollmentID` since the `Enrollment` entity's primary key is `EnrollmentID`).

Conventional behavior can be overridden. For example, you can explicitly specify table names, as you saw earlier in this tutorial. And you can set column names and set any property as primary key or foreign key, as you'll see in a later tutorial in this series.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server is enabled to handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time, but for low traffic situations the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the `async` keyword, `Task<T>` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
public async Task<IActionResult> Index()
{
    return View(await _context.Students.ToListAsync());
}
```

- The `async` keyword tells the compiler to generate callbacks for parts of the method body and to automatically create the `Task<IActionResult>` object that's returned.
- The return type `Task<IActionResult>` represents ongoing work with a result of type `IActionResult`.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when you are writing asynchronous code that uses the Entity Framework:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes, for example, `ToListAsync`, `SingleOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include, for example, statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF context isn't thread safe: don't try to do multiple operations in parallel. When you call any async EF method, always use the `await` keyword.
- If you want to take advantage of the performance benefits of async code, make sure that any library packages that you're using (such as for paging), also use async if they call any Entity Framework methods that cause queries to be sent to the database.

For more information about asynchronous programming in .NET, see Async Overview.

Download or view the completed application.

Next steps

In this tutorial, you:

- Created ASP.NET Core MVC web app
- Set up the site style

- Learned about EF Core NuGet packages
- Created the data model
- Created the database context
- Registered the SchoolContext
- Initialized DB with test data
- Created controller and views
- Viewed the database

In the following tutorial, you'll learn how to perform basic CRUD (create, read, update, delete) operations.

Advance to the next tutorial to learn how to perform basic CRUD (create, read, update, delete) operations.

Implement basic CRUD functionality

Tutorial: Implement CRUD Functionality - ASP.NET MVC with EF Core

9/22/2020 • 19 minutes to read • Edit Online

In the previous tutorial, you created an MVC application that stores and displays data using the Entity Framework and SQL Server LocalDB. In this tutorial, you'll review and customize the CRUD (create, read, update, delete) code that the MVC scaffolding automatically creates for you in controllers and views.

> **NOTE**
> It's a common practice to implement the repository pattern in order to create an abstraction layer between your controller and the data access layer. To keep these tutorials simple and focused on teaching how to use the Entity Framework itself, they don't use repositories. For information about repositories with EF, see the last tutorial in this series.

In this tutorial, you:

- Customize the Details page
- Update the Create page
- Update the Edit page
- Update the Delete page
- Close database connections

Prerequisites

- Get started with EF Core and ASP.NET Core MVC

Customize the Details page

The scaffolded code for the Students Index page left out the `Enrollments` property, because that property holds a collection. In the **Details** page, you'll display the contents of the collection in an HTML table.

In *Controllers/StudentsController.cs*, the action method for the Details view uses the `SingleOrDefaultAsync` method to retrieve a single `Student` entity. Add code that calls `Include`. `ThenInclude`, and `AsNoTracking` methods, as shown in the following highlighted code.

```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Students
        .Include(s => s.Enrollments)
            .ThenInclude(e => e.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (student == null)
    {
        return NotFound();
    }

    return View(student);
}
```

The `Include` and `ThenInclude` methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the `Enrollment.Course` navigation property. You'll learn more about these methods in the read related data tutorial.

The `AsNoTracking` method improves performance in scenarios where the entities returned won't be updated in the current context's lifetime. You'll learn more about `AsNoTracking` at the end of this tutorial.

Route data

The key value that's passed to the `Details` method comes from *route data*. Route data is data that the model binder found in a segment of the URL. For example, the default route specifies controller, action, and id segments:

```
app.UseMvc(routes =>
{
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

In the following URL, the default route maps Instructor as the controller, Index as the action, and 1 as the id; these are route data values.

```
http://localhost:1230/Instructor/Index/1?courseID=2021
```

The last part of the URL ("?courseID=2021") is a query string value. The model binder will also pass the ID value to the `Index` method `id` parameter if you pass it as a query string value:

```
http://localhost:1230/Instructor/Index?id=1&CourseID=2021
```

In the Index page, hyperlink URLs are created by tag helper statements in the Razor view. In the following Razor code, the `id` parameter matches the default route, so `id` is added to the route data.

```
<a asp-action="Edit" asp-route-id="@item.ID">Edit</a>
```

This generates the following HTML when `item.ID` is 6:

```
<a href="/Students/Edit/6">Edit</a>
```

In the following Razor code, `studentID` doesn't match a parameter in the default route, so it's added as a query string.

```
<a asp-action="Edit" asp-route-studentID="@item.ID">Edit</a>
```

This generates the following HTML when `item.ID` is 6:

```
<a href="/Students/Edit?studentID=6">Edit</a>
```

For more information about tag helpers, see Tag Helpers in ASP.NET Core.

Add enrollments to the Details view

Open *Views/Students/Details.cshtml*. Each field is displayed using `DisplayNameFor` and `DisplayFor` helpers, as shown in the following example:

```
<dt class="col-sm-2">
    @Html.DisplayNameFor(model => model.LastName)
</dt>
<dd class="col-sm-10">
    @Html.DisplayFor(model => model.LastName)
</dd>
```

After the last field and immediately before the closing `</dl>` tag, add the following code to display a list of enrollments:

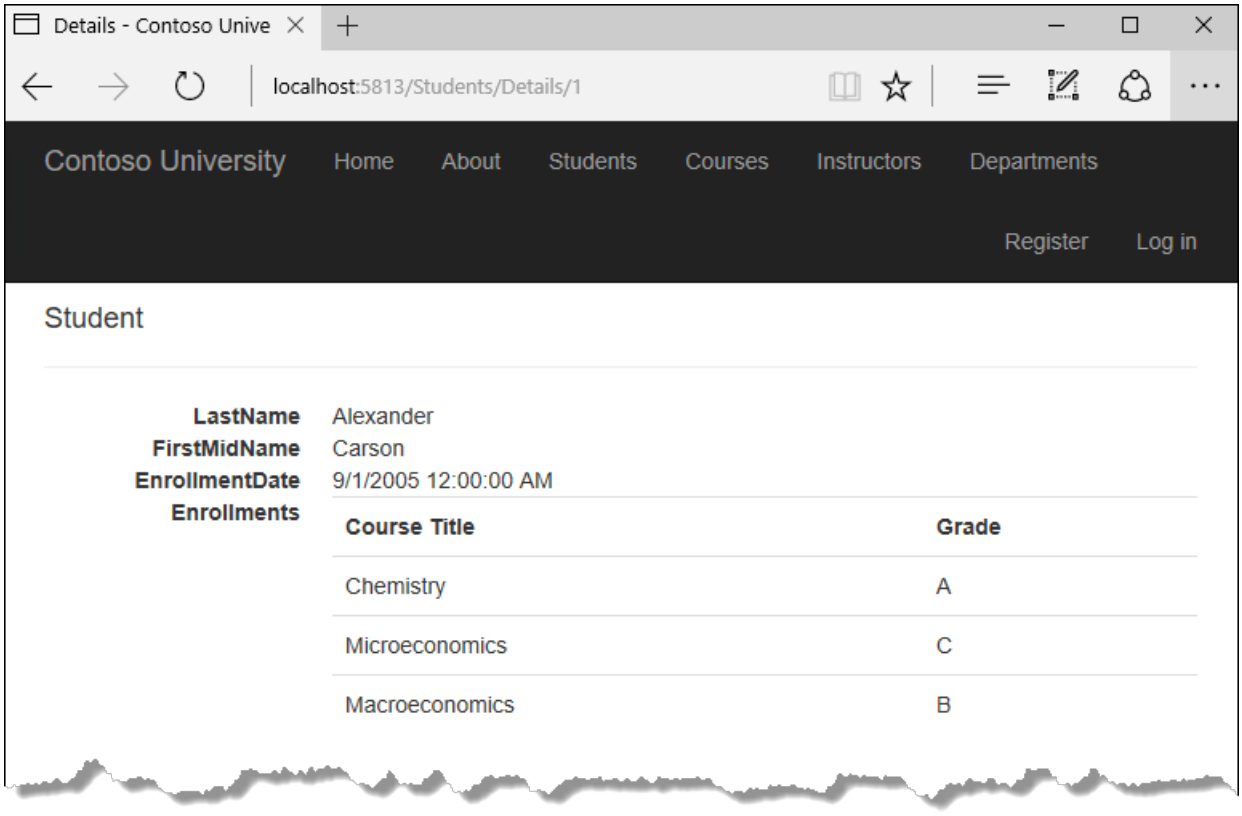
```
<dt class="col-sm-2">
    @Html.DisplayNameFor(model => model.Enrollments)
</dt>
<dd class="col-sm-10">
    <table class="table">
        <tr>
            <th>Course Title</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Course.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
</dd>
```

If code indentation is wrong after you paste the code, press CTRL-K-D to correct it.

This code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the Course entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. You see the list of courses and grades

for the selected student:



Update the Create page

In *StudentsController.cs*, modify the HttpPost `Create` method by adding a try-catch block and removing ID from the `Bind` attribute.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("EnrollmentDate,FirstMidName,LastName")] Student student)
{
    try
    {
        if (ModelState.IsValid)
        {
            _context.Add(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.
        ModelState.AddModelError("", "Unable to save changes. " +
            "Try again, and if the problem persists " +
            "see your system administrator.");
    }
    return View(student);
}
```

This code adds the Student entity created by the ASP.NET Core MVC model binder to the Students entity set and then saves the changes to the database. (Model binder refers to the ASP.NET Core MVC functionality that makes it easier for you to work with data submitted by a form; a model binder converts posted form values to CLR types and passes them to the action method in parameters. In this case, the model binder instantiates a Student entity for you using property values from the Form collection.)

You removed `ID` from the `Bind` attribute because ID is the primary key value which SQL Server will set automatically when the row is inserted. Input from the user doesn't set the ID value.

Other than the `Bind` attribute, the try-catch block is the only change you've made to the scaffolded code. If an exception that derives from `DbUpdateException` is caught while the changes are being saved, a generic error message is displayed. `DbUpdateException` exceptions are sometimes caused by something external to the application rather than a programming error, so the user is advised to try again. Although not implemented in this sample, a production quality application would log the exception. For more information, see the **Log for insight** section in Monitoring and Telemetry (Building Real-World Cloud Apps with Azure).

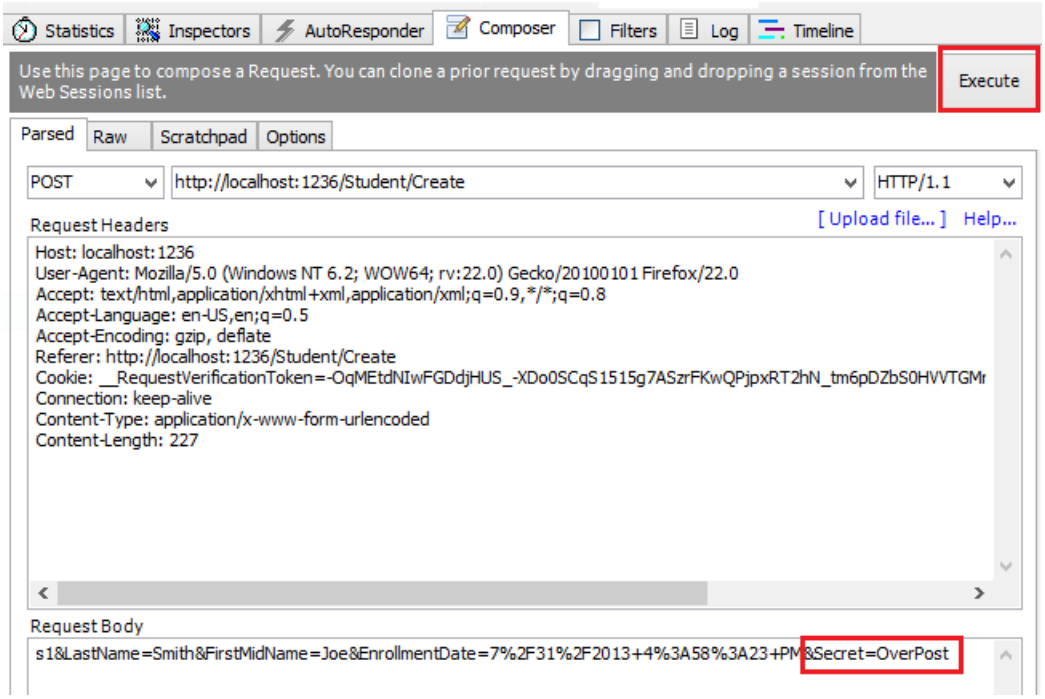
The `ValidateAntiForgeryToken` attribute helps prevent cross-site request forgery (CSRF) attacks. The token is automatically injected into the view by the FormTagHelper and is included when the form is submitted by the user. The token is validated by the `ValidateAntiForgeryToken` attribute. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Security note about overposting

The `Bind` attribute that the scaffolded code includes on the `Create` method is one way to protect against overposting in create scenarios. For example, suppose the Student entity includes a `Secret` property that you don't want this web page to set.

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if you don't have a `Secret` field on the web page, a hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. Without the `Bind` attribute limiting the fields that the model binder uses when it creates a Student instance, the model binder would pick up that `Secret` form value and use it to create the Student entity instance. Then whatever value the hacker specified for the `Secret` form field would be updated in your database. The following image shows the Fiddler tool adding the `Secret` field (with the value "OverPost") to the posted form values.



The value "OverPost" would then be successfully added to the `Secret` property of the inserted row, although you never intended that the web page be able to set that property.

You can prevent overposting in edit scenarios by reading the entity from the database first and then calling `TryUpdateModel`, passing in an explicit allowed properties list. That's the method used in these tutorials.

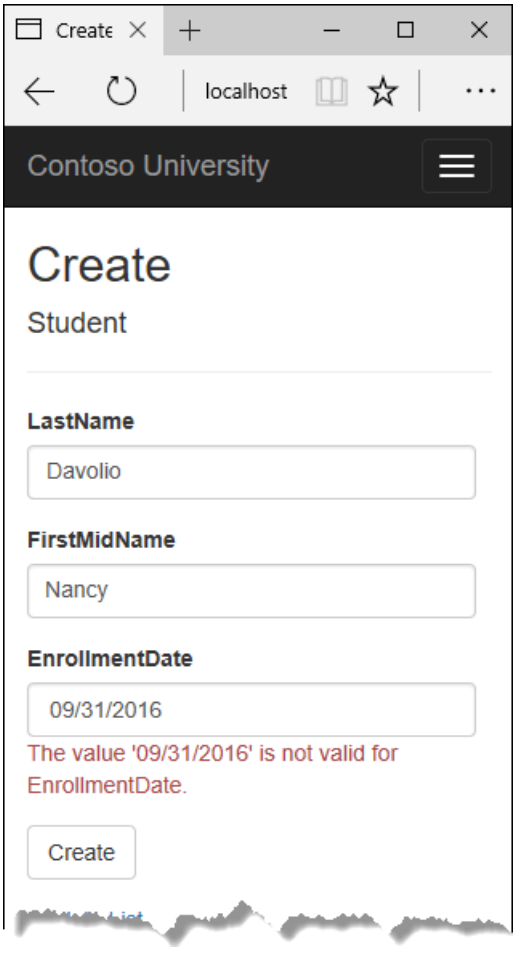
An alternative way to prevent overposting that's preferred by many developers is to use view models rather than entity classes with model binding. Include only the properties you want to update in the view model. Once the MVC model binder has finished, copy the view model properties to the entity instance, optionally using a tool such as AutoMapper. Use `_context.Entry` on the entity instance to set its state to `Unchanged`, and then set `Property("PropertyName").IsModified` to true on each entity property that's included in the view model. This method works in both edit and create scenarios.

Test the Create page

The code in *Views/Students/Create.cshtml* uses `label`, `input`, and `span` (for validation messages) tag helpers for each field.

Run the app, select the **Students** tab, and click **Create New**.

Enter names and a date. Try entering an invalid date if your browser lets you do that. (Some browsers force you to use a date picker.) Then click **Create** to see the error message.



This is server-side validation that you get by default; in a later tutorial you'll see how to add attributes that will generate code for client-side validation also. The following highlighted code shows the model validation check in the `Create` method.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("EnrollmentDate,FirstMidName,LastName")] Student student)
{
    try
    {
        if (ModelState.IsValid)
        {
            _context.Add(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.
        ModelState.AddModelError("", "Unable to save changes. " +
            "Try again, and if the problem persists " +
            "see your system administrator.");
    }
    return View(student);
}
```

Change the date to a valid value and click **Create** to see the new student appear in the **Index** page.

Update the Edit page

In *StudentController.cs*, the HttpGet `Edit` method (the one without the `HttpPost` attribute) uses the `SingleOrDefaultAsync` method to retrieve the selected Student entity, as you saw in the `Details` method. You don't need to change this method.

Recommended HttpPost Edit code: Read and update

Replace the HttpPost Edit action method with the following code.

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }
    var studentToUpdate = await _context.Students.FirstOrDefaultAsync(s => s.ID == id);
    if (await TryUpdateModelAsync<Student>(
        studentToUpdate,
        "",
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        try
        {
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
    }
    return View(studentToUpdate);
}
```

These changes implement a security best practice to prevent overposting. The scaffolder generated a `Bind` attribute and added the entity created by the model binder to the entity set with a `Modified` flag. That code isn't recommended for many scenarios because the `Bind` attribute clears out any pre-existing data in fields not listed in the `Include` parameter.

The new code reads the existing entity and calls `TryUpdateModel` to update fields in the retrieved entity based on user input in the posted form data. The Entity Framework's automatic change tracking sets the `Modified` flag on the fields that are changed by form input. When the `SaveChanges` method is called, the Entity Framework creates SQL statements to update the database row. Concurrency conflicts are ignored, and only the table columns that were updated by the user are updated in the database. (A later tutorial shows how to handle concurrency conflicts.)

As a best practice to prevent overposting, the fields that you want to be updateable by the **Edit** page are declared in the `TryUpdateModel` parameters. (The empty string preceding the list of fields in the parameter list is for a prefix to use with the form fields names.) Currently there are no extra fields that you're protecting, but listing the fields that you want the model binder to bind ensures that if you add fields to the data model in the future, they're automatically protected until you explicitly add them here.

As a result of these changes, the method signature of the HttpPost `Edit` method is the same as the HttpGet `Edit` method; therefore you've renamed the method `EditPost`.

Alternative HttpPost Edit code: Create and attach

The recommended HttpPost edit code ensures that only changed columns get updated and preserves data in properties that you don't want included for model binding. However, the read-first approach requires an extra database read, and can result in more complex code for handling concurrency conflicts. An alternative is to attach an entity created by the model binder to the EF context and mark it as modified. (Don't update your project with this code, it's only shown to illustrate an optional approach.)

```
public async Task<IActionResult> Edit(int id, [Bind("ID,EnrollmentDate,FirstMidName,LastName")] Student
student)
{
    if (id != student.ID)
    {
        return NotFound();
    }
    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
    }
    return View(student);
}
```

You can use this approach when the web page UI includes all of the fields in the entity and can update any of them.

The scaffolded code uses the create-and-attach approach but only catches `DbUpdateConcurrencyException` exceptions and returns 404 error codes. The example shown catches any database update exception and displays an error message.

Entity States

The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database, and this information determines what happens when you call the `SaveChanges` method. For example, when you pass a new entity to the `Add` method, that entity's state is set to `Added`. Then when you call the `SaveChanges` method, the database context issues a SQL INSERT command.

An entity may be in one of the following states:

- `Added`. The entity doesn't yet exist in the database. The `SaveChanges` method issues an INSERT statement.
- `Unchanged`. Nothing needs to be done with this entity by the `SaveChanges` method. When you read an entity from the database, the entity starts out with this status.
- `Modified`. Some or all of the entity's property values have been modified. The `SaveChanges` method issues an UPDATE statement.
- `Deleted`. The entity has been marked for deletion. The `SaveChanges` method issues a DELETE statement.
- `Detached`. The entity isn't being tracked by the database context.

In a desktop application, state changes are typically set automatically. You read an entity and make changes to some of its property values. This causes its entity state to automatically be changed to `Modified`. Then when you call `SaveChanges`, the Entity Framework generates a SQL UPDATE statement that updates only the actual properties that you changed.

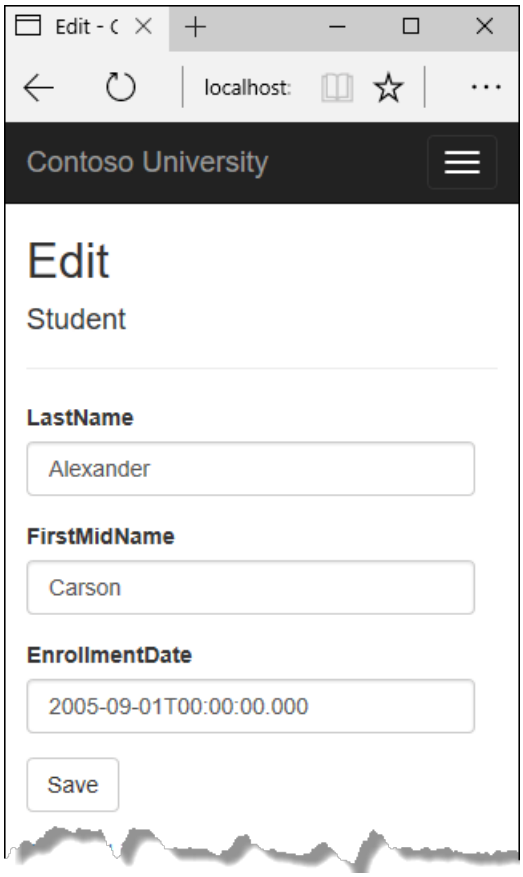
In a web app, the `DbContext` that initially reads an entity and displays its data to be edited is disposed after a page is rendered. When the HttpPost `Edit` action method is called, a new web request is made and you have a new instance of the `DbContext`. If you re-read the entity in that new context, you simulate desktop processing.

But if you don't want to do the extra read operation, you have to use the entity object created by the model binder. The simplest way to do this is to set the entity state to Modified as is done in the alternative HttpPost Edit code shown earlier. Then when you call `SaveChanges`, the Entity Framework updates all columns of the database row, because the context has no way to know which properties you changed.

If you want to avoid the read-first approach, but you also want the SQL UPDATE statement to update only the fields that the user actually changed, the code is more complex. You have to save the original values in some way (such as by using hidden fields) so that they're available when the HttpPost `Edit` method is called. Then you can create a Student entity using the original values, call the `Attach` method with that original version of the entity, update the entity's values to the new values, and then call `SaveChanges`.

Test the Edit page

Run the app, select the **Students** tab, then click an **Edit** hyperlink.



Change some of the data and click **Save**. The **Index** page opens and you see the changed data.

Update the Delete page

In *StudentController.cs*, the template code for the HttpGet `Delete` method uses the `SingleOrDefaultAsync` method to retrieve the selected Student entity, as you saw in the Details and Edit methods. However, to implement a custom error message when the call to `SaveChanges` fails, you'll add some functionality to this method and its corresponding view.

As you saw for update and create operations, delete operations require two action methods. The method that's called in response to a GET request displays a view that gives the user a chance to approve or cancel the delete operation. If the user approves it, a POST request is created. When that happens, the HttpPost `Delete` method is called and then that method actually performs the delete operation.

You'll add a try-catch block to the HttpPost `Delete` method to handle any errors that might occur when the database is updated. If an error occurs, the HttpPost Delete method calls the HttpGet Delete method, passing it a parameter that indicates that an error has occurred. The HttpGet Delete method then redisplays the confirmation

page along with the error message, giving the user an opportunity to cancel or try again.

Replace the HttpGet `Delete` action method with the following code, which manages error reporting.

```
public async Task<IActionResult> Delete(int? id, bool? saveChangesError = false)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Students
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (student == null)
    {
        return NotFound();
    }

    if (saveChangesError.GetValueOrDefault())
    {
        ViewData["ErrorMessage"] =
            "Delete failed. Try again, and if the problem persists " +
            "see your system administrator.";
    }

    return View(student);
}
```

This code accepts an optional parameter that indicates whether the method was called after a failure to save changes. This parameter is false when the HttpGet `Delete` method is called without a previous failure. When it's called by the HttpPost `Delete` method in response to a database update error, the parameter is true and an error message is passed to the view.

The read-first approach to HttpPost Delete

Replace the HttpPost `Delete` action method (named `DeleteConfirmed`) with the following code, which performs the actual delete operation and catches any database update errors.

```
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    var student = await _context.Students.FindAsync(id);
    if (student == null)
    {
        return RedirectToAction(nameof(Index));
    }

    try
    {
        _context.Students.Remove(student);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { id = id, saveChangesError = true });
    }
}
```

This code retrieves the selected entity, then calls the `Remove` method to set the entity's status to `Deleted`. When

`SaveChanges` is called, a SQL DELETE command is generated.

The create-and-attach approach to HttpPost Delete

If improving performance in a high-volume application is a priority, you could avoid an unnecessary SQL query by instantiating a Student entity using only the primary key value and then setting the entity state to `Deleted`. That's all that the Entity Framework needs in order to delete the entity. (Don't put this code in your project; it's here just to illustrate an alternative.)

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    try
    {
        Student studentToDelete = new Student() { ID = id };
        _context.Entry(studentToDelete).State = EntityState.Deleted;
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { id = id, saveChangesError = true });
    }
}
```

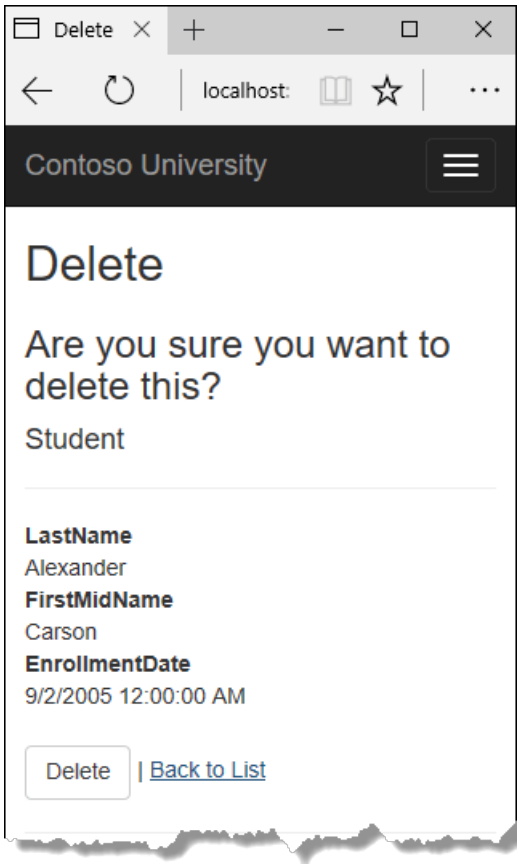
If the entity has related data that should also be deleted, make sure that cascade delete is configured in the database. With this approach to entity deletion, EF might not realize there are related entities to be deleted.

Update the Delete view

In *Views/Student/Delete.cshtml*, add an error message between the h2 heading and the h3 heading, as shown in the following example:

```
<h2>Delete</h2>
<p class="text-danger">@ViewData["ErrorMessage"]</p>
<h3>Are you sure you want to delete this?</h3>
```

Run the app, select the **Students** tab, and click a **Delete** hyperlink:



Click **Delete**. The Index page is displayed without the deleted student. (You'll see an example of the error handling code in action in the concurrency tutorial.)

Close database connections

To free up the resources that a database connection holds, the context instance must be disposed as soon as possible when you are done with it. The ASP.NET Core built-in dependency injection takes care of that task for you.

In *Startup.cs*, you call the AddDbContext extension method to provision the `DbContext` class in the ASP.NET Core DI container. That method sets the service lifetime to `Scoped` by default. `Scoped` means the context object lifetime coincides with the web request life time, and the `Dispose` method will be called automatically at the end of the web request.

Handle transactions

By default the Entity Framework implicitly implements transactions. In scenarios where you make changes to multiple rows or tables and then call `SaveChanges`, the Entity Framework automatically makes sure that either all of your changes succeed or they all fail. If some changes are done first and then an error happens, those changes are automatically rolled back. For scenarios where you need more control -- for example, if you want to include operations done outside of Entity Framework in a transaction -- see Transactions.

No-tracking queries

When a database context retrieves table rows and creates entity objects that represent them, by default it keeps track of whether the entities in memory are in sync with what's in the database. The data in memory acts as a cache and is used when you update an entity. This caching is often unnecessary in a web application because context instances are typically short-lived (a new one is created and disposed for each request) and the context that reads an entity is typically disposed before that entity is used again.

You can disable tracking of entity objects in memory by calling the `AsNoTracking` method. Typical scenarios in which you might want to do that include the following:

- During the context lifetime you don't need to update any entities, and you don't need EF to automatically load navigation properties with entities retrieved by separate queries. Frequently these conditions are met in a controller's HttpGet action methods.
- You are running a query that retrieves a large volume of data, and only a small portion of the returned data will be updated. It may be more efficient to turn off tracking for the large query, and run a query later for the few entities that need to be updated.
- You want to attach an entity in order to update it, but earlier you retrieved the same entity for a different purpose. Because the entity is already being tracked by the database context, you can't attach the entity that you want to change. One way to handle this situation is to call `AsNoTracking` on the earlier query.

For more information, see Tracking vs. No-Tracking.

Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- Customized the Details page
- Updated the Create page
- Updated the Edit page
- Updated the Delete page
- Closed database connections

Advance to the next tutorial to learn how to expand the functionality of the **Index** page by adding sorting, filtering, and paging.

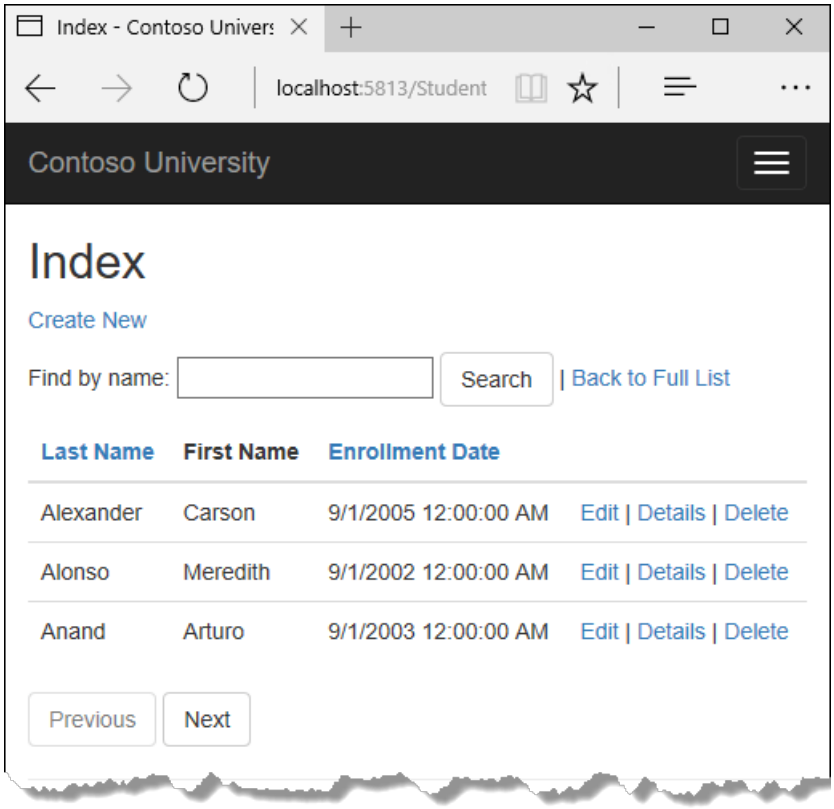
Next: Sorting, filtering, and paging

Tutorial: Add sorting, filtering, and paging - ASP.NET MVC with EF Core

9/22/2020 • 14 minutes to read • Edit Online

In the previous tutorial, you implemented a set of web pages for basic CRUD operations for Student entities. In this tutorial you'll add sorting, filtering, and paging functionality to the Students Index page. You'll also create a page that does simple grouping.

The following illustration shows what the page will look like when you're done. The column headings are links that the user can click to sort by that column. Clicking a column heading repeatedly toggles between ascending and descending sort order.



In this tutorial, you:

- Add column sort links
- Add a Search box
- Add paging to Students Index
- Add paging to Index method
- Add paging links
- Create an About page

Prerequisites

- Implement CRUD Functionality

Add column sort links

To add sorting to the Student Index page, you'll change the `Index` method of the Students controller and add code

to the Student Index view.

Add sorting Functionality to the Index method

In *StudentsController.cs*, replace the `Index` method with the following code:

```
public async Task<IActionResult> Index(string sortOrder)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in _context.Students
                   select s;
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

This code receives a `sortOrder` parameter from the query string in the URL. The query string value is provided by ASP.NET Core MVC as a parameter to the action method. The parameter will be a string that's either "Name" or "Date", optionally followed by an underscore and the string "desc" to specify descending order. The default sort order is ascending.

The first time the Index page is requested, there's no query string. The students are displayed in ascending order by last name, which is the default as established by the fall-through case in the `switch` statement. When the user clicks a column heading hyperlink, the appropriate `sortOrder` value is provided in the query string.

The two `ViewData` elements (NameSortParm and DateSortParm) are used by the view to configure the column heading hyperlinks with the appropriate query string values.

```
public async Task<IActionResult> Index(string sortOrder)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in _context.Students
                   select s;
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

These are ternary statements. The first one specifies that if the `sortOrder` parameter is null or empty, NameSortParm should be set to "name_desc"; otherwise, it should be set to an empty string. These two statements enable the view to set the column heading hyperlinks as follows:

CURRENT SORT ORDER	LAST NAME HYPERLINK	DATE HYPERLINK
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code creates an `IQueryable` variable before the switch statement, modifies it in the switch statement, and calls the `ToListAsync` method after the `switch` statement. When you create and modify `IQueryable` variables, no query is sent to the database. The query isn't executed until you convert the `IQueryable` object into a collection by calling a method such as `ToListAsync`. Therefore, this code results in a single query that's not executed until the `return View` statement.

This code could get verbose with a large number of columns. The last tutorial in this series shows how to write code that lets you pass the name of the `OrderBy` column in a string variable.

Add column heading hyperlinks to the Student Index view

Replace the code in *Views/Students/Index.cshtml*, with the following code to add column heading hyperlinks. The changed lines are highlighted.

```
@model IEnumerable<ContosoUniversity.Models.Student>

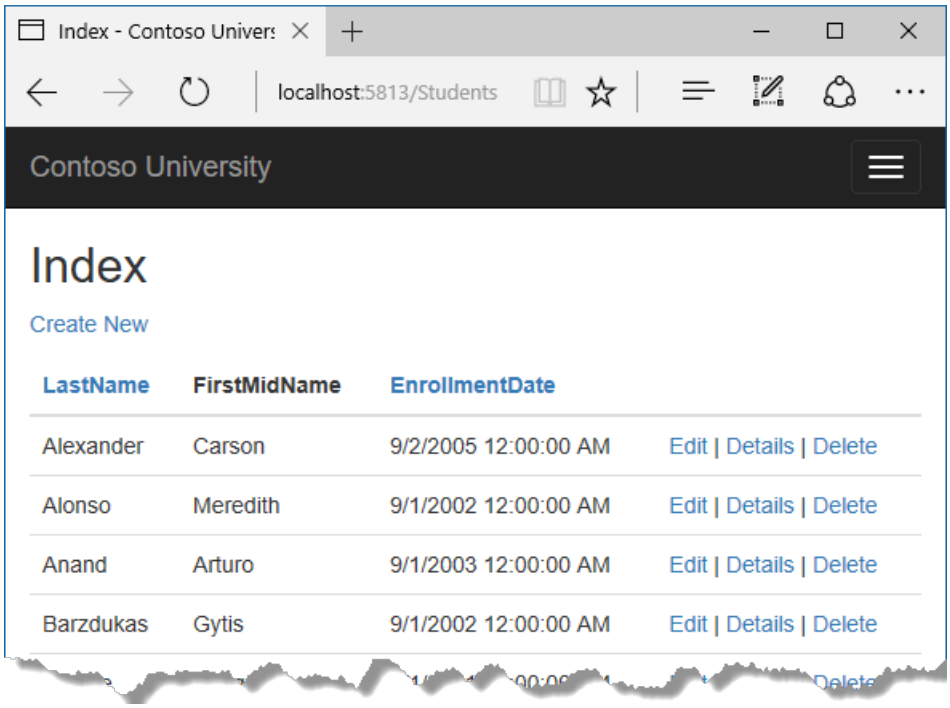
@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    <a asp-action="Index" asp-route-
sortOrder="@ViewData["NameSortParm"]">@Html.DisplayNameFor(model => model.LastName)</a>
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.FirstMidName)
                </th>
                <th>
                    <a asp-action="Index" asp-route-
sortOrder="@ViewData["DateSortParm"]">@Html.DisplayNameFor(model => model.EnrollmentDate)</a>
                </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.LastName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.FirstMidName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
                <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

This code uses the information in `ViewData` properties to set up hyperlinks with the appropriate query string values.

Run the app, select the **Students** tab, and click the **Last Name** and **Enrollment Date** column headings to verify that sorting works.



Add a Search box

To add filtering to the Students Index page, you'll add a text box and a submit button to the view and make corresponding changes in the `Index` method. The text box will let you enter a string to search for in the first name and last name fields.

Add filtering functionality to the Index method

In *StudentsController.cs*, replace the `Index` method with the following code (the changes are highlighted).

```
public async Task<IActionResult> Index(string sortOrder, string searchString)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

You've added a `searchString` parameter to the `Index` method. The search string value is received from a text box that you'll add to the Index view. You've also added to the LINQ statement a where clause that selects only students whose first name or last name contains the search string. The statement that adds the where clause is executed only if there's a value to search for.

> **NOTE**
>
> Here you are calling the `Where` method on an `IQueryable` object, and the filter will be processed on the server. In some scenarios you might be calling the `Where` method as an extension method on an in-memory collection. (For example, suppose you change the reference to `_context.Students` so that instead of an EF `DbSet` it references a repository method that returns an `IEnumerable` collection.) The result would normally be the same but in some cases may be different.
>
> For example, the .NET Framework implementation of the `Contains` method performs a case-sensitive comparison by default, but in SQL Server this is determined by the collation setting of the SQL Server instance. That setting defaults to case-insensitive. You could call the `ToUpper` method to make the test explicitly case-insensitive: *Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())*. That would ensure that results stay the same if you change the code later to use a repository which returns an `IEnumerable` collection instead of an `IQueryable` object. (When you call the `Contains` method on an `IEnumerable` collection, you get the .NET Framework implementation; when you call it on an `IQueryable` object, you get the database provider implementation.) However, there's a performance penalty for this solution. The `ToUpper` code would put a function in the WHERE clause of the TSQL SELECT statement. That would prevent the optimizer from using an index. Given that SQL is mostly installed as case-insensitive, it's best to avoid the `ToUpper` code until you migrate to a case-sensitive data store.

Add a Search Box to the Student Index View

In *Views/Student/Index.cshtml*, add the highlighted code immediately before the opening table tag in order to create a caption, a text box, and a **Search** button.

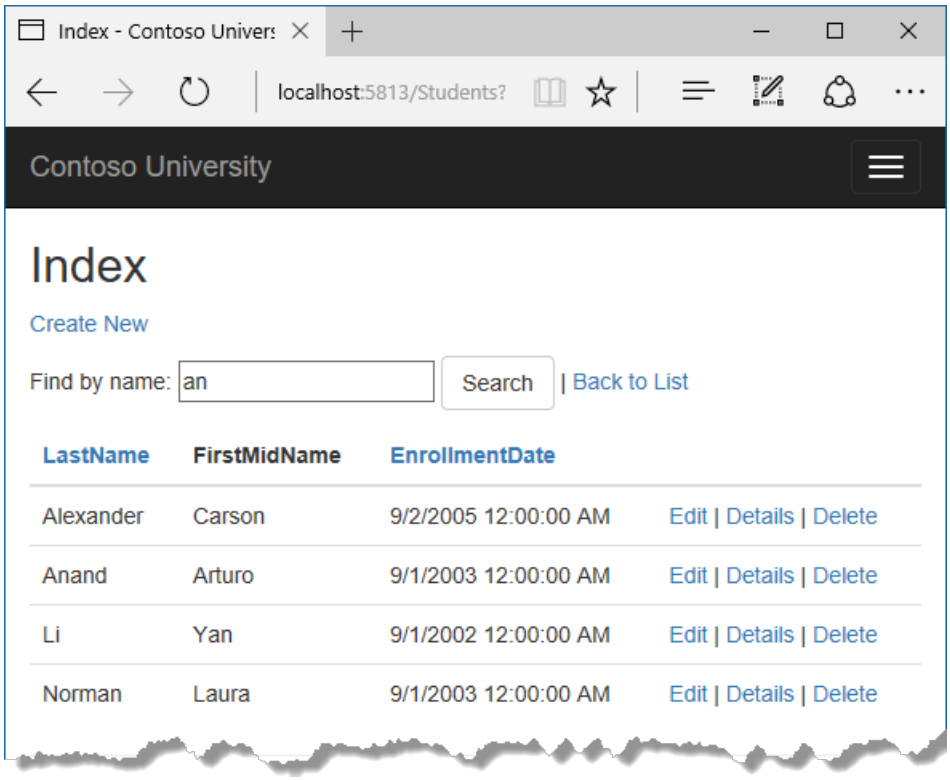
```
<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-action="Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name: <input type="text" name="SearchString" value="@ViewData["CurrentFilter"]" />
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-action="Index">Back to Full List</a>
        </p>
    </div>
</form>

<table class="table">
```

This code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST, which means that parameters are passed in the HTTP message body and not in the URL as query strings. When you specify HTTP GET, the form data is passed in the URL as query strings, which enables users to bookmark the URL. The W3C guidelines recommend that you should use GET when the action doesn't result in an update.

Run the app, select the **Students** tab, enter a search string, and click Search to verify that filtering is working.



Notice that the URL contains the search string.

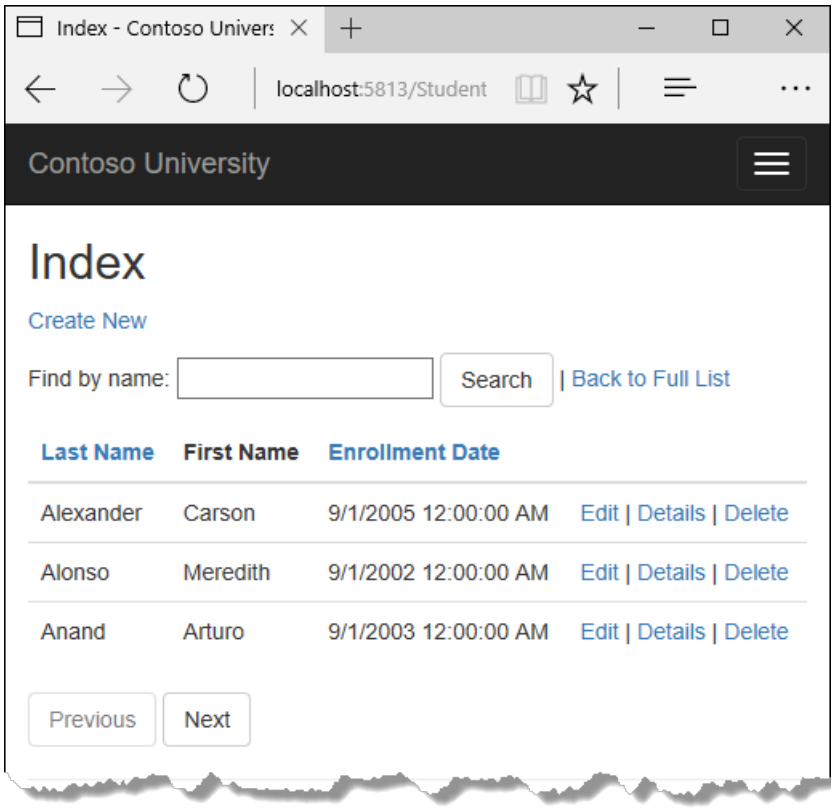
```
http://localhost:5813/Students?SearchString=an
```

If you bookmark this page, you'll get the filtered list when you use the bookmark. Adding `method="get"` to the `form` tag is what caused the query string to be generated.

At this stage, if you click a column heading sort link you'll lose the filter value that you entered in the **Search** box. You'll fix that in the next section.

Add paging to Students Index

To add paging to the Students Index page, you'll create a `PaginatedList` class that uses `Skip` and `Take` statements to filter data on the server instead of always retrieving all rows of the table. Then you'll make additional changes in the `Index` method and add paging buttons to the `Index` view. The following illustration shows the paging buttons.



In the project folder, create `PaginatedList.cs`, and then replace the template code with the following code.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }

        public bool HasPreviousPage
        {
            get
            {
                return (PageIndex > 1);
            }
        }

        public bool HasNextPage
        {
            get
            {
                return (PageIndex < TotalPages);
            }
        }

        public static async Task<PaginatedList<T>> CreateAsync(IQueryable<T> source, int pageIndex, int
pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip((pageIndex - 1) * pageSize).Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in this code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it will return a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` can be used to enable or disable **Previous** and **Next** paging buttons.

A `CreateAsync` method is used instead of a constructor to create the `PaginatedList<T>` object because constructors can't run asynchronous code.

Add paging to Index method

In *StudentsController.cs*, replace the `Index` method with the following code.

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
{
    ViewData["CurrentSort"] = sortOrder;
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";

    if (searchString != null)
    {
        pageNumber = 1;
    }
    else
    {
        searchString = currentFilter;
    }

    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }

    int pageSize = 3;
    return View(await PaginatedList<Student>.CreateAsync(students.AsNoTracking(), pageNumber ?? 1, pageSize));
}
```

This code adds a page number parameter, a current sort order parameter, and a current filter parameter to the method signature.

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
```

The first time the page is displayed, or if the user hasn't clicked a paging or sorting link, all the parameters will be null. If a paging link is clicked, the page variable will contain the page number to display.

The `ViewData` element named CurrentSort provides the view with the current sort order, because this must be included in the paging links in order to keep the sort order the same while paging.

The `ViewData` element named CurrentFilter provides the view with the current filter string. This value must be included in the paging links in order to maintain the filter settings during paging, and it must be restored to the text box when the page is redisplayed.

If the search string is changed during paging, the page has to be reset to 1, because the new filter can result in different data to display. The search string is changed when a value is entered in the text box and the Submit button is pressed. In that case, the `searchString` parameter isn't null.

```
if (searchString != null)
{
    pageNumber = 1;
}
else
{
    searchString = currentFilter;
}
```

At the end of the `Index` method, the `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is then passed to the view.

```
return View(await PaginatedList<Student>.CreateAsync(students.AsNoTracking(), pageNumber ?? 1, pageSize));
```

The `PaginatedList.CreateAsync` method takes a page number. The two question marks represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type; the expression `(pageNumber ?? 1)` means return the value of `pageNumber` if it has a value, or return 1 if `pageNumber` is null.

Add paging links

In *Views/Students/Index.cshtml*, replace the existing code with the following code. The changes are highlighted.

```
@model PaginatedList<ContosoUniversity.Models.Student>

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-action="Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name: <input type="text" name="SearchString" value="@ViewData["CurrentFilter"]" />
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-action="Index">Back to Full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-action="Index" asp-route-sortOrder="@ViewData["NameSortParm"]" asp-route-
currentFilter="@ViewData["CurrentFilter"]">Last Name</a>
            </th>
            <th>
                First Name
```

```
                First Name
            </th>
            <th>
                <a asp-action="Index" asp-route-sortOrder="@ViewData["DateSortParm"]" asp-route-
currentFilter="@ViewData["CurrentFilter"]">Enrollment Date</a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@{
    var prevDisabled = !Model.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.HasNextPage ? "disabled" : "";
}

<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex - 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @prevDisabled">
    Previous
</a>
<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex + 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @nextDisabled">
    Next
</a>
```

The `@model` statement at the top of the page specifies that the view now gets a `PaginatedList<T>` object instead of a `List<T>` object.

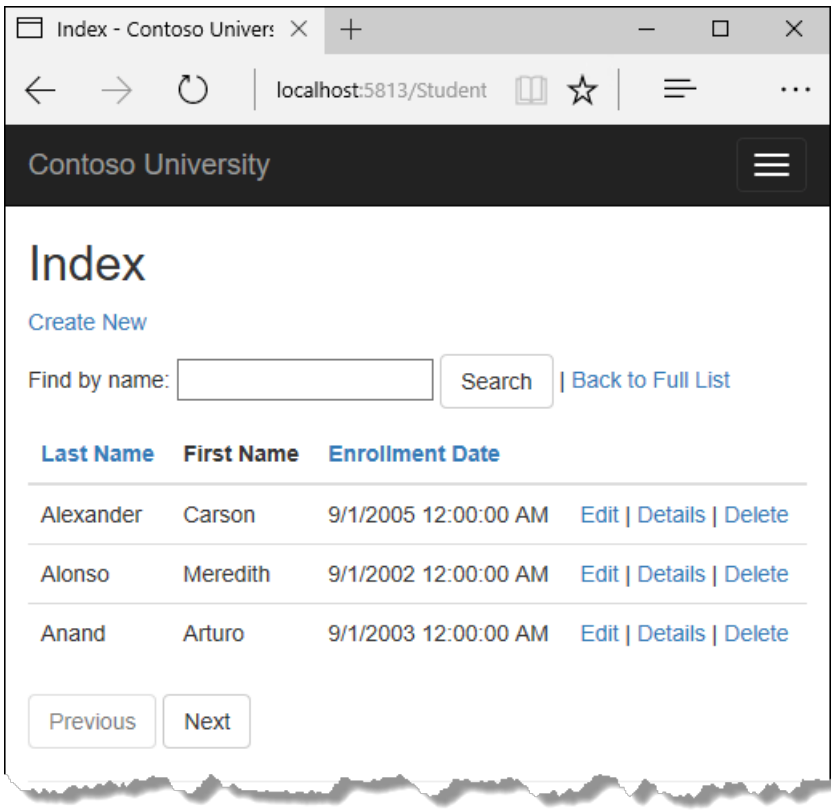
The column header links use the query string to pass the current search string to the controller so that the user can sort within filter results:

```
<a asp-action="Index" asp-route-sortOrder="@ViewData["DateSortParm"]" asp-route-currentFilter
="@ViewData["CurrentFilter"]">Enrollment Date</a>
```

The paging buttons are displayed by tag helpers:

```
<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex - 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @prevDisabled">
   Previous
</a>
```

Run the app and go to the Students page.



Click the paging links in different sort orders to make sure paging works. Then enter a search string and try paging again to verify that paging also works correctly with sorting and filtering.

Create an About page

For the Contoso University website's **About** page, you'll display how many students have enrolled for each enrollment date. This requires grouping and simple calculations on the groups. To accomplish this, you'll do the following:

- Create a view model class for the data that you need to pass to the view.
- Create the About method in the Home controller.
- Create the About view.

Create the view model

Create a *SchoolViewModels* folder in the *Models* folder.

In the new folder, add a class file *EnrollmentDateGroup.cs* and replace the template code with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Modify the Home Controller

In *HomeController.cs*, add the following using statements at the top of the file:

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Data;
using ContosoUniversity.Models.SchoolViewModels;
```

Add a class variable for the database context immediately after the opening curly brace for the class, and get an instance of the context from ASP.NET Core DI:

```
public class HomeController : Controller
{
    private readonly SchoolContext _context;

    public HomeController(SchoolContext context)
    {
        _context = context;
    }
```

Add an `About` method with the following code:

```
public async Task<ActionResult> About()
{
    IQueryable<EnrollmentDateGroup> data =
        from student in _context.Students
        group student by student.EnrollmentDate into dateGroup
        select new EnrollmentDateGroup()
        {
            EnrollmentDate = dateGroup.Key,
            StudentCount = dateGroup.Count()
        };
    return View(await data.AsNoTracking().ToListAsync());
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Create the About View

Add a *Views/Home/About.cshtml* file with the following code:

```
@model IEnumerable<ContosoUniversity.Models.SchoolViewModels.EnrollmentDateGroup>

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Run the app and go to the About page. The count of students for each enrollment date is displayed in a table.

Download or view the completed application.

Next steps

In this tutorial, you:

- Added column sort links
- Added a Search box
- Added paging to Students Index
- Added paging to Index method
- Added paging links
- Created an About page

Advance to the next tutorial to learn how to handle data model changes by using migrations.

Next: Handle data model changes

Tutorial: Using the migrations feature - ASP.NET MVC with EF Core

9/22/2020 • 7 minutes to read • Edit Online

In this tutorial, you start using the EF Core migrations feature for managing data model changes. In later tutorials, you'll add more migrations as you change the data model.

In this tutorial, you:

- Learn about migrations
- Change the connection string
- Create an initial migration
- Examine Up and Down methods
- Learn about the data model snapshot
- Apply the migration

Prerequisites

- Sorting, filtering, and paging

About migrations

When you develop a new application, your data model changes frequently, and each time the model changes, it gets out of sync with the database. You started these tutorials by configuring the Entity Framework to create the database if it doesn't exist. Then each time you change the data model -- add, remove, or change entity classes or change your DbContext class -- you can delete the database and EF creates a new one that matches the model, and seeds it with test data.

This method of keeping the database in sync with the data model works well until you deploy the application to production. When the application is running in production it's usually storing data that you want to keep, and you don't want to lose everything each time you make a change such as adding a new column. The EF Core Migrations feature solves this problem by enabling EF to update the database schema instead of creating a new database.

To work with migrations, you can use the **Package Manager Console** (PMC) or the CLI. These tutorials show how to use CLI commands. Information about the PMC is at the end of this tutorial.

Change the connection string

In the *appsettings.json* file, change the name of the database in the connection string to ContosoUniversity2 or some other name that you haven't used on the computer you're using.

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity2;Trusted_Connection=True;MultipleActiveResultSets=true"
  },
```

This change sets up the project so that the first migration will create a new database. This isn't required to get started with migrations, but you'll see later why it's a good idea.

NOTE

As an alternative to changing the database name, you can delete the database. Use **SQL Server Object Explorer** (SSOX) or the `database drop` CLI command:

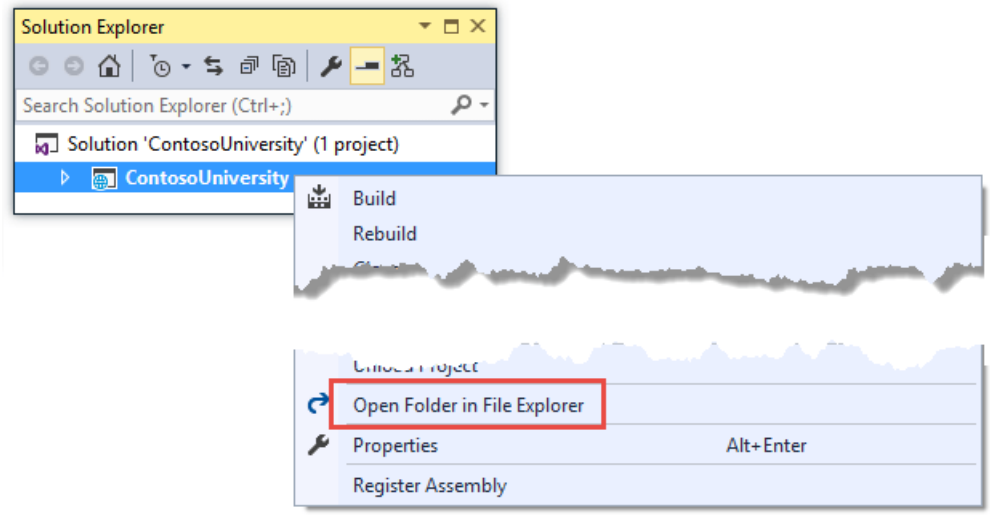
```
dotnet ef database drop
```

The following section explains how to run CLI commands.

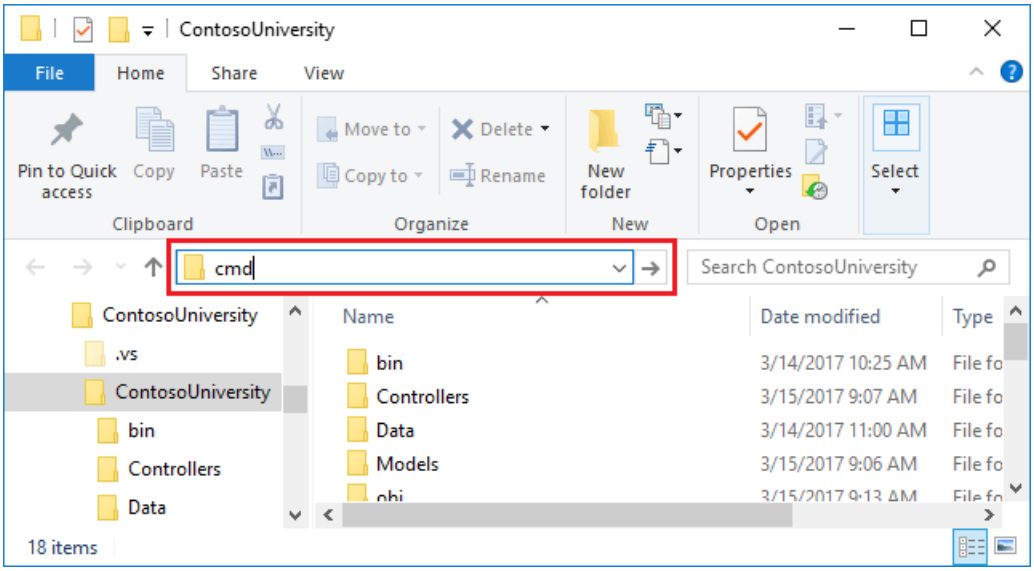
Create an initial migration

Save your changes and build the project. Then open a command window and navigate to the project folder. Here's a quick way to do that:

- In **Solution Explorer**, right-click the project and choose **Open Folder in File Explorer** from the context menu.



- Enter "cmd" in the address bar and press Enter.



Enter the following command in the command window:

```
dotnet tool install --global dotnet-ef
dotnet ef migrations add InitialCreate
```

`dotnet tool install --global dotnet-ef` installs `dotnet ef` as a global tool.

In the preceding commands, output similar to the following is displayed:

```
info: Microsoft.EntityFrameworkCore.Infrastructure[10403]
      Entity Framework Core 2.2.0-rtm-35687 initialized 'SchoolContext' using provider
'Microsoft.EntityFrameworkCore.SqlServer' with options: None
Done. To undo this action, use 'ef migrations remove'
```

If you see an error message "*cannot access the file ... ContosoUniversity.dll because it is being used by another process.*", find the IIS Express icon in the Windows System Tray, and right-click it, then click **ContosoUniversity > Stop Site**.

Examine Up and Down methods

When you executed the `migrations add` command, EF generated the code that will create the database from scratch. This code is in the *Migrations* folder, in the file named *<timestamp>_InitialCreate.cs*. The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets, and the `Down` method deletes them, as shown in the following example.

```
public partial class InitialCreate : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.CreateTable(
            name: "Course",
            columns: table => new
            {
                CourseID = table.Column<int>(nullable: false),
                Credits = table.Column<int>(nullable: false),
                Title = table.Column<string>(nullable: true)
            },
            constraints: table =>
            {
                table.PrimaryKey("PK_Course", x => x.CourseID);
            });

        // Additional code not shown
    }

    protected override void Down(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.DropTable(
            name: "Enrollment");
        // Additional code not shown
    }
}
```

Migrations calls the `Up` method to implement the data model changes for a migration. When you enter a command to roll back the update, Migrations calls the `Down` method.

This code is for the initial migration that was created when you entered the `migrations add InitialCreate` command. The migration name parameter ("InitialCreate" in the example) is used for the file name and can be whatever you want. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, you might name a later migration "AddDepartmentTable".

If you created the initial migration when the database already exists, the database creation code is generated but it doesn't have to run because the database already matches the data model. When you deploy the app to another environment where the database doesn't exist yet, this code will run to create your database, so it's a good idea to

test it first. That's why you changed the name of the database in the connection string earlier -- so that migrations can create a new one from scratch.

The data model snapshot

Migrations creates a *snapshot* of the current database schema in *Migrations/SchoolContextModelSnapshot.cs*. When you add a migration, EF determines what changed by comparing the data model to the snapshot file.

Use the dotnet ef migrations remove command to remove a migration. `dotnet ef migrations remove` deletes the migration and ensures the snapshot is correctly reset. If `dotnet ef migrations remove` fails, use `dotnet ef migrations remove -v` to get more information on the failure.

See EF Core Migrations in Team Environments for more information about how the snapshot file is used.

Apply the migration

In the command window, enter the following command to create the database and tables in it.

```
dotnet ef database update
```

The output from the command is similar to the `migrations add` command, except that you see logs for the SQL commands that set up the database. Most of the logs are omitted in the following sample output. If you prefer not to see this level of detail in log messages, you can change the log level in the *appsettings.Development.json* file. For more information, see Logging in .NET Core and ASP.NET Core.

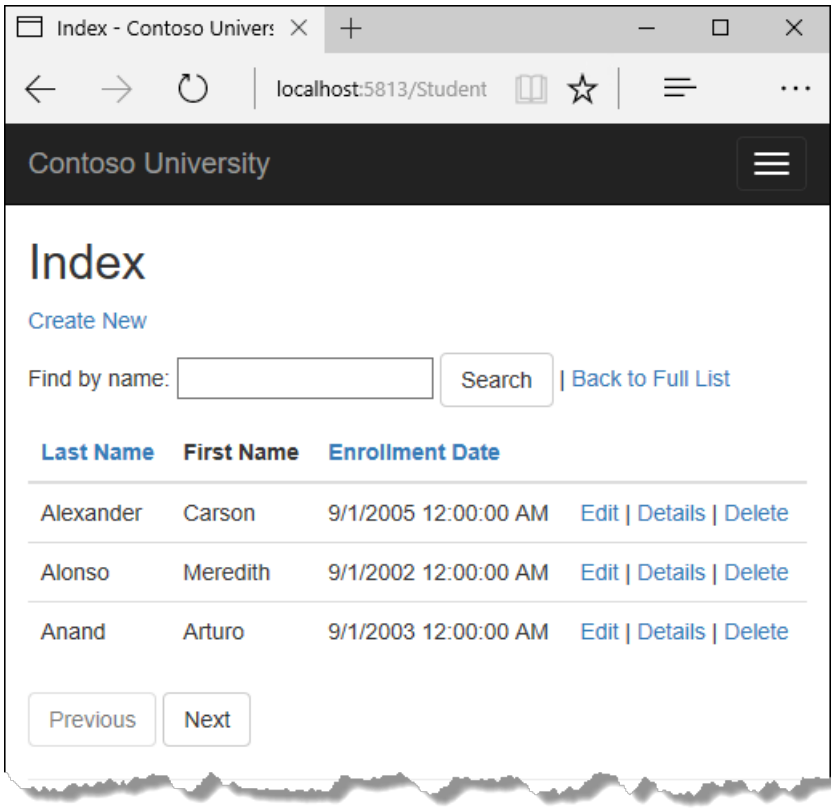
```
info: Microsoft.EntityFrameworkCore.Infrastructure[10403]
      Entity Framework Core 2.2.0-rtm-35687 initialized 'SchoolContext' using provider
'Microsoft.EntityFrameworkCore.SqlServer' with options: None
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (274ms) [Parameters=[], CommandType='Text', CommandTimeout='60']
      CREATE DATABASE [ContosoUniversity2];
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (60ms) [Parameters=[], CommandType='Text', CommandTimeout='60']
      IF SERVERPROPERTY('EngineEdition') <> 5
      BEGIN
          ALTER DATABASE [ContosoUniversity2] SET READ_COMMITTED_SNAPSHOT ON;
      END;
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (15ms) [Parameters=[], CommandType='Text', CommandTimeout='30']
      CREATE TABLE [__EFMigrationsHistory] (
          [MigrationId] nvarchar(150) NOT NULL,
          [ProductVersion] nvarchar(32) NOT NULL,
          CONSTRAINT [PK___EFMigrationsHistory] PRIMARY KEY ([MigrationId])
      );

<logs omitted for brevity>

info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (3ms) [Parameters=[], CommandType='Text', CommandTimeout='30']
      INSERT INTO [__EFMigrationsHistory] ([MigrationId], [ProductVersion])
      VALUES (N'20190327172701_InitialCreate', N'2.2.0-rtm-35687');
Done.
```

Use **SQL Server Object Explorer** to inspect the database as you did in the first tutorial. You'll notice the addition of an __EFMigrationsHistory table that keeps track of which migrations have been applied to the database. View the data in that table and you'll see one row for the first migration. (The last log in the preceding CLI output example shows the INSERT statement that creates this row.)

Run the application to verify that everything still works the same as before.



Compare CLI and PMC

The EF tooling for managing migrations is available from .NET Core CLI commands or from PowerShell cmdlets in the Visual Studio **Package Manager Console** (PMC) window. This tutorial shows how to use the CLI, but you can use the PMC if you prefer.

The EF commands for the PMC commands are in the Microsoft.EntityFrameworkCore.Tools package. This package is included in the Microsoft.AspNetCore.App metapackage, so you don't need to add a package reference if your app has a package reference for `Microsoft.AspNetCore.App`.

Important: This isn't the same package as the one you install for the CLI by editing the *.csproj* file. The name of this one ends in `Tools`, unlike the CLI package name which ends in `Tools.DotNet`.

For more information about the CLI commands, see .NET Core CLI.

For more information about the PMC commands, see Package Manager Console (Visual Studio).

Next step

In this tutorial, you:

- Learned about migrations
- Learned about NuGet migration packages
- Changed the connection string
- Created an initial migration
- Examined Up and Down methods
- Learned about the data model snapshot
- Applied the migration

Advance to the next tutorial to begin looking at more advanced topics about expanding the data model. Along the way you'll create and apply additional migrations.

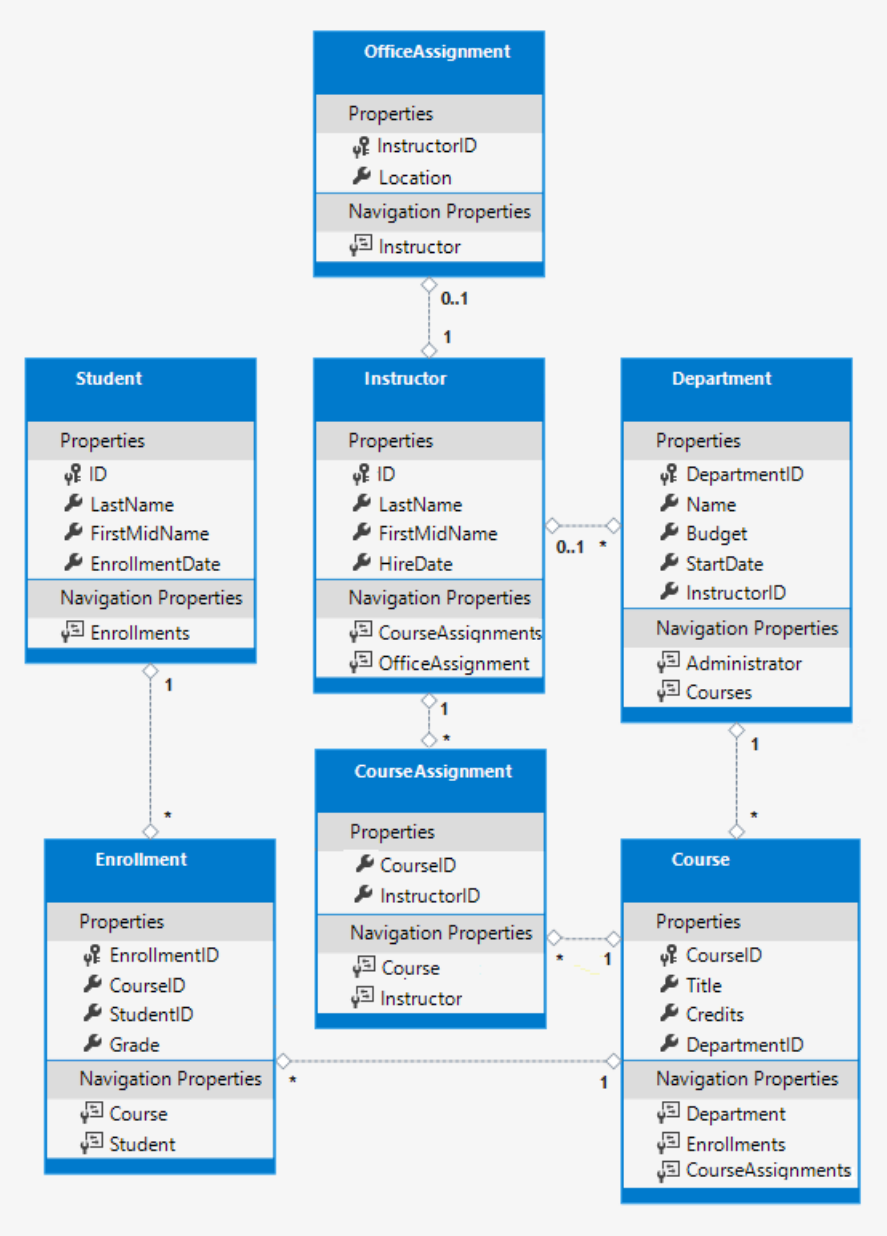
Create and apply additional migrations

Tutorial: Create a complex data model - ASP.NET MVC with EF Core

9/22/2020 • 30 minutes to read • Edit Online

In the previous tutorials, you worked with a simple data model that was composed of three entities. In this tutorial, you'll add more entities and relationships and you'll customize the data model by specifying formatting, validation, and database mapping rules.

When you're finished, the entity classes will make up the completed data model that's shown in the following illustration:



In this tutorial, you:

- Customize the Data model
- Make changes to Student entity
- Create Instructor entity
- Create OfficeAssignment entity

- Modify Course entity
- Create Department entity
- Modify Enrollment entity
- Update the database context
- Seed database with test data
- Add a migration
- Change the connection string
- Update the database

Prerequisites

- Using EF Core migrations

Customize the Data model

In this section you'll see how to customize the data model by using attributes that specify formatting, validation, and database mapping rules. Then in several of the following sections you'll create the complete School data model by adding attributes to the classes you already created and creating new classes for the remaining entity types in the model.

The DataType attribute

For student enrollment dates, all of the web pages currently display the time along with the date, although all you care about for this field is the date. By using data annotation attributes, you can make one code change that will fix the display format in every view that shows the data. To see an example of how to do that, you'll add an attribute to the `EnrollmentDate` property in the `Student` class.

In *Models/Student.cs*, add a `using` statement for the `System.ComponentModel.DataAnnotations` namespace and add `DataType` and `DisplayFormat` attributes to the `EnrollmentDate` property, as shown in the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type. In this case we only want to keep track of the date, not the date and time. The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`, and a date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers can understand. The `DataType` attributes don't provide any validation.

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
```

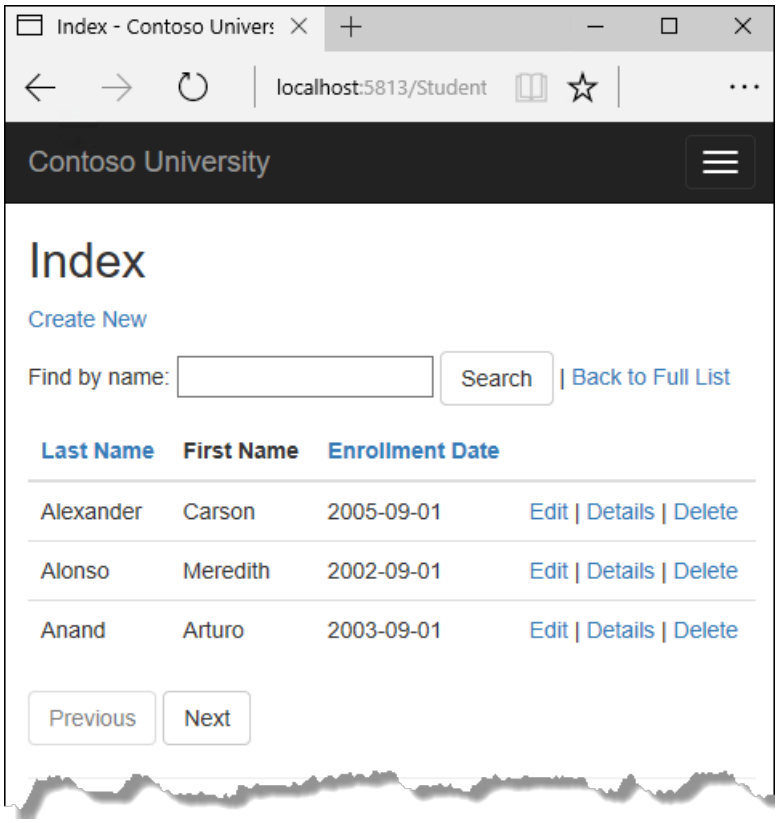
The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some fields -- for example, for currency values, you might not want the currency symbol in the text box for editing.)

You can use the `DisplayFormat` attribute by itself, but it's generally a good idea to use the `DataType` attribute also. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with `DisplayFormat`:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, some client-side input validation, etc.).
- By default, the browser will render data using the correct format based on your locale.

For more information, see the <input> tag helper documentation.

Run the app, go to the Students Index page and notice that times are no longer displayed for the enrollment dates. The same will be true for any view that uses the Student model.



The StringLength attribute

You can also specify data validation rules and validation error messages using attributes. The `StringLength` attribute sets the maximum length in the database and provides client side and server side validation for ASP.NET Core MVC. You can also specify the minimum string length in this attribute, but the minimum value has no impact on the database schema.

Suppose you want to ensure that users don't enter more than 50 characters for a name. To add this limitation, add `StringLength` attributes to the `LastName` and `FirstMidName` properties, as shown in the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50)]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `StringLength` attribute won't prevent a user from entering white space for a name. You can use the `RegularExpression` attribute to apply restrictions to the input. For example, the following code requires the first character to be upper case and the remaining characters to be alphabetical:

```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

The `MaxLength` attribute provides functionality similar to the `StringLength` attribute but doesn't provide client side validation.

The database model has now changed in a way that requires a change in the database schema. You'll use migrations to update the schema without losing any data that you may have added to the database by using the application UI.

Save your changes and build the project. Then open the command window in the project folder and enter the following commands:

```
dotnet ef migrations add MaxLengthOnNames
```

```
dotnet ef database update
```

The `migrations add` command warns that data loss may occur, because the change makes the maximum length shorter for two columns. Migrations creates a file named *<timeStamp>_MaxLengthOnNames.cs*. This file contains code in the `Up` method that will update the database to match the current data model. The `database update` command ran that code.

The timestamp prefixed to the migrations file name is used by Entity Framework to order the migrations. You can create multiple migrations before running the update-database command, and then all of the migrations are applied in the order in which they were created.

Run the app, select the **Students** tab, click **Create New**, and try to enter either name longer than 50 characters. The application should prevent you from doing this.

The Column attribute

You can also use attributes to control how your classes and properties are mapped to the database. Suppose you had used the name `FirstMidName` for the first-name field because the field might also contain a middle name. But you want the database column to be named `FirstName`, because users who will be writing ad-hoc queries against

the database are accustomed to that name. To make this mapping, you can use the `Column` attribute.

The `Column` attribute specifies that when the database is created, the column of the `Student` table that maps to the `FirstMidName` property will be named `FirstName`. In other words, when your code refers to `Student.FirstMidName`, the data will come from or be updated in the `FirstName` column of the `Student` table. If you don't specify column names, they're given the same name as the property name.

In the *Student.cs* file, add a `using` statement for `System.ComponentModel.DataAnnotations.Schema` and add the column name attribute to the `FirstMidName` property, as shown in the following highlighted code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50)]
        [Column("FirstName")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

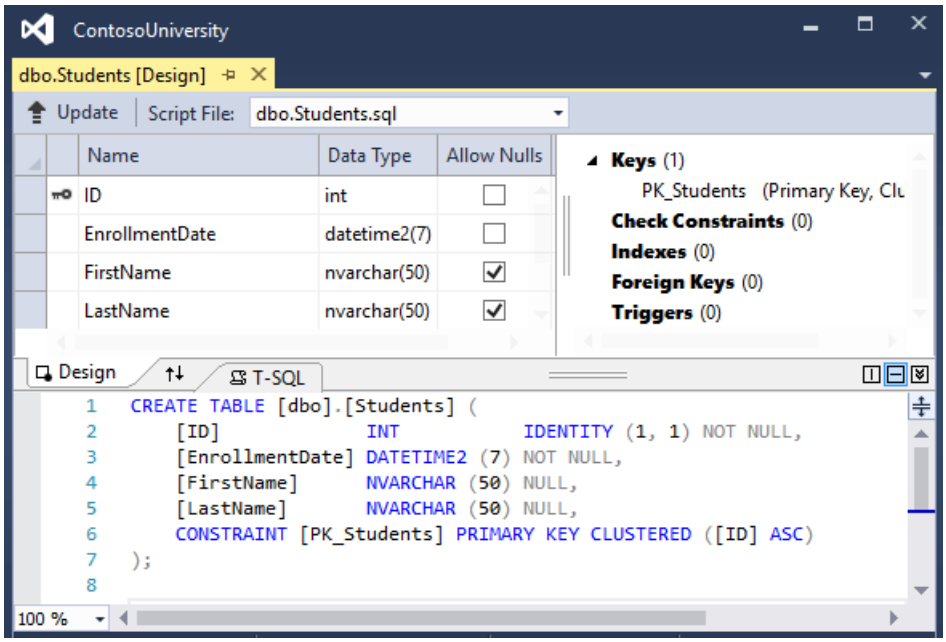
The addition of the `Column` attribute changes the model backing the `SchoolContext`, so it won't match the database.

Save your changes and build the project. Then open the command window in the project folder and enter the following commands to create another migration:

```
dotnet ef migrations add ColumnFirstName
```

```
dotnet ef database update
```

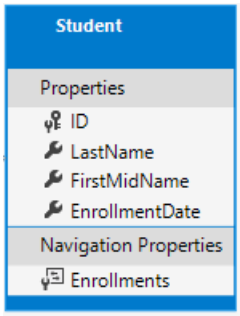
In **SQL Server Object Explorer**, open the Student table designer by double-clicking the **Student** table.



Before you applied the first two migrations, the name columns were of type nvarchar(MAX). They're now nvarchar(50) and the column name has changed from FirstMidName to FirstName.

> **NOTE**
> If you try to compile before you finish creating all of the entity classes in the following sections, you might get compiler errors.

Changes to Student entity



In *Models/Student.cs*, replace the code you added earlier with the following code. The changes are highlighted.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50)]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The Required attribute

The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (DateTime, int, double, float, etc.). Types that can't be null are automatically treated as required fields.

The `Required` attribute must be used with `MinimumLength` for the `MinimumLength` to be enforced.

```
[Display(Name = "Last Name")]
[Required]
[StringLength(50, MinimumLength=2)]
public string LastName { get; set; }
```

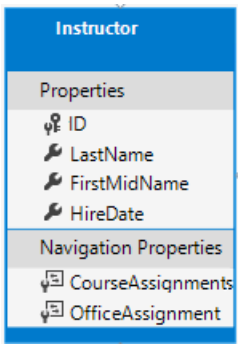
The Display attribute

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date" instead of the property name in each instance (which has no space dividing the words).

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. Therefore it has only a get accessor, and no `FullName` column will be generated in the database.

Create Instructor entity



Create *Models/Instructor.cs*, replacing the template code with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Notice that several properties are the same in the Student and Instructor entities. In the Implementing Inheritance tutorial later in this series, you'll refactor this code to eliminate the redundancy.

You can put multiple attributes on one line, so you could also write the `HireDate` attributes as follows:

```
[DataType(DataType.Date),Display(Name = "Hire Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

The CourseAssignments and OfficeAssignment navigation properties

The `CourseAssignments` and `OfficeAssignment` properties are navigation properties.

An instructor can teach any number of courses, so `CourseAssignments` is defined as a collection.

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

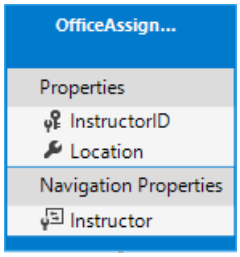
If a navigation property can hold multiple entities, its type must be a list in which entries can be added, deleted, and updated. You can specify `ICollection<T>` or a type such as `List<T>` or `HashSet<T>`. If you specify `ICollection<T>`, EF creates a `HashSet<T>` collection by default.

The reason why these are `CourseAssignment` entities is explained below in the section about many-to-many relationships.

Contoso University business rules state that an instructor can only have at most one office, so the `OfficeAssignment` property holds a single OfficeAssignment entity (which may be null if no office is assigned).

```
public OfficeAssignment OfficeAssignment { get; set; }
```

Create OfficeAssignment entity



Create *Models/OfficeAssignment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public Instructor Instructor { get; set; }
    }
}
```

The Key attribute

There's a one-to-zero-or-one relationship between the Instructor and the OfficeAssignment entities. An office assignment only exists in relation to the instructor it's assigned to, and therefore its primary key is also its foreign key to the Instructor entity. But the Entity Framework can't automatically recognize InstructorID as the primary key of this entity because its name doesn't follow the ID or classnameID naming convention. Therefore, the `Key` attribute is used to identify it as the key:

```
[Key]
public int InstructorID { get; set; }
```

You can also use the `Key` attribute if the entity does have its own primary key but you want to name the property something other than classnameID or ID.

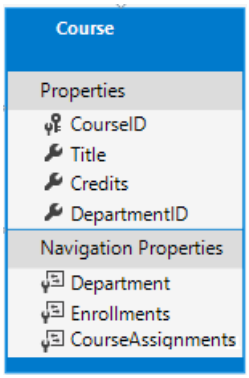
By default, EF treats the key as non-database-generated because the column is for an identifying relationship.

The Instructor navigation property

The Instructor entity has a nullable `OfficeAssignment` navigation property (because an instructor might not have an office assignment), and the OfficeAssignment entity has a non-nullable `Instructor` navigation property (because an office assignment can't exist without an instructor -- `InstructorID` is non-nullable). When an Instructor entity has a related OfficeAssignment entity, each entity will have a reference to the other one in its navigation property.

You could put a `[Required]` attribute on the Instructor navigation property to specify that there must be a related instructor, but you don't have to do that because the `InstructorID` foreign key (which is also the key to this table) is non-nullable.

Modify Course entity



In *Models/Course.cs*, replace the code you added earlier with the following code. The changes are highlighted.

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<CourseAssignment> CourseAssignments { get; set; }
    }
}
```

The course entity has a foreign key property `DepartmentID` which points to the related Department entity and it has a `Department` navigation property.

The Entity Framework doesn't require you to add a foreign key property to your data model when you have a

navigation property for a related entity. EF automatically creates foreign keys in the database wherever they're needed and creates shadow properties for them. But having the foreign key in the data model can make updates simpler and more efficient. For example, when you fetch a course entity to edit, the Department entity is null if you don't load it, so when you update the course entity, you would have to first fetch the Department entity. When the foreign key property `DepartmentID` is included in the data model, you don't need to fetch the Department entity before you update.

The DatabaseGenerated attribute

The `DatabaseGenerated` attribute with the `None` parameter on the `CourseID` property specifies that primary key values are provided by the user rather than generated by the database.

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, Entity Framework assumes that primary key values are generated by the database. That's what you want in most scenarios. However, for Course entities, you'll use a user-specified course number such as a 1000 series for one department, a 2000 series for another department, and so on.

The `DatabaseGenerated` attribute can also be used to generate default values, as in the case of database columns used to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key properties and navigation properties in the Course entity reflect the following relationships:

A course is assigned to one department, so there's a `DepartmentID` foreign key and a `Department` navigation property for the reasons mentioned above.

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

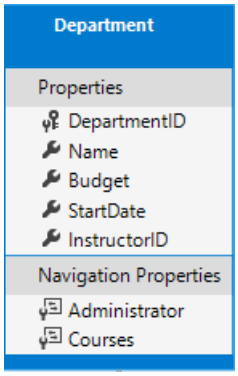
A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `CourseAssignments` navigation property is a collection (the type `CourseAssignment` is explained later):

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

Create Department entity



Create *Models/Department.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Earlier you used the `Column` attribute to change column name mapping. In the code for the Department entity, the `Column` attribute is being used to change SQL data type mapping so that the column will be defined using the SQL Server money type in the database:

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required, because the Entity Framework chooses the appropriate SQL Server data type based on the CLR type that you define for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. But in this case you know that the column will be holding currency amounts, and the money data type is more appropriate for that.

Foreign key and navigation properties

The foreign key and navigation properties reflect the following relationships:

A department may or may not have an administrator, and an administrator is always an instructor. Therefore the `InstructorID` property is included as the foreign key to the Instructor entity, and a question mark is added after the `int` type designation to mark the property as nullable. The navigation property is named `Administrator` but holds an Instructor entity:

```
public int? InstructorID { get; set; }
public Instructor Administrator { get; set; }
```

A department may have many courses, so there's a Courses navigation property:

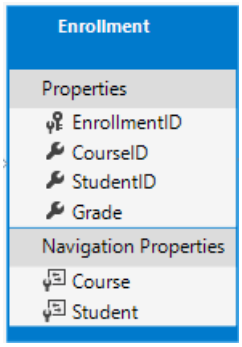
```
public ICollection<Course> Courses { get; set; }
```

NOTE

By convention, the Entity Framework enables cascade delete for non-nullable foreign keys and for many-to-many relationships. This can result in circular cascade delete rules, which will cause an exception when you try to add a migration. For example, if you didn't define the Department.InstructorID property as nullable, EF would configure a cascade delete rule to delete the department when you delete the instructor, which isn't what you want to have happen. If your business rules required the `InstructorID` property to be non-nullable, you would have to use the following fluent API statement to disable cascade delete on the relationship:

```
modelBuilder.Entity<Department>()
    .HasOne(d => d.Administrator)
    .WithMany()
    .OnDelete(DeleteBehavior.Restrict)
```

Modify Enrollment entity



In *Models/Enrollment.cs*, replace the code you added earlier with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

Foreign key and navigation properties

The foreign key properties and navigation properties reflect the following relationships:

An enrollment record is for a single course, so there's a `CourseID` foreign key property and a `Course` navigation

property:

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

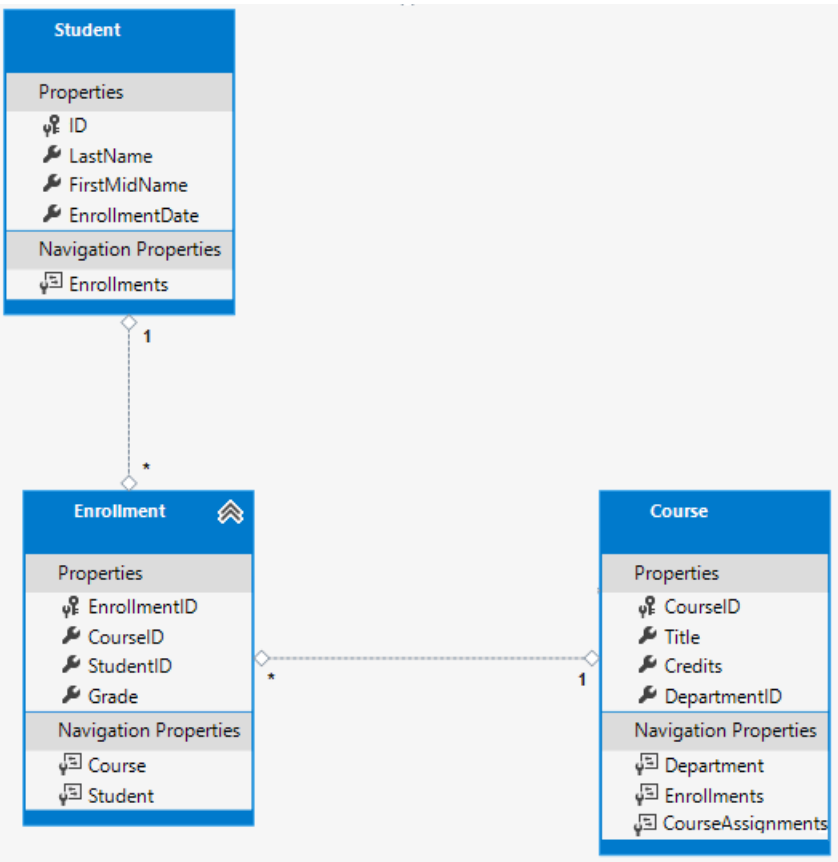
An enrollment record is for a single student, so there's a `StudentID` foreign key property and a `Student` navigation property:

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many relationships

There's a many-to-many relationship between the Student and Course entities, and the Enrollment entity functions as a many-to-many join table *with payload* in the database. "With payload" means that the Enrollment table contains additional data besides foreign keys for the joined tables (in this case, a primary key and a Grade property).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using the Entity Framework Power Tools for EF 6.x; creating the diagram isn't part of the tutorial, it's just being used here as an illustration.)

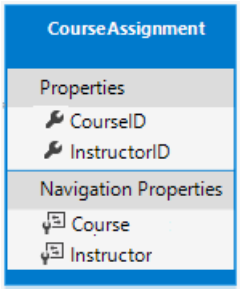


Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the Enrollment table didn't include grade information, it would only need to contain the two foreign keys CourseID and StudentID. In that case, it would be a many-to-many join table without payload (or a pure join table) in the database. The Instructor and Course entities have that kind of many-to-many relationship, and your next step is to create an entity class to function as a join table without payload.

(EF 6.x supports implicit join tables for many-to-many relationships, but EF Core doesn't. For more information, see the discussion in the EF Core GitHub repository.)

The CourseAssignment entity



Create *Models/CourseAssignment.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class CourseAssignment
    {
        public int InstructorID { get; set; }
        public int CourseID { get; set; }
        public Instructor Instructor { get; set; }
        public Course Course { get; set; }
    }
}
```

Join entity names

A join table is required in the database for the Instructor-to-Courses many-to-many relationship, and it has to be represented by an entity set. It's common to name a join entity `EntityName1EntityName2`, which in this case would be `CourseInstructor`. However, we recommend that you choose a name that describes the relationship. Data models start out simple and grow, with no-payload joins frequently getting payloads later. If you start with a descriptive entity name, you won't have to change the name later. Ideally, the join entity would have its own natural (possibly single word) name in the business domain. For example, Books and Customers could be linked through Ratings. For this relationship, `CourseAssignment` is a better choice than `CourseInstructor`.

Composite key

Since the foreign keys are not nullable and together uniquely identify each row of the table, there's no need for a separate primary key. The *InstructorID* and *CourseID* properties should function as a composite primary key. The only way to identify composite primary keys to EF is by using the *fluent API* (it can't be done by using attributes). You'll see how to configure the composite primary key in the next section.

The composite key ensures that while you can have multiple rows for one course, and multiple rows for one instructor, you can't have multiple rows for the same instructor and course. The `Enrollment` join entity defines its own primary key, so duplicates of this sort are possible. To prevent such duplicates, you could add a unique index on the foreign key fields, or configure `Enrollment` with a primary composite key similar to `CourseAssignment`. For more information, see Indexes.

Update the database context

Add the following highlighted code to the *Data/SchoolContext.cs* file:

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>().ToTable("CourseAssignment");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

This code adds the new entities and configures the CourseAssignment entity's composite primary key.

About a fluent API alternative

The code in the `OnModelCreating` method of the `DbContext` class uses the *fluent API* to configure EF behavior. The API is called "fluent" because it's often used by stringing a series of method calls together into a single statement, as in this example from the EF Core documentation:

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```

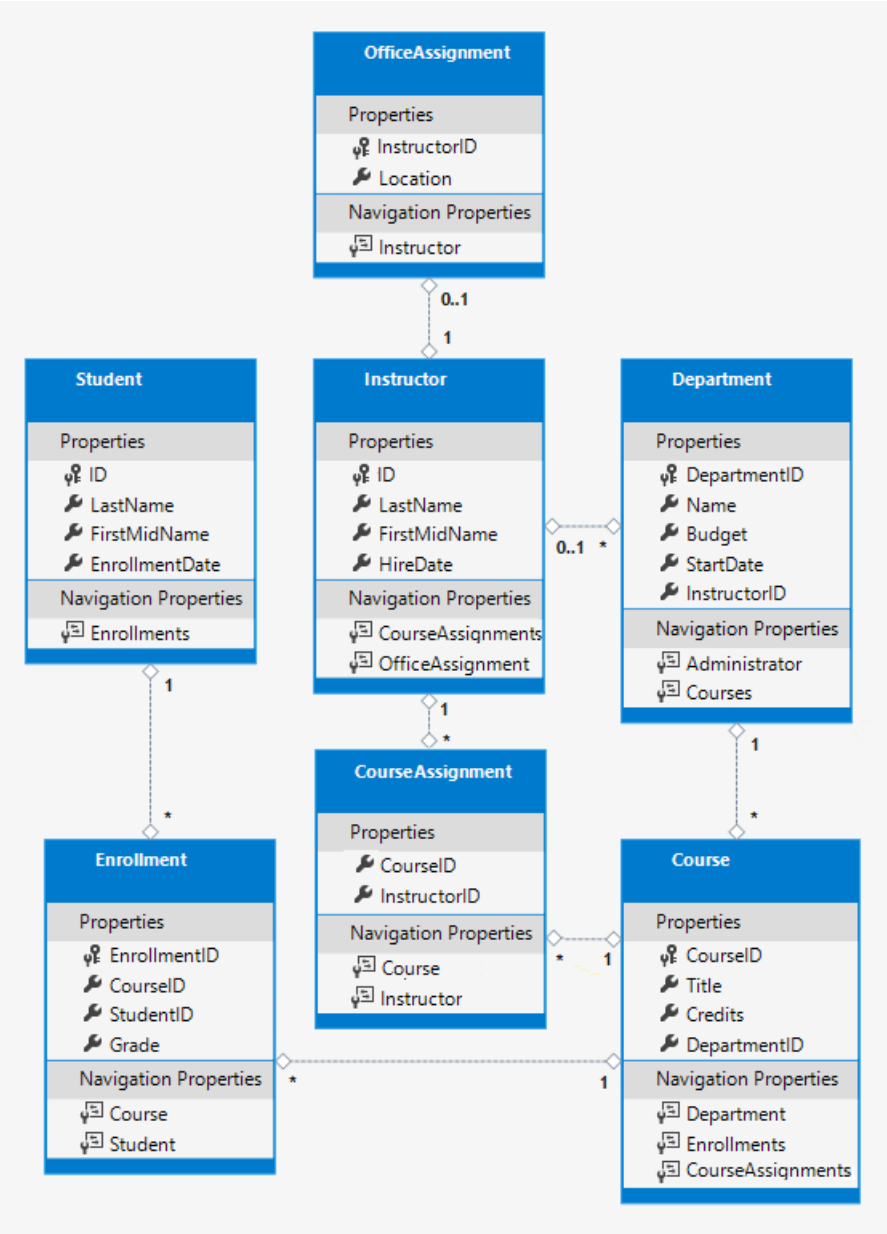
In this tutorial, you're using the fluent API only for database mapping that you can't do with attributes. However, you can also use the fluent API to specify most of the formatting, validation, and mapping rules that you can do by using attributes. Some attributes such as `MinimumLength` can't be applied with the fluent API. As mentioned previously, `MinimumLength` doesn't change the schema, it only applies a client and server side validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." You can mix attributes and fluent API if you want, and there are a few customizations that can only be done by using fluent API, but in general the recommended practice is to choose one of these two approaches and use that consistently as much as possible. If you do use both, note that wherever there's a conflict, Fluent API overrides attributes.

For more information about attributes vs. fluent API, see Methods of configuration.

Entity Diagram Showing Relationships

The following illustration shows the diagram that the Entity Framework Power Tools create for the completed School model.



Besides the one-to-many relationship lines (1 to *), you can see here the one-to-zero-or-one relationship line (1 to 0..1) between the Instructor and OfficeAssignment entities and the zero-or-one-to-many relationship line (0..1 to *) between the Instructor and Department entities.

Seed database with test data

Replace the code in the *Data/DbInitializer.cs* file with the following code in order to provide seed data for the new entities you've created.

```
using System;
using System.Linq;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
```

```
{
    public static void Initialize(SchoolContext context)
    {
        //context.Database.EnsureCreated();

        // Look for any students.
        if (context.Students.Any())
        {
            return;   // DB has been seeded
        }

        var students = new Student[]
        {
            new Student { FirstMidName = "Carson",   LastName = "Alexander",
                EnrollmentDate = DateTime.Parse("2010-09-01") },
            new Student { FirstMidName = "Meredith", LastName = "Alonso",
                EnrollmentDate = DateTime.Parse("2012-09-01") },
            new Student { FirstMidName = "Arturo",   LastName = "Anand",
                EnrollmentDate = DateTime.Parse("2013-09-01") },
            new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                EnrollmentDate = DateTime.Parse("2012-09-01") },
            new Student { FirstMidName = "Yan",      LastName = "Li",
                EnrollmentDate = DateTime.Parse("2012-09-01") },
            new Student { FirstMidName = "Peggy",    LastName = "Justice",
                EnrollmentDate = DateTime.Parse("2011-09-01") },
            new Student { FirstMidName = "Laura",    LastName = "Norman",
                EnrollmentDate = DateTime.Parse("2013-09-01") },
            new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                EnrollmentDate = DateTime.Parse("2005-09-01") }
        };

        foreach (Student s in students)
        {
            context.Students.Add(s);
        }
        context.SaveChanges();

        var instructors = new Instructor[]
        {
            new Instructor { FirstMidName = "Kim",     LastName = "Abercrombie",
                HireDate = DateTime.Parse("1995-03-11") },
            new Instructor { FirstMidName = "Fadi",    LastName = "Fakhouri",
                HireDate = DateTime.Parse("2002-07-06") },
            new Instructor { FirstMidName = "Roger",   LastName = "Harui",
                HireDate = DateTime.Parse("1998-07-01") },
            new Instructor { FirstMidName = "Candace", LastName = "Kapoor",
                HireDate = DateTime.Parse("2001-01-15") },
            new Instructor { FirstMidName = "Roger",   LastName = "Zheng",
                HireDate = DateTime.Parse("2004-02-12") }
        };

        foreach (Instructor i in instructors)
        {
            context.Instructors.Add(i);
        }
        context.SaveChanges();

        var departments = new Department[]
        {
            new Department { Name = "English",     Budget = 350000,
                StartDate = DateTime.Parse("2007-09-01"),
                InstructorID  = instructors.Single( i => i.LastName == "Abercrombie").ID },
            new Department { Name = "Mathematics", Budget = 100000,
                StartDate = DateTime.Parse("2007-09-01"),
                InstructorID  = instructors.Single( i => i.LastName == "Fakhouri").ID },
            new Department { Name = "Engineering", Budget = 350000,
                StartDate = DateTime.Parse("2007-09-01"),
                InstructorID  = instructors.Single( i => i.LastName == "Harui").ID },
            new Department { Name = "Economics",   Budget = 100000,
```

```
        StartDate = DateTime.Parse("2007-09-01"),
        InstructorID  = instructors.Single( i => i.LastName == "Kapoor").ID }
};

foreach (Department d in departments)
{
    context.Departments.Add(d);
}
context.SaveChanges();

var courses = new Course[]
{
    new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3,
        DepartmentID = departments.Single( s => s.Name == "Engineering").DepartmentID
    },
    new Course {CourseID = 4022, Title = "Microeconomics", Credits = 3,
        DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID
    },
    new Course {CourseID = 4041, Title = "Macroeconomics", Credits = 3,
        DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID
    },
    new Course {CourseID = 1045, Title = "Calculus",       Credits = 4,
        DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID
    },
    new Course {CourseID = 3141, Title = "Trigonometry",   Credits = 4,
        DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID
    },
    new Course {CourseID = 2021, Title = "Composition",    Credits = 3,
        DepartmentID = departments.Single( s => s.Name == "English").DepartmentID
    },
    new Course {CourseID = 2042, Title = "Literature",     Credits = 4,
        DepartmentID = departments.Single( s => s.Name == "English").DepartmentID
    },
};

foreach (Course c in courses)
{
    context.Courses.Add(c);
}
context.SaveChanges();

var officeAssignments = new OfficeAssignment[]
{
    new OfficeAssignment {
        InstructorID = instructors.Single( i => i.LastName == "Fakhouri").ID,
        Location = "Smith 17" },
    new OfficeAssignment {
        InstructorID = instructors.Single( i => i.LastName == "Harui").ID,
        Location = "Gowan 27" },
    new OfficeAssignment {
        InstructorID = instructors.Single( i => i.LastName == "Kapoor").ID,
        Location = "Thompson 304" },
};

foreach (OfficeAssignment o in officeAssignments)
{
    context.OfficeAssignments.Add(o);
}
context.SaveChanges();

var courseInstructors = new CourseAssignment[]
{
    new CourseAssignment {
        CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
        InstructorID = instructors.Single(i => i.LastName == "Kapoor").ID
        },
    new CourseAssignment {
        CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
        InstructorID = instructors.Single(i => i.LastName == "Harui").ID
```

```
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Zheng").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Zheng").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Fakhouri").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Harui").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Abercrombie").ID
            },
        new CourseAssignment {
            CourseID = courses.Single(c => c.Title == "Literature" ).CourseID,
            InstructorID = instructors.Single(i => i.LastName == "Abercrombie").ID
            },
    };

    foreach (CourseAssignment ci in courseInstructors)
    {
        context.CourseAssignments.Add(ci);
    }
    context.SaveChanges();

    var enrollments = new Enrollment[]
    {
        new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alexander").ID,
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
            Grade = Grade.A
        },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alexander").ID,
            CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
            Grade = Grade.C
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alexander").ID,
            CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Alonso").ID,
            CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
            Grade = Grade.B
            },
            new Enrollment {
            StudentID = students.Single(s => s.LastName == "Anand").ID,
            CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID
            },
```

```
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Anand").ID,
                    CourseID = courses.Single(c => c.Title == "Microeconomics").CourseID,
                    Grade = Grade.B
                    },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Barzdukas").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Li").ID,
                    CourseID = courses.Single(c => c.Title == "Composition").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Justice").ID,
                    CourseID = courses.Single(c => c.Title == "Literature").CourseID,
                    Grade = Grade.B
                    }
            };

            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollments.Where(
                    s =>
                            s.Student.ID == e.StudentID &&
                            s.Course.CourseID == e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
                    context.Enrollments.Add(e);
                }
            }
            context.SaveChanges();
        }
    }
}
```

As you saw in the first tutorial, most of this code simply creates new entity objects and loads sample data into properties as required for testing. Notice how the many-to-many relationships are handled: the code creates relationships by creating entities in the `Enrollments` and `CourseAssignment` join entity sets.

Add a migration

Save your changes and build the project. Then open the command window in the project folder and enter the `migrations add` command (don't do the update-database command yet):

```
dotnet ef migrations add ComplexDataModel
```

You get a warning about possible data loss.

```
An operation was scaffolded that may result in the loss of data. Please review the migration for accuracy.
Done. To undo this action, use 'ef migrations remove'
```

If you tried to run the `database update` command at this point (don't do it yet), you would get the following error:

> The ALTER TABLE statement conflicted with the FOREIGN KEY constraint "FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.

Sometimes when you execute migrations with existing data, you need to insert stub data into the database to satisfy foreign key constraints. The generated code in the `Up` method adds a non-nullable DepartmentID foreign key to the Course table. If there are already rows in the Course table when the code runs, the `AddColumn` operation fails because SQL Server doesn't know what value to put in the column that can't be null. For this tutorial you'll run the migration on a new database, but in a production application you'd have to make the migration handle existing data, so the following directions show an example of how to do that.

To make this migration work with existing data you have to change the code to give the new column a default value, and create a stub department named "Temp" to act as the default department. As a result, existing Course rows will all be related to the "Temp" department after the `Up` method runs.

- Open the *{timestamp}_ComplexDataModel.cs* file.
- Comment out the line of code that adds the DepartmentID column to the Course table.

```
migrationBuilder.AlterColumn<string>(
    name: "Title",
    table: "Course",
    maxLength: 50,
    nullable: true,
    oldClrType: typeof(string),
    oldNullable: true);

//migrationBuilder.AddColumn<int>(
//    name: "DepartmentID",
//    table: "Course",
//    nullable: false,
//    defaultValue: 0);
```

- Add the following highlighted code after the code that creates the Department table:

```
migrationBuilder.CreateTable(
    name: "Department",
    columns: table => new
    {
        DepartmentID = table.Column<int>(nullable: false)
            .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
        Budget = table.Column<decimal>(type: "money", nullable: false),
        InstructorID = table.Column<int>(nullable: true),
        Name = table.Column<string>(maxLength: 50, nullable: true),
        StartDate = table.Column<DateTime>(nullable: false)
    },
    constraints: table =>
    {
        table.PrimaryKey("PK_Department", x => x.DepartmentID);
        table.ForeignKey(
            name: "FK_Department_Instructor_InstructorID",
            column: x => x.InstructorID,
            principalTable: "Instructor",
            principalColumn: "ID",
            onDelete: ReferentialAction.Restrict);
    });

migrationBuilder.Sql("INSERT INTO dbo.Department (Name, Budget, StartDate) VALUES ('Temp', 0.00,
GETDATE())");
// Default value for FK points to department created above, with
// defaultValue changed to 1 in following AddColumn statement.

migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    nullable: false,
    defaultValue: 1);
```

In a production application, you would write code or scripts to add Department rows and relate Course rows to the new Department rows. You would then no longer need the "Temp" department or the default value on the Course.DepartmentID column.

Save your changes and build the project.

Change the connection string

You now have new code in the `DbInitializer` class that adds seed data for the new entities to an empty database. To make EF create a new empty database, change the name of the database in the connection string in *appsettings.json* to ContosoUniversity3 or some other name that you haven't used on the computer you're using.

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity3;Trusted_Connection=True;MultipleActiveResultSets=true"
  },
```

Save your change to *appsettings.json*.

NOTE

As an alternative to changing the database name, you can delete the database. Use **SQL Server Object Explorer** (SSOX) or the `database drop` CLI command:

```
dotnet ef database drop
```

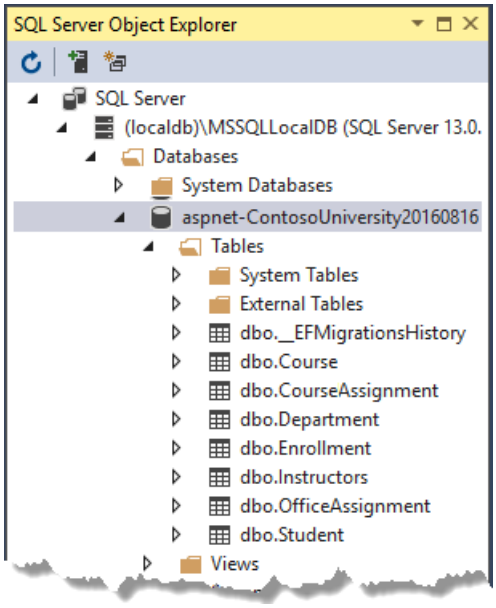
Update the database

After you have changed the database name or deleted the database, run the `database update` command in the command window to execute the migrations.

```
dotnet ef database update
```

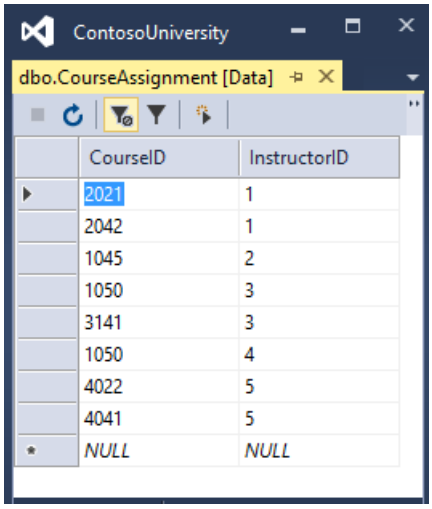
Run the app to cause the `DbInitializer.Initialize` method to run and populate the new database.

Open the database in SSOX as you did earlier, and expand the **Tables** node to see that all of the tables have been created. (If you still have SSOX open from the earlier time, click the **Refresh** button.)



Run the app to trigger the initializer code that seeds the database.

Right-click the **CourseAssignment** table and select **View Data** to verify that it has data in it.



Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- Customized the Data model
- Made changes to Student entity
- Created Instructor entity
- Created OfficeAssignment entity
- Modified Course entity
- Created Department entity
- Modified Enrollment entity
- Updated the database context
- Seeded database with test data
- Added a migration
- Changed the connection string
- Updated the database

Advance to the next tutorial to learn more about how to access related data.

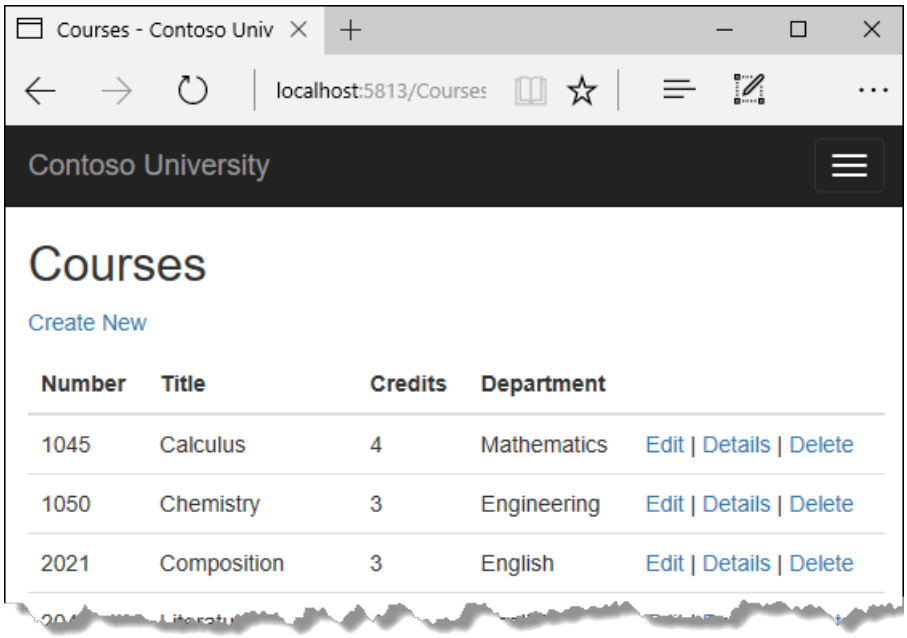
Next: Access related data

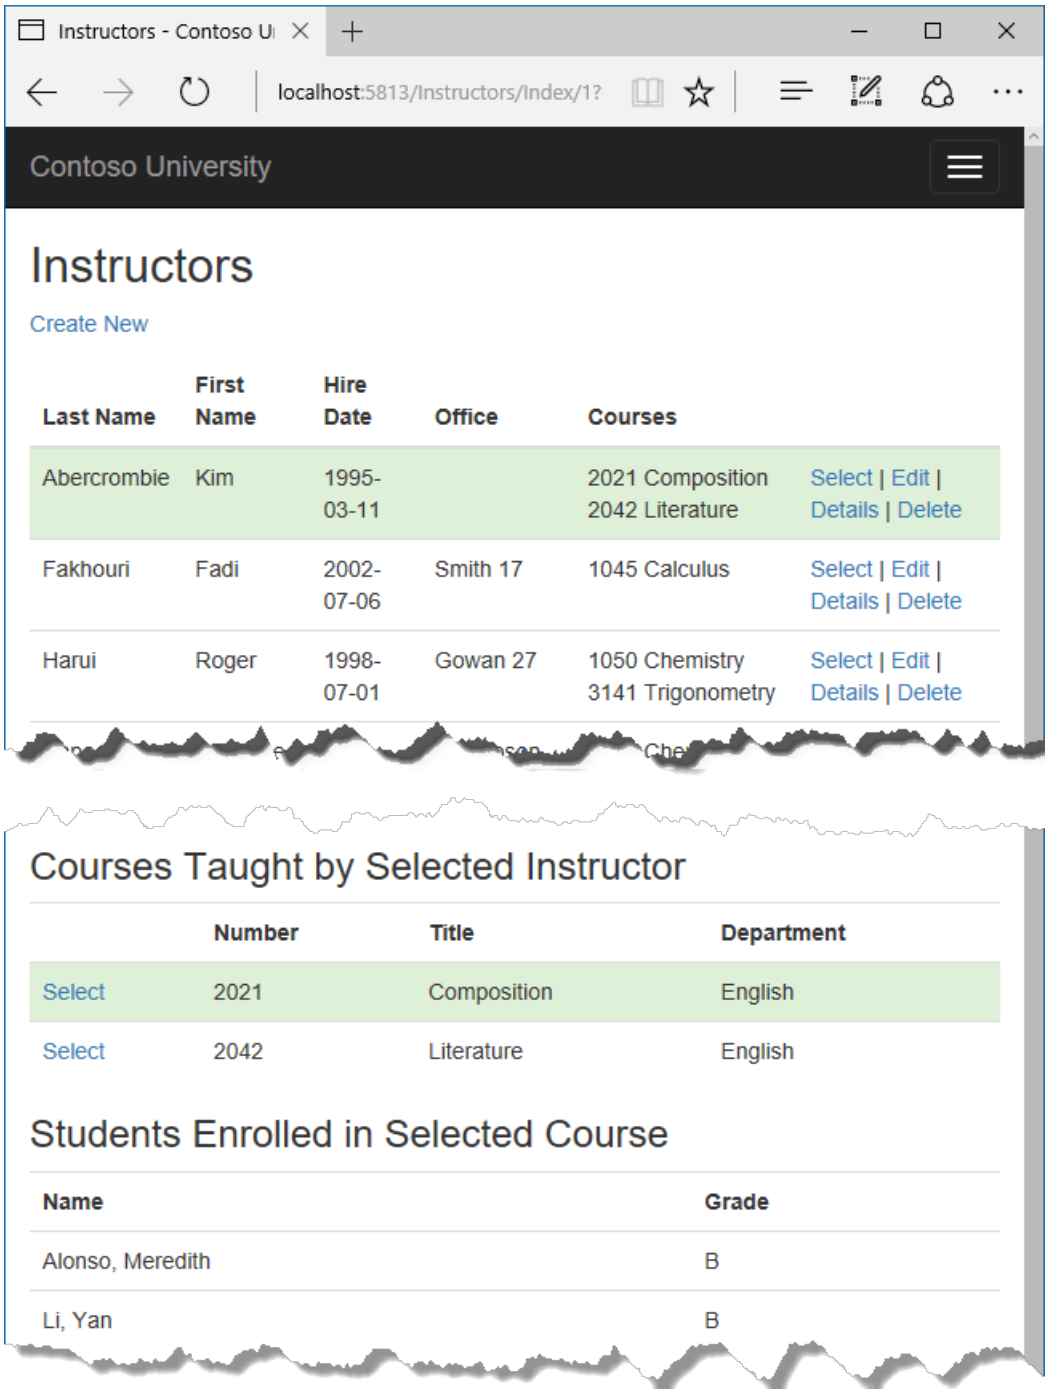
Tutorial: Read related data - ASP.NET MVC with EF Core

9/22/2020 • 14 minutes to read • Edit Online

In the previous tutorial, you completed the School data model. In this tutorial, you'll read and display related data -- that is, data that the Entity Framework loads into navigation properties.

The following illustrations show the pages that you'll work with.





In this tutorial, you:

- Learn how to load related data
- Create a Courses page
- Create an Instructors page
- Learn about explicit loading

Prerequisites

- Create a complex data model

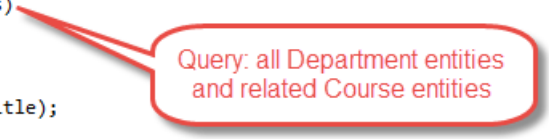
Learn how to load related data

There are several ways that Object-Relational Mapping (ORM) software such as Entity Framework can load related data into the navigation properties of an entity:

- Eager loading. When the entity is read, related data is retrieved along with it. This typically results in a single

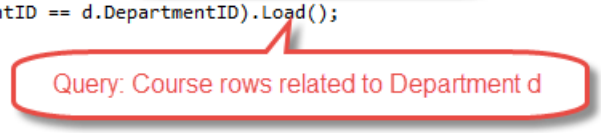
join query that retrieves all of the data that's needed. You specify eager loading in Entity Framework Core by using the `Include` and `ThenInclude` methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```



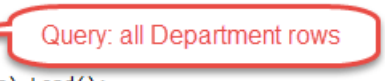
You can retrieve some of the data in separate queries, and EF "fixes up" the navigation properties. That is, EF automatically adds the separately retrieved entities where they belong in navigation properties of previously retrieved entities. For the query that retrieves related data, you can use the `Load` method instead of a method that returns a list or object, such as `ToList` or `Single`.

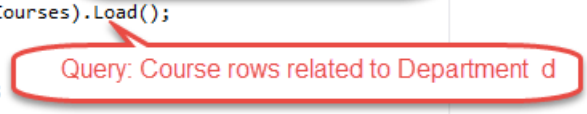
```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Courses.Where(c => c.DepartmentID == d.DepartmentID).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```



- Explicit loading. When the entity is first read, related data isn't retrieved. You write code that retrieves the related data if it's needed. As in the case of eager loading with separate queries, explicit loading results in multiple queries sent to the database. The difference is that with explicit loading, the code specifies the navigation properties to be loaded. In Entity Framework Core 1.1 you can use the `Load` method to do explicit loading. For example:

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Entry(d).Collection(p => p.Courses).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```





- Lazy loading. When the entity is first read, related data isn't retrieved. However, the first time you attempt to access a navigation property, the data required for that navigation property is automatically retrieved. A query is sent to the database each time you try to get data from a navigation property for the first time. Entity Framework Core 1.0 doesn't support lazy loading.

Performance considerations

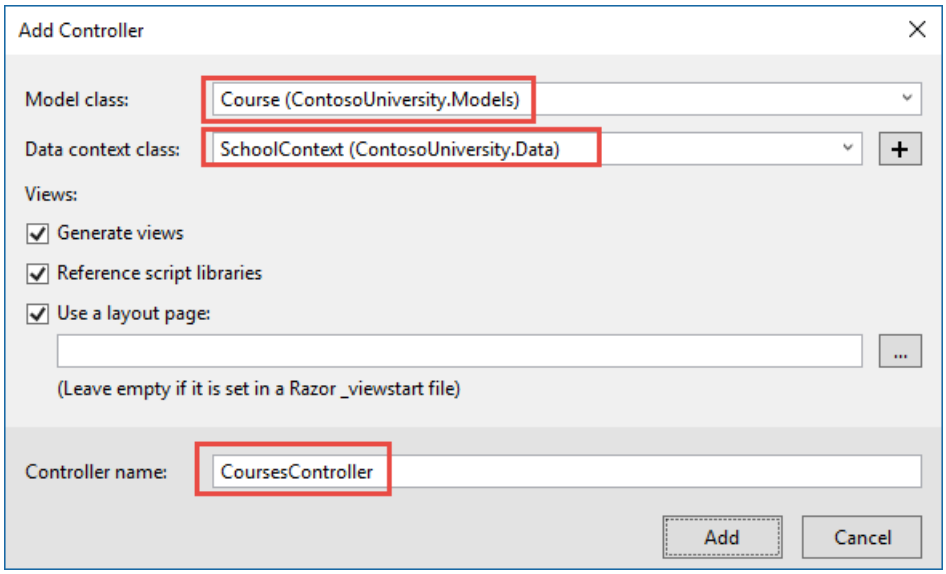
If you know you need related data for every entity retrieved, eager loading often offers the best performance, because a single query sent to the database is typically more efficient than separate queries for each entity retrieved. For example, suppose that each department has ten related courses. Eager loading of all related data would result in just a single (join) query and a single round trip to the database. A separate query for courses for each department would result in eleven round trips to the database. The extra round trips to the database are especially detrimental to performance when latency is high.

On the other hand, in some scenarios separate queries is more efficient. Eager loading of all related data in one query might cause a very complex join to be generated, which SQL Server can't process efficiently. Or if you need to access an entity's navigation properties only for a subset of a set of the entities you're processing, separate queries might perform better because eager loading of everything up front would retrieve more data than you need. If performance is critical, it's best to test performance both ways in order to make the best choice.

Create a Courses page

The Course entity includes a navigation property that contains the Department entity of the department that the course is assigned to. To display the name of the assigned department in a list of courses, you need to get the Name property from the Department entity that's in the `Course.Department` navigation property.

Create a controller named CoursesController for the Course entity type, using the same options for the **MVC Controller with views, using Entity Framework** scaffolder that you did earlier for the Students controller, as shown in the following illustration:



Open *CoursesController.cs* and examine the `Index` method. The automatic scaffolding has specified eager loading for the `Department` navigation property by using the `Include` method.

Replace the `Index` method with the following code that uses a more appropriate name for the `IQueryable` that returns Course entities (`courses` instead of `schoolContext`):

```
public async Task<IActionResult> Index()
{
    var courses = _context.Courses
        .Include(c => c.Department)
        .AsNoTracking();
    return View(await courses.ToListAsync());
}
```

Open *Views/Courses/Index.cshtml* and replace the template code with the following code. The changes are highlighted:

```
@model IEnumerable<ContosoUniversity.Models.Course>

@{
    ViewData["Title"] = "Courses";
}

<h2>Courses</h2>

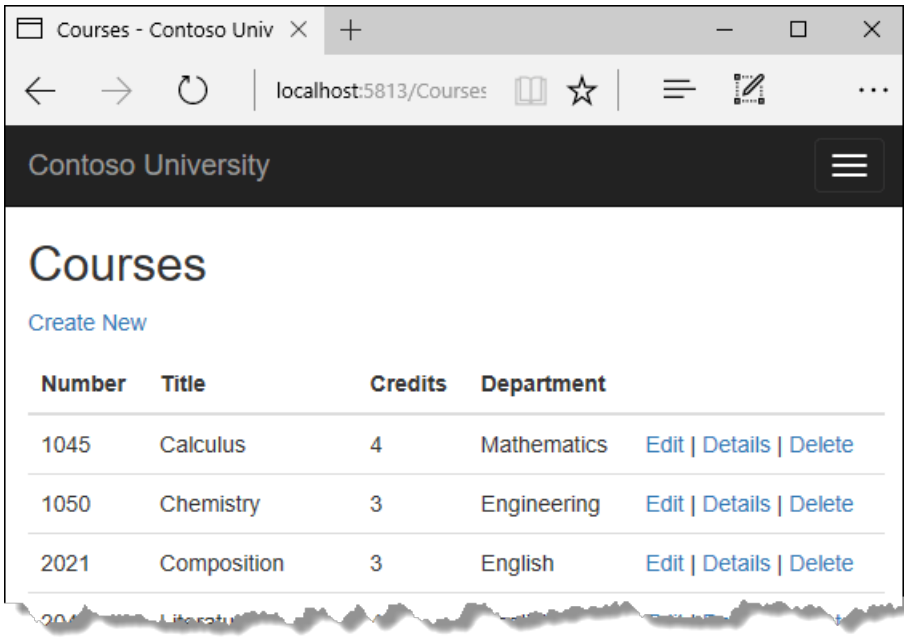
<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.CourseID)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Credits)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Department.Name)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.CourseID">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.CourseID">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.CourseID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

You've made the following changes to the scaffolded code:

- Changed the heading from Index to Courses.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful and you want to show it.
- Changed the **Department** column to display the department name. The code displays the `Name` property of the Department entity that's loaded into the `Department` navigation property:

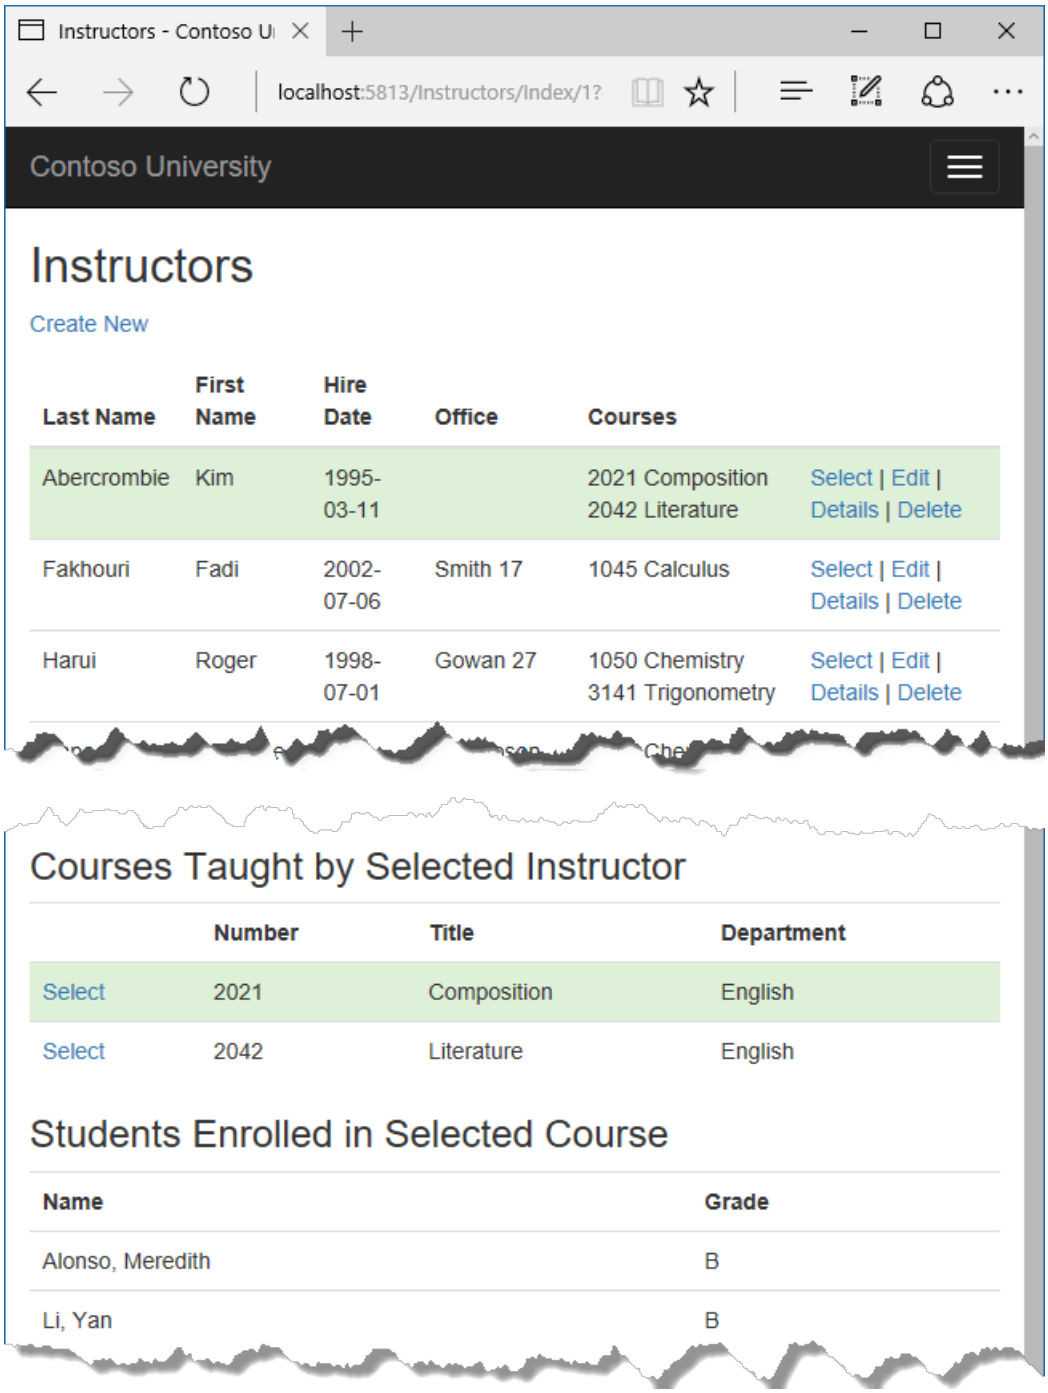
```
@Html.DisplayFor(modelItem => item.Department.Name)
```

Run the app and select the **Courses** tab to see the list with department names.



Create an Instructors page

In this section, you'll create a controller and view for the Instructor entity in order to display the Instructors page:



This page reads and displays related data in the following ways:

- The list of instructors displays related data from the OfficeAssignment entity. The Instructor and OfficeAssignment entities are in a one-to-zero-or-one relationship. You'll use eager loading for the OfficeAssignment entities. As explained earlier, eager loading is typically more efficient when you need the related data for all retrieved rows of the primary table. In this case, you want to display office assignments for all displayed instructors.
- When the user selects an instructor, related Course entities are displayed. The Instructor and Course entities are in a many-to-many relationship. You'll use eager loading for the Course entities and their related Department entities. In this case, separate queries might be more efficient because you need courses only for the selected instructor. However, this example shows how to use eager loading for navigation properties within entities that are themselves in navigation properties.
- When the user selects a course, related data from the Enrollments entity set is displayed. The Course and Enrollment entities are in a one-to-many relationship. You'll use separate queries for Enrollment entities and their related Student entities.

Create a view model for the Instructor Index view

The Instructors page shows data from three different tables. Therefore, you'll create a view model that includes three properties, each holding the data for one of the tables.

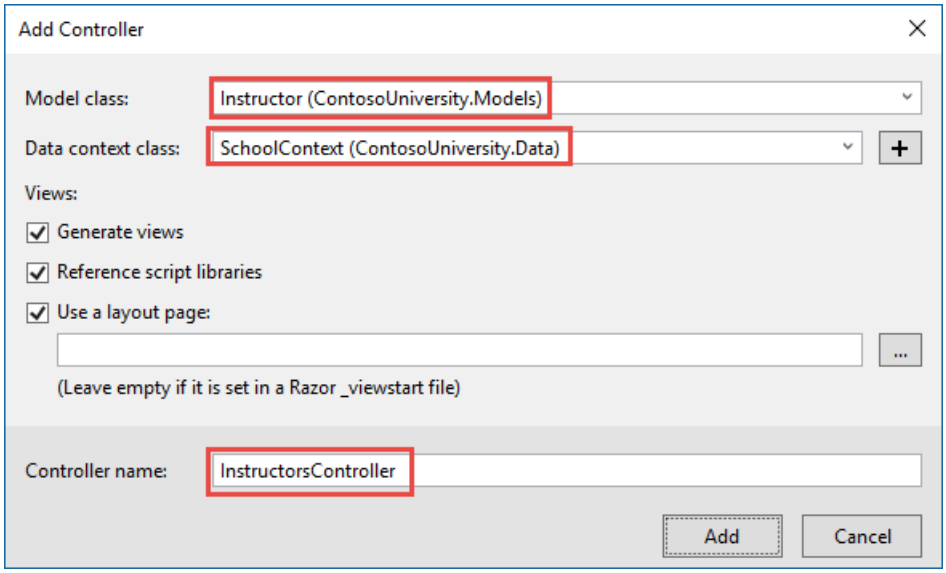
In the *SchoolViewModels* folder, create *InstructorIndexData.cs* and replace the existing code with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Create the Instructor controller and views

Create an Instructors controller with EF read/write actions as shown in the following illustration:



Open *InstructorsController.cs* and add a using statement for the ViewModels namespace:

```
using ContosoUniversity.Models.SchoolViewModels;
```

Replace the Index method with the following code to do eager loading of related data and put it in the view model.

```
public async Task<IActionResult> Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Enrollments)
                    .ThenInclude(i => i.Student)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        ViewData["InstructorID"] = id.Value;
        Instructor instructor = viewModel.Instructors.Where(
            i => i.ID == id.Value).Single();
        viewModel.Courses = instructor.CourseAssignments.Select(s => s.Course);
    }

    if (courseID != null)
    {
        ViewData["CourseID"] = courseID.Value;
        viewModel.Enrollments = viewModel.Courses.Where(
            x => x.CourseID == courseID).Single().Enrollments;
    }

    return View(viewModel);
}
```

The method accepts optional route data (`id`) and a query string parameter (`courseID`) that provide the ID values of the selected instructor and selected course. The parameters are provided by the **Select** hyperlinks on the page.

The code begins by creating an instance of the view model and putting in it the list of instructors. The code specifies eager loading for the `Instructor.OfficeAssignment` and the `Instructor.CourseAssignments` navigation properties. Within the `CourseAssignments` property, the `Course` property is loaded, and within that, the `Enrollments` and `Department` properties are loaded, and within each `Enrollment` entity the `Student` property is loaded.

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

Since the view always requires the OfficeAssignment entity, it's more efficient to fetch that in the same query. Course entities are required when an instructor is selected in the web page, so a single query is better than multiple queries only if the page is displayed more often with a course selected than without.

The code repeats `CourseAssignments` and `Course` because you need two properties from `Course`. The first string of `ThenInclude` calls gets `CourseAssignment.Course`, `Course.Enrollments`, and `Enrollment.Student`.

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

At that point in the code, another `ThenInclude` would be for navigation properties of `Student`, which you don't need. But calling `Include` starts over with `Instructor` properties, so you have to go through the chain again, this time specifying `Course.Department` instead of `Course.Enrollments`.

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

The following code executes when an instructor was selected. The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is then loaded with the Course entities from that instructor's `CourseAssignments` navigation property.

```
if (id != null)
{
    ViewData["InstructorID"] = id.Value;
    Instructor instructor = viewModel.Instructors.Where(
        i => i.ID == id.Value).Single();
    viewModel.Courses = instructor.CourseAssignments.Select(s => s.Course);
}
```

The `Where` method returns a collection, but in this case the criteria passed to that method result in only a single Instructor entity being returned. The `Single` method converts the collection into a single Instructor entity, which gives you access to that entity's `CourseAssignments` property. The `CourseAssignments` property contains `CourseAssignment` entities, from which you want only the related `Course` entities.

You use the `Single` method on a collection when you know the collection will have only one item. The Single method throws an exception if the collection passed to it's empty or if there's more than one item. An alternative is `SingleOrDefault`, which returns a default value (null in this case) if the collection is empty. However, in this case that would still result in an exception (from trying to find a `Courses` property on a null reference), and the exception message would less clearly indicate the cause of the problem. When you call the `Single` method, you can also pass in the Where condition instead of calling the `Where` method separately:

```
.Single(i => i.ID == id.Value)
```

Instead of:

```
.Where(i => i.ID == id.Value).Single()
```

Next, if a course was selected, the selected course is retrieved from the list of courses in the view model. Then the view model's `Enrollments` property is loaded with the Enrollment entities from that course's `Enrollments` navigation property.

```
if (courseID != null)
{
    ViewData["CourseID"] = courseID.Value;
    viewModel.Enrollments = viewModel.Courses.Where(
        x => x.CourseID == courseID).Single().Enrollments;
}
```

Modify the Instructor Index view

In *Views/Instructors/Index.cshtml*, replace the template code with the following code. The changes are highlighted.

```
@model ContosoUniversity.Models.SchoolViewModels.InstructorIndexData

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Instructors)
        {
            string selectedRow = "";
            if (item.ID == (int?)ViewData["InstructorID"])
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @{
                        foreach (var course in item.CourseAssignments)
                        {
                            @course.Course.CourseID @:  @course.Course.Title <br />
                        }
                    }
                </td>
                <td>
                    <a asp-action="Index" asp-route-id="@item.ID">Select</a> |
                    <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.ID">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
                </td>
            </tr>
           }
    </tbody>
</table>
```

You've made the following changes to the existing code:

- Changed the model class to `InstructorIndexData`.
- Changed the page title from **Index** to **Instructors**.
- Added an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. (Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.)

```
@if (item.OfficeAssignment != null)
{
    @item.OfficeAssignment.Location
}
```

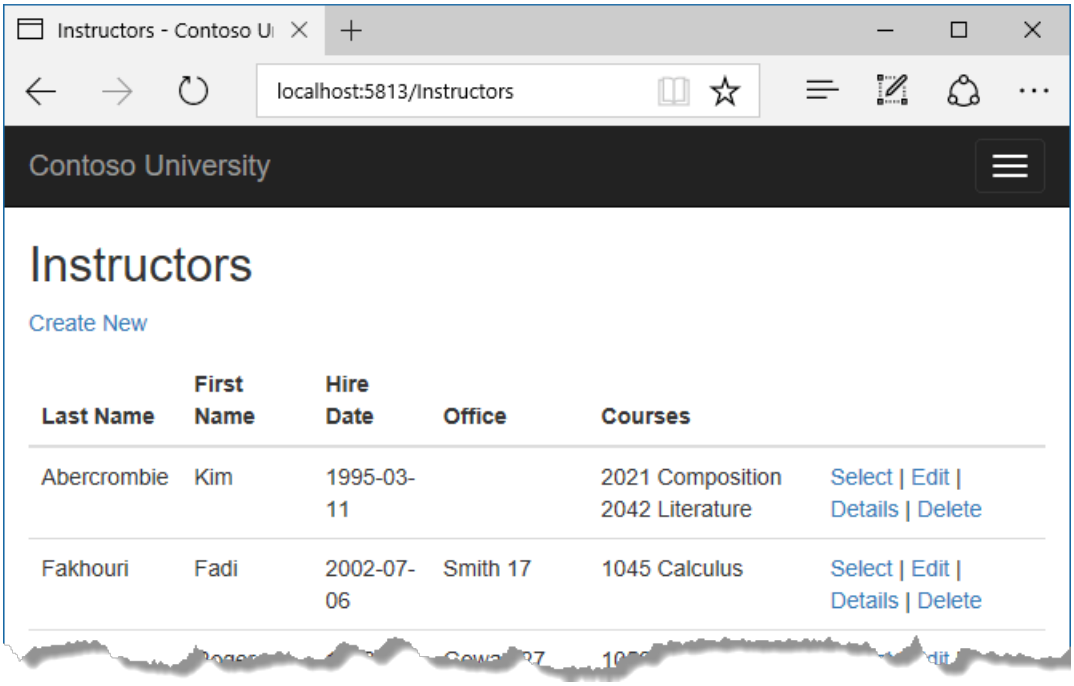
- Added a **Courses** column that displays courses taught by each instructor. For more information, see the Explicit line transition section of the Razor syntax article.
- Added code that dynamically adds `class="success"` to the `tr` element of the selected instructor. This sets a background color for the selected row using a Bootstrap class.

```
string selectedRow = "";
if (item.ID == (int?)ViewData["InstructorID"])
{
    selectedRow = "success";
}
<tr class="@selectedRow">
```

- Added a new hyperlink labeled **Select** immediately before the other links in each row, which causes the selected instructor's ID to be sent to the `Index` method.

```
<a asp-action="Index" asp-route-id="@item.ID">Select</a> |
```

Run the app and select the **Instructors** tab. The page displays the Location property of related OfficeAssignment entities and an empty table cell when there's no related OfficeAssignment entity.



In the *Views/Instructors/Index.cshtml* file, after the closing table element (at the end of the file), add the following code. This code displays a list of courses related to an instructor when an instructor is selected.

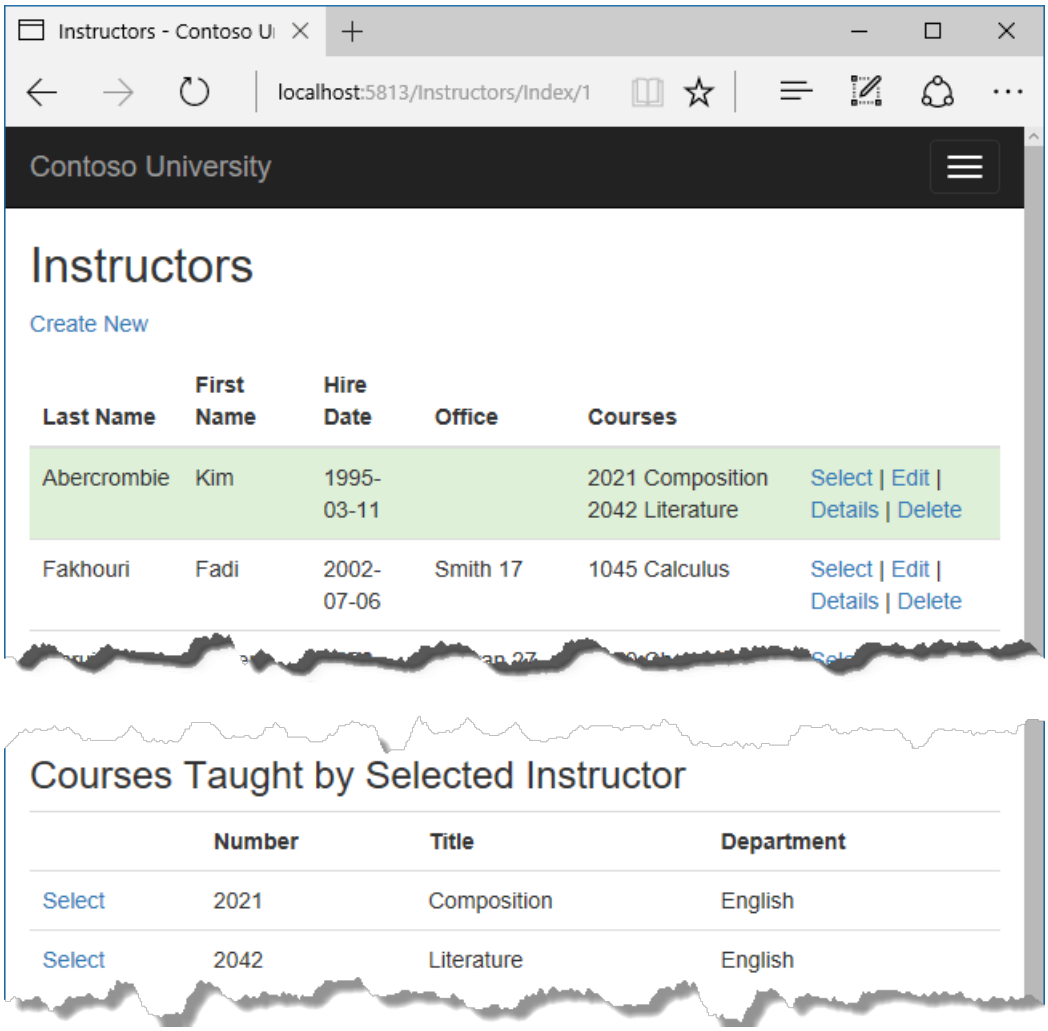
```
@if (Model.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

        @foreach (var item in Model.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == (int?)ViewData["CourseID"])
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.ActionLink("Select", "Index", new { courseID = item.CourseID })
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}
```

This code reads the `Courses` property of the view model to display a list of courses. It also provides a **Select** hyperlink that sends the ID of the selected course to the `Index` action method.

Refresh the page and select an instructor. Now you see a grid that displays courses assigned to the selected instructor, and for each course you see the name of the assigned department.



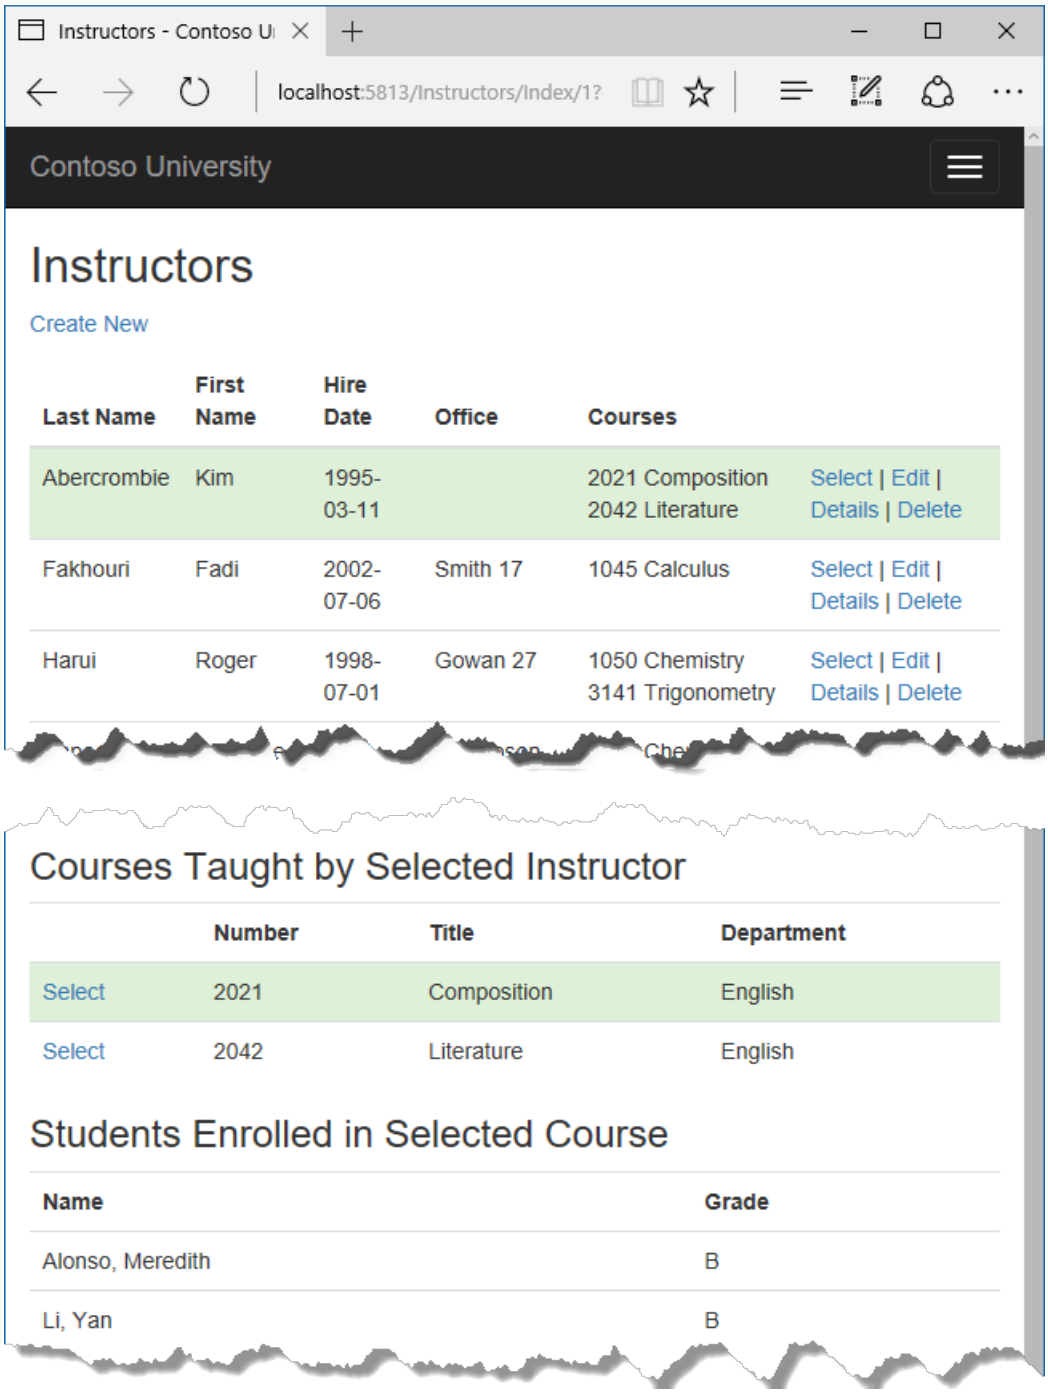
After the code block you just added, add the following code. This displays a list of the students who are enrolled in a course when that course is selected.

```
@if (Model.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

This code reads the Enrollments property of the view model in order to display a list of students enrolled in the course.

Refresh the page again and select an instructor. Then select a course to see the list of enrolled students and their

grades.



About explicit loading

When you retrieved the list of instructors in *InstructorsController.cs*, you specified eager loading for the `CourseAssignments` navigation property.

Suppose you expected users to only rarely want to see enrollments in a selected instructor and course. In that case, you might want to load the enrollment data only if it's requested. To see an example of how to do explicit loading, replace the `Index` method with the following code, which removes eager loading for Enrollments and loads that property explicitly. The code changes are highlighted.

```
public async Task<IActionResult> Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        ViewData["InstructorID"] = id.Value;
        Instructor instructor = viewModel.Instructors.Where(
            i => i.ID == id.Value).Single();
        viewModel.Courses = instructor.CourseAssignments.Select(s => s.Course);
    }

    if (courseID != null)
    {
        ViewData["CourseID"] = courseID.Value;
        var selectedCourse = viewModel.Courses.Where(x => x.CourseID == courseID).Single();
        await _context.Entry(selectedCourse).Collection(x => x.Enrollments).LoadAsync();
        foreach (Enrollment enrollment in selectedCourse.Enrollments)
        {
            await _context.Entry(enrollment).Reference(x => x.Student).LoadAsync();
        }
        viewModel.Enrollments = selectedCourse.Enrollments;
    }

    return View(viewModel);
}
```

The new code drops the *ThenInclude* method calls for enrollment data from the code that retrieves instructor entities. It also drops `AsNoTracking`. If an instructor and course are selected, the highlighted code retrieves Enrollment entities for the selected course, and Student entities for each Enrollment.

Run the app, go to the Instructors Index page now and you'll see no difference in what's displayed on the page, although you've changed how the data is retrieved.

Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- Learned how to load related data
- Created a Courses page
- Created an Instructors page
- Learned about explicit loading

Advance to the next tutorial to learn how to update related data.

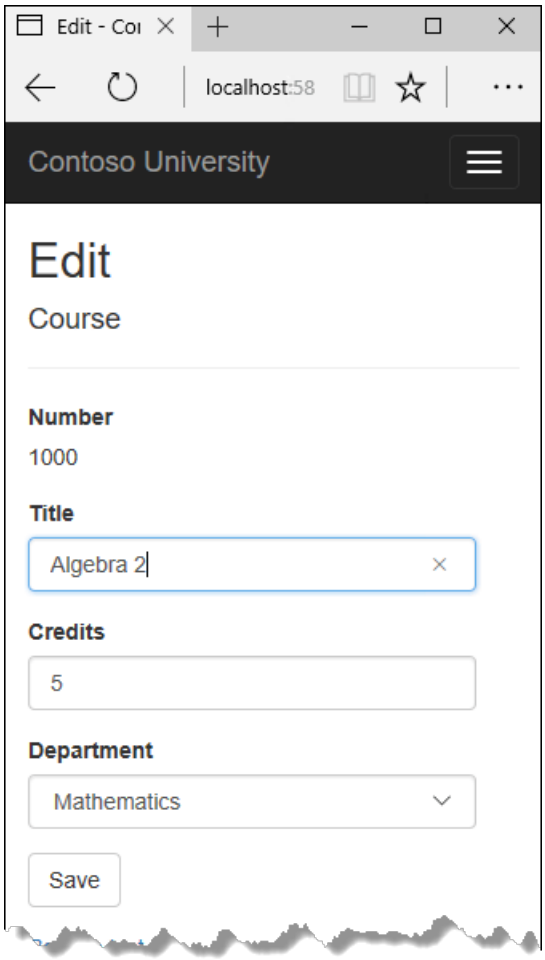
Update related data

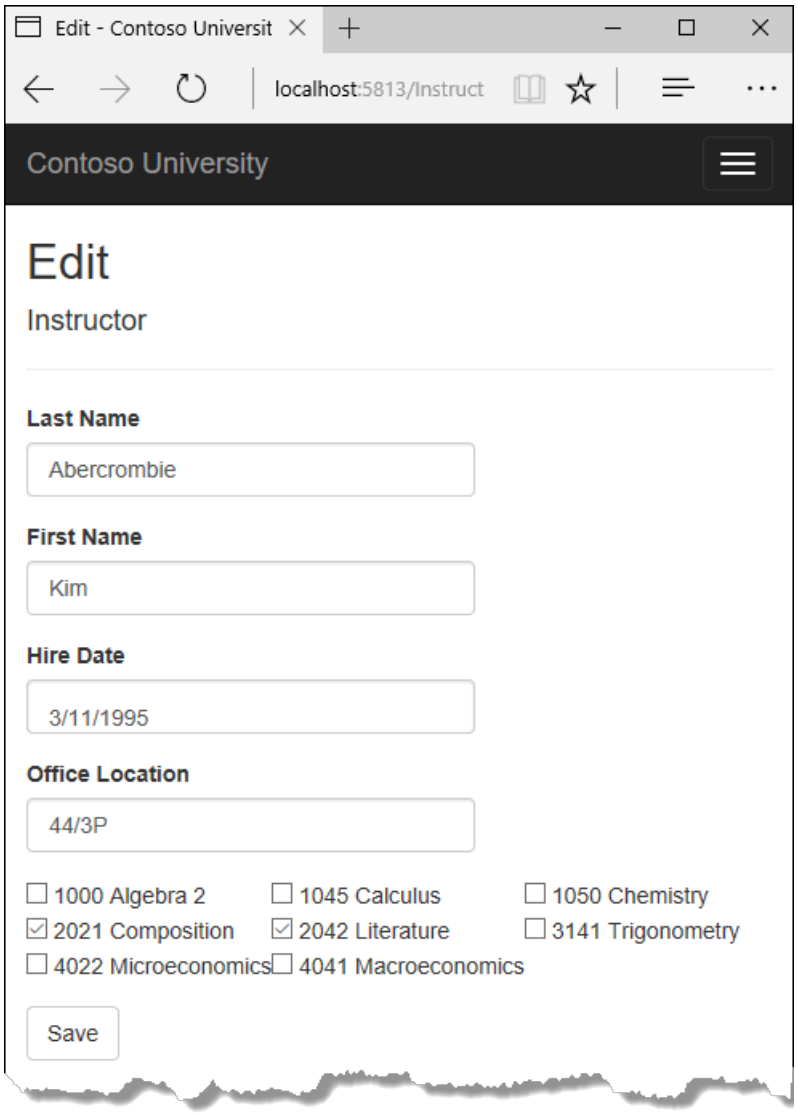
Tutorial: Update related data - ASP.NET MVC with EF Core

9/22/2020 • 18 minutes to read • Edit Online

In the previous tutorial you displayed related data; in this tutorial you'll update related data by updating foreign key fields and navigation properties.

The following illustrations show some of the pages that you'll work with.





In this tutorial, you:

- Customize Courses pages
- Add Instructors Edit page
- Add courses to Edit page
- Update Delete page
- Add office location and courses to Create page

Prerequisites

- Read related data

Customize Courses pages

When a new course entity is created, it must have a relationship to an existing department. To facilitate this, the scaffolded code includes controller methods and Create and Edit views that include a drop-down list for selecting the department. The drop-down list sets the `Course.DepartmentID` foreign key property, and that's all the Entity Framework needs in order to load the `Department` navigation property with the appropriate Department entity. You'll use the scaffolded code, but change it slightly to add error handling and sort the drop-down list.

In *CoursesController.cs*, delete the four Create and Edit methods and replace them with the following code:

```
public IActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create([Bind("CourseID,Credits,DepartmentID,Title")] Course course)
{
    if (ModelState.IsValid)
    {
        _context.Add(course);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var courseToUpdate = await _context.Courses
        .FirstOrDefaultAsync(c => c.CourseID == id);

    if (await TryUpdateModelAsync<Course>(courseToUpdate,
        "",
        c => c.Credits, c => c.DepartmentID, c => c.Title))
    {
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    PopulateDepartmentsDropDownList(courseToUpdate.DepartmentID);
    return View(courseToUpdate);
}
```

After the `Edit` HttpPost method, create a new method that loads department info for the drop-down list.

```
private void PopulateDepartmentsDropDownList(object selectedDepartment = null)
{
    var departmentsQuery = from d in _context.Departments
                           orderby d.Name
                           select d;
    ViewBag.DepartmentID = new SelectList(departmentsQuery.AsNoTracking(), "DepartmentID", "Name",
selectedDepartment);
}
```

The `PopulateDepartmentsDropDownList` method gets a list of all departments sorted by name, creates a `SelectList` collection for a drop-down list, and passes the collection to the view in `ViewBag`. The method accepts the optional `selectedDepartment` parameter that allows the calling code to specify the item that will be selected when the drop-down list is rendered. The view will pass the name "DepartmentID" to the `<select>` tag helper, and the helper then knows to look in the `ViewBag` object for a `SelectList` named "DepartmentID".

The HttpGet `Create` method calls the `PopulateDepartmentsDropDownList` method without setting the selected item, because for a new course the department isn't established yet:

```
public IActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

The HttpGet `Edit` method sets the selected item, based on the ID of the department that's already assigned to the

course being edited:

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

The HttpPost methods for both `Create` and `Edit` also include code that sets the selected item when they redisplay the page after an error. This ensures that when the page is redisplayed to show the error message, whatever department was selected stays selected.

Add .AsNoTracking to Details and Delete methods

To optimize performance of the Course Details and Delete pages, add `AsNoTracking` calls in the `Details` and HttpGet `Delete` methods.

```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }

    return View(course);
}
```

```
public async Task<IActionResult> Delete(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }

    return View(course);
}
```

Modify the Course views

In *Views/Courses/Create.cshtml*, add a "Select Department" option to the **Department** drop-down list, change the caption from **DepartmentID** to **Department**, and add a validation message.

```
<div class="form-group">
    <label asp-for="Department" class="control-label"></label>
    <select asp-for="DepartmentID" class="form-control" asp-items="ViewBag.DepartmentID">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="DepartmentID" class="text-danger" />
```

In *Views/Courses/Edit.cshtml*, make the same change for the Department field that you just did in *Create.cshtml*.

Also in *Views/Courses/Edit.cshtml*, add a course number field before the **Title** field. Because the course number is the primary key, it's displayed, but it can't be changed.

```
<div class="form-group">
    <label asp-for="CourseID" class="control-label"></label>
    <div>@Html.DisplayFor(model => model.CourseID)</div>
</div>
```

There's already a hidden field (`<input type="hidden">`) for the course number in the Edit view. Adding a `<label>` tag helper doesn't eliminate the need for the hidden field because it doesn't cause the course number to be included in the posted data when the user clicks **Save** on the **Edit** page.

In *Views/Courses/Delete.cshtml*, add a course number field at the top and change department ID to department name.

```
@model ContosoUniversity.Models.Course

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

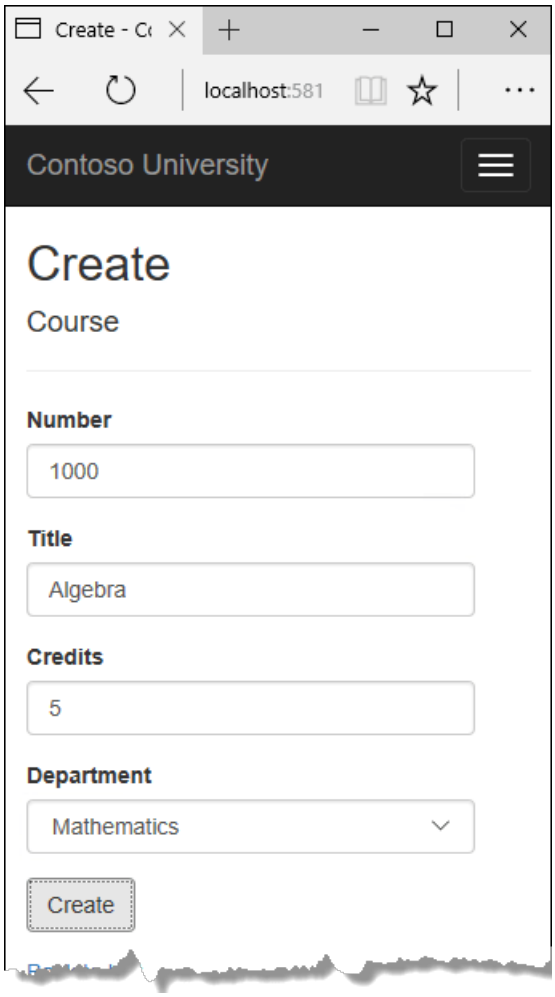
<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
    </dl>

    <form asp-action="Delete">
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-action="Index">Back to List</a>
        </div>
    </form>
</div>
```

In *Views/Courses/Details.cshtml*, make the same change that you just did for *Delete.cshtml*.

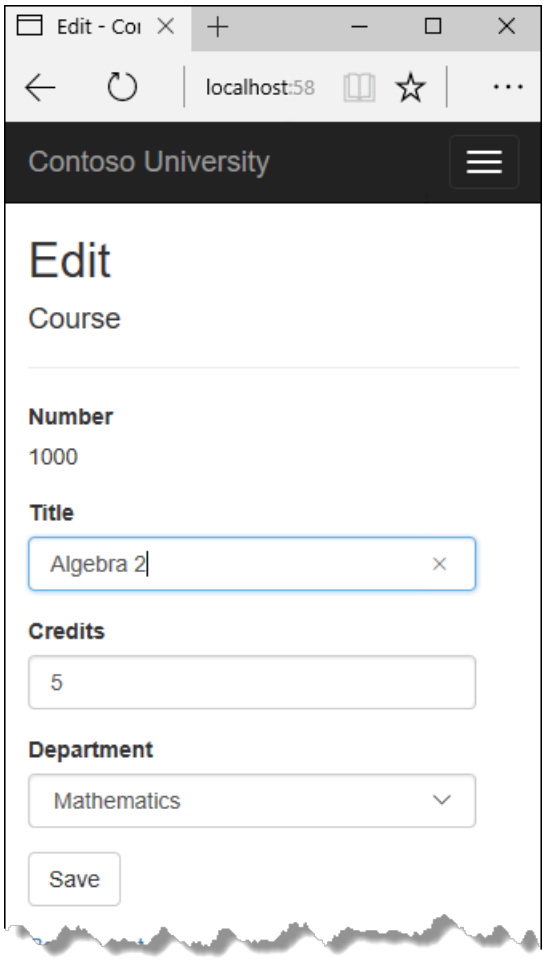
Test the Course pages

Run the app, select the **Courses** tab, click **Create New**, and enter data for a new course:



Click **Create**. The Courses Index page is displayed with the new course added to the list. The department name in the Index page list comes from the navigation property, showing that the relationship was established correctly.

Click **Edit** on a course in the Courses Index page.



Change data on the page and click **Save**. The Courses Index page is displayed with the updated course data.

Add Instructors Edit page

When you edit an instructor record, you want to be able to update the instructor's office assignment. The Instructor entity has a one-to-zero-or-one relationship with the OfficeAssignment entity, which means your code has to handle the following situations:

- If the user clears the office assignment and it originally had a value, delete the OfficeAssignment entity.
- If the user enters an office assignment value and it originally was empty, create a new OfficeAssignment entity.
- If the user changes the value of an office assignment, change the value in an existing OfficeAssignment entity.

Update the Instructors controller

In *InstructorsController.cs*, change the code in the HttpGet `Edit` method so that it loads the Instructor entity's `OfficeAssignment` navigation property and calls `AsNoTracking`:

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructor = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (instructor == null)
    {
        return NotFound();
    }
    return View(instructor);
}
```

Replace the HttpPost `Edit` method with the following code to handle office assignment updates:

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructorToUpdate = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .FirstOrDefaultAsync(s => s.ID == id);

    if (await TryUpdateModelAsync<Instructor>(
        instructorToUpdate,
        "",
        i => i.FirstMidName, i => i.LastName, i => i.HireDate, i => i.OfficeAssignment))
    {
        if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
        {
            instructorToUpdate.OfficeAssignment = null;
        }
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    return View(instructorToUpdate);
}
```

The code does the following:

- Changes the method name to `EditPost` because the signature is now the same as the HttpGet `Edit` method (the `ActionName` attribute specifies that the `/Edit/` URL is still used).
- Gets the current Instructor entity from the database using eager loading for the `OfficeAssignment` navigation

property. This is the same as what you did in the HttpGet `Edit` method.

- Updates the retrieved Instructor entity with values from the model binder. The `TryUpdateModel` overload enables you to declare the properties you want to include. This prevents over-posting, as explained in the second tutorial.

```
if (await TryUpdateModelAsync<Instructor>(
    instructorToUpdate,
    "",
    i => i.FirstMidName, i => i.LastName, i => i.HireDate, i => i.OfficeAssignment))
```

- If the office location is blank, sets the Instructor.OfficeAssignment property to null so that the related row in the OfficeAssignment table will be deleted.

```
if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
{
    instructorToUpdate.OfficeAssignment = null;
}
```

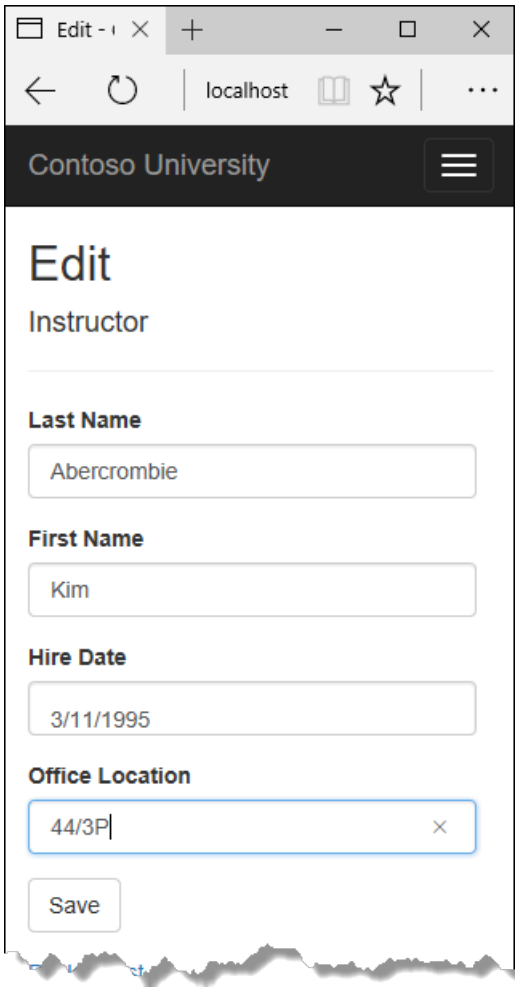
- Saves the changes to the database.

Update the Instructor Edit view

In *Views/Instructors/Edit.cshtml*, add a new field for editing the office location, at the end before the **Save** button:

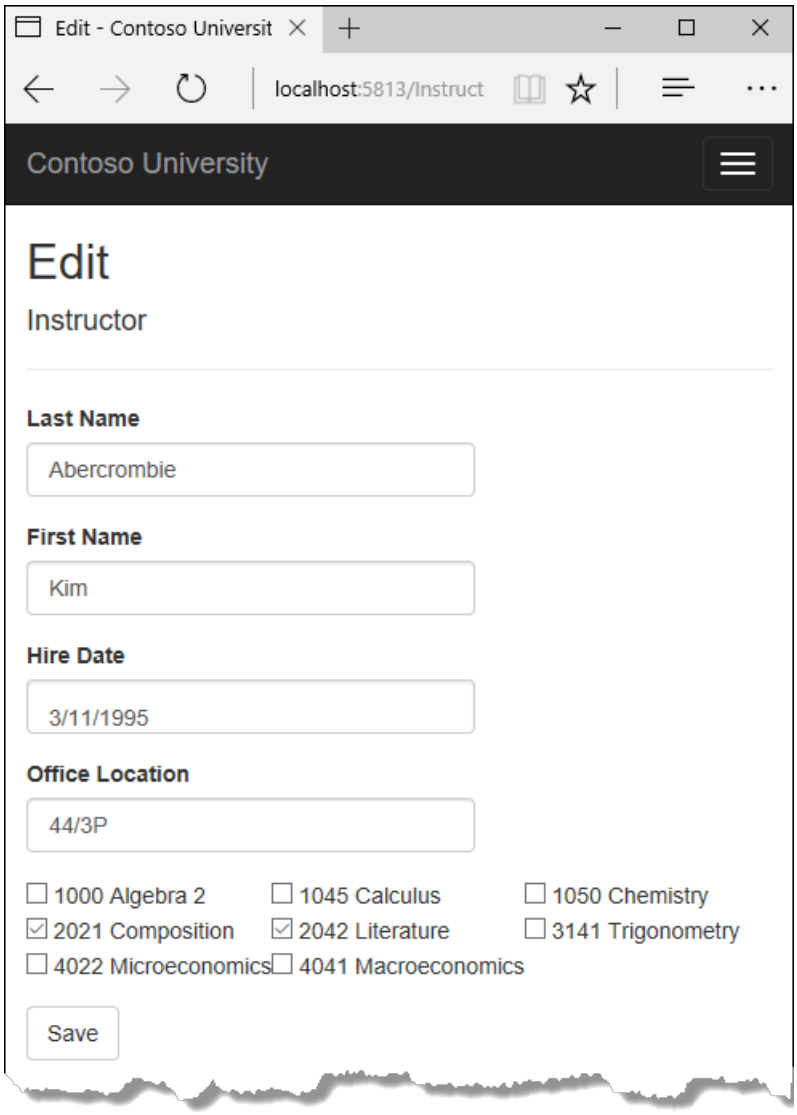
```
<div class="form-group">
    <label asp-for="OfficeAssignment.Location" class="control-label"></label>
    <input asp-for="OfficeAssignment.Location" class="form-control" />
    <span asp-validation-for="OfficeAssignment.Location" class="text-danger" />
</div>
```

Run the app, select the **Instructors** tab, and then click **Edit** on an instructor. Change the **Office Location** and click **Save**.



Add courses to Edit page

Instructors may teach any number of courses. Now you'll enhance the Instructor Edit page by adding the ability to change course assignments using a group of check boxes, as shown in the following screen shot:



The relationship between the Course and Instructor entities is many-to-many. To add and remove relationships, you add and remove entities to and from the CourseAssignments join entity set.

The UI that enables you to change which courses an instructor is assigned to is a group of check boxes. A check box for every course in the database is displayed, and the ones that the instructor is currently assigned to are selected. The user can select or clear check boxes to change course assignments. If the number of courses were much greater, you would probably want to use a different method of presenting the data in the view, but you'd use the same method of manipulating a join entity to create or delete relationships.

Update the Instructors controller

To provide data to the view for the list of check boxes, you'll use a view model class.

Create *AssignedCourseData.cs* in the *SchoolViewModels* folder and replace the existing code with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

In *InstructorsController.cs*, replace the HttpGet `Edit` method with the following code. The changes are highlighted.

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructor = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.CourseAssignments).ThenInclude(i => i.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (instructor == null)
    {
        return NotFound();
    }
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}

private void PopulateAssignedCourseData(Instructor instructor)
{
    var allCourses = _context.Courses;
    var instructorCourses = new HashSet<int>(instructor.CourseAssignments.Select(c => c.CourseID));
    var viewModel = new List<AssignedCourseData>();
    foreach (var course in allCourses)
    {
        viewModel.Add(new AssignedCourseData
        {
            CourseID = course.CourseID,
            Title = course.Title,
            Assigned = instructorCourses.Contains(course.CourseID)
        });
    }
    ViewData["Courses"] = viewModel;
}
```

The code adds eager loading for the `Courses` navigation property and calls the new `PopulateAssignedCourseData` method to provide information for the check box array using the `AssignedCourseData` view model class.

The code in the `PopulateAssignedCourseData` method reads through all Course entities in order to load a list of courses using the view model class. For each course, the code checks whether the course exists in the instructor's `Courses` navigation property. To create efficient lookup when checking whether a course is assigned to the instructor, the courses assigned to the instructor are put into a `HashSet` collection. The `Assigned` property is set to true for courses the instructor is assigned to. The view will use this property to determine which check boxes must

be displayed as selected. Finally, the list is passed to the view in `ViewData`.

Next, add the code that's executed when the user clicks **Save**. Replace the `EditPost` method with the following code, and add a new method that updates the `Courses` navigation property of the Instructor entity.

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int? id, string[] selectedCourses)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructorToUpdate = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
        .FirstOrDefaultAsync(m => m.ID == id);

    if (await TryUpdateModelAsync<Instructor>(
        instructorToUpdate,
        "",
        i => i.FirstMidName, i => i.LastName, i => i.HireDate, i => i.OfficeAssignment))
    {
        if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
        {
            instructorToUpdate.OfficeAssignment = null;
        }
        UpdateInstructorCourses(selectedCourses, instructorToUpdate);
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    UpdateInstructorCourses(selectedCourses, instructorToUpdate);
    PopulateAssignedCourseData(instructorToUpdate);
    return View(instructorToUpdate);
}
```

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new CourseAssignment { InstructorID =
instructorToUpdate.ID, CourseID = course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove = instructorToUpdate.CourseAssignments.FirstOrDefault(i =>
i.CourseID == course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

The method signature is now different from the HttpGet `Edit` method, so the method name changes from `EditPost` back to `Edit`.

Since the view doesn't have a collection of Course entities, the model binder can't automatically update the `CourseAssignments` navigation property. Instead of using the model binder to update the `CourseAssignments` navigation property, you do that in the new `UpdateInstructorCourses` method. Therefore, you need to exclude the `CourseAssignments` property from model binding. This doesn't require any change to the code that calls `TryUpdateModel` because you're using the overload that requires explicit approval and `CourseAssignments` isn't in the include list.

If no check boxes were selected, the code in `UpdateInstructorCourses` initializes the `CourseAssignments` navigation property with an empty collection and returns:

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new CourseAssignment { InstructorID =
instructorToUpdate.ID, CourseID = course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove = instructorToUpdate.CourseAssignments.FirstOrDefault(i =>
i.CourseID == course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the view. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the check box for a course was selected but the course isn't in the `Instructor.CourseAssignments` navigation property, the course is added to the collection in the navigation property.

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new CourseAssignment { InstructorID =
instructorToUpdate.ID, CourseID = course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove = instructorToUpdate.CourseAssignments.FirstOrDefault(i =>
i.CourseID == course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

If the check box for a course wasn't selected, but the course is in the `Instructor.CourseAssignments` navigation property, the course is removed from the navigation property.

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c => c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new CourseAssignment { InstructorID =
instructorToUpdate.ID, CourseID = course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove = instructorToUpdate.CourseAssignments.FirstOrDefault(i =>
i.CourseID == course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

Update the Instructor views

In *Views/Instructors/Edit.cshtml*, add a **Courses** field with an array of check boxes by adding the following code immediately after the `div` elements for the **Office** field and before the `div` element for the **Save** button.

> **NOTE**
>
> When you paste the code in Visual Studio, line breaks might be changed in a way that breaks the code. If the code looks different after pasting, press Ctrl+Z one time to undo the automatic formatting. This will fix the line breaks so that they look like what you see here. The indentation doesn't have to be perfect, but the `@:</tr><tr>`, `@:<td>`, `@:</td>`, and `@:</tr>` lines must each be on a single line as shown or you'll get a runtime error. With the block of new code selected, press Tab three times to line up the new code with the existing code. This problem is fixed in Visual Studio 2019.

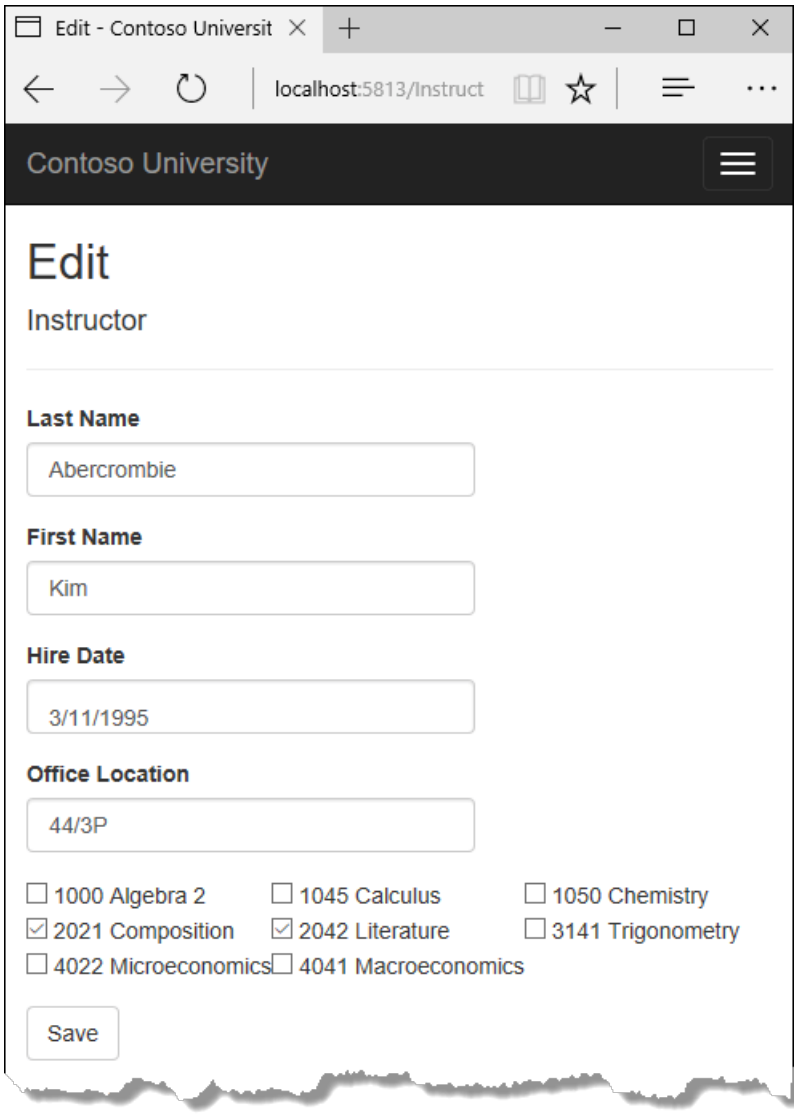
```
<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;
                    List<ContosoUniversity.Models.SchoolViewModels.AssignedCourseData> courses =
ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                                   name="selectedCourses"
                                   value="@course.CourseID"
                                   @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                   @course.CourseID @:  @course.Title
                        @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

This code creates an HTML table that has three columns. In each column is a check box followed by a caption that consists of the course number and title. The check boxes all have the same name ("selectedCourses"), which informs the model binder that they're to be treated as a group. The value attribute of each check box is set to the value of `CourseID`. When the page is posted, the model binder passes an array to the controller that consists of the `CourseID` values for only the check boxes which are selected.

When the check boxes are initially rendered, those that are for courses assigned to the instructor have checked attributes, which selects them (displays them checked).

Run the app, select the **Instructors** tab, and click **Edit** on an instructor to see the **Edit** page.



Change some course assignments and click Save. The changes you make are reflected on the Index page.

> **NOTE**
> The approach taken here to edit instructor course data works well when there's a limited number of courses. For collections that are much larger, a different UI and a different updating method would be required.

Update Delete page

In *InstructorsController.cs*, delete the `DeleteConfirmed` method and insert the following code in its place.

```
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    Instructor instructor = await _context.Instructors
        .Include(i => i.CourseAssignments)
        .SingleAsync(i => i.ID == id);

    var departments = await _context.Departments
        .Where(d => d.InstructorID == id)
        .ToListAsync();
    departments.ForEach(d => d.InstructorID = null);

    _context.Instructors.Remove(instructor);

    await _context.SaveChangesAsync();
    return RedirectToAction(nameof(Index));
}
```

This code makes the following changes:

- Does eager loading for the `CourseAssignments` navigation property. You have to include this or EF won't know about related `CourseAssignment` entities and won't delete them. To avoid needing to read them here you could configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

Add office location and courses to Create page

In *InstructorsController.cs*, delete the HttpGet and HttpPost `Create` methods, and then add the following code in their place:

```
public IActionResult Create()
{
    var instructor = new Instructor();
    instructor.CourseAssignments = new List<CourseAssignment>();
    PopulateAssignedCourseData(instructor);
    return View();
}

// POST: Instructors/Create
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create([Bind("FirstMidName,HireDate,LastName,OfficeAssignment")] Instructor
instructor, string[] selectedCourses)
{
    if (selectedCourses != null)
    {
        instructor.CourseAssignments = new List<CourseAssignment>();
        foreach (var course in selectedCourses)
        {
            var courseToAdd = new CourseAssignment { InstructorID = instructor.ID, CourseID = int.Parse(course)
};
            instructor.CourseAssignments.Add(courseToAdd);
        }
    }
    if (ModelState.IsValid)
    {
        _context.Add(instructor);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}
```

This code is similar to what you saw for the `Edit` methods except that initially no courses are selected. The HttpGet `Create` method calls the `PopulateAssignedCourseData` method not because there might be courses selected but in order to provide an empty collection for the `foreach` loop in the view (otherwise the view code would throw a null reference exception).

The HttpPost `Create` method adds each selected course to the `CourseAssignments` navigation property before it checks for validation errors and adds the new instructor to the database. Courses are added even if there are model errors so that when there are model errors (for an example, the user keyed an invalid date), and the page is redisplayed with an error message, any course selections that were made are automatically restored.

Notice that in order to be able to add courses to the `CourseAssignments` navigation property you have to initialize the property as an empty collection:

```
instructor.CourseAssignments = new List<CourseAssignment>();
```

As an alternative to doing this in controller code, you could do it in the Instructor model by changing the property getter to automatically create the collection if it doesn't exist, as shown in the following example:

```
private ICollection<CourseAssignment> _courseAssignments;
public ICollection<CourseAssignment> CourseAssignments
{
    get
    {
        return _courseAssignments ?? (_courseAssignments = new List<CourseAssignment>());
    }
    set
    {
        _courseAssignments = value;
    }
}
```

If you modify the `CourseAssignments` property in this way, you can remove the explicit property initialization code in the controller.

In *Views/Instructor/Create.cshtml*, add an office location text box and check boxes for courses before the Submit button. As in the case of the Edit page, fix the formatting if Visual Studio reformats the code when you paste it.

```
<div class="form-group">
    <label asp-for="OfficeAssignment.Location" class="control-label"></label>
    <input asp-for="OfficeAssignment.Location" class="form-control" />
    <span asp-validation-for="OfficeAssignment.Location" class="text-danger" />
</div>

<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;
                    List<ContosoUniversity.Models.SchoolViewModels.AssignedCourseData> courses =
ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                                   name="selectedCourses"
                                   value="@course.CourseID"
                                   @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                                   @course.CourseID @:  @course.Title
                            @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

Test by running the app and creating an instructor.

Handling Transactions

As explained in the CRUD tutorial, the Entity Framework implicitly implements transactions. For scenarios where you need more control -- for example, if you want to include operations done outside of Entity Framework in a transaction -- see Transactions.

Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- Customized Courses pages
- Added Instructors Edit page
- Added courses to Edit page
- Updated Delete page
- Added office location and courses to Create page

Advance to the next tutorial to learn how to handle concurrency conflicts.

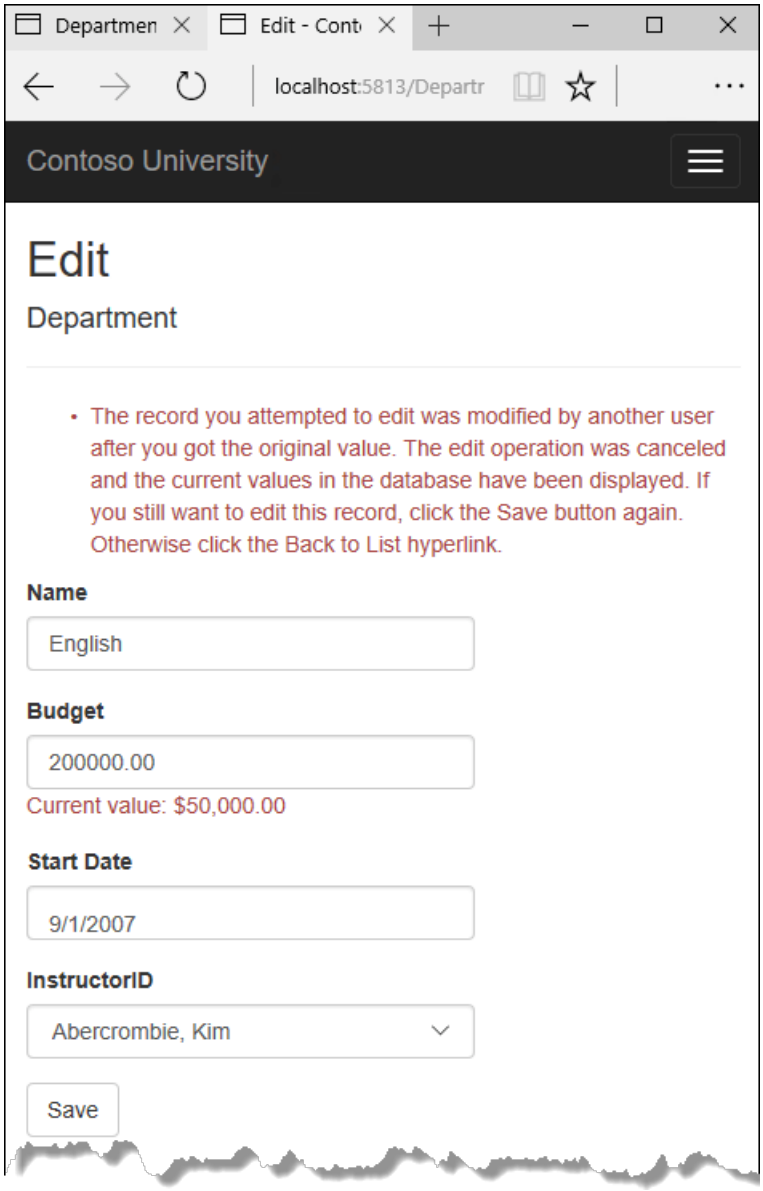
Handle concurrency conflicts

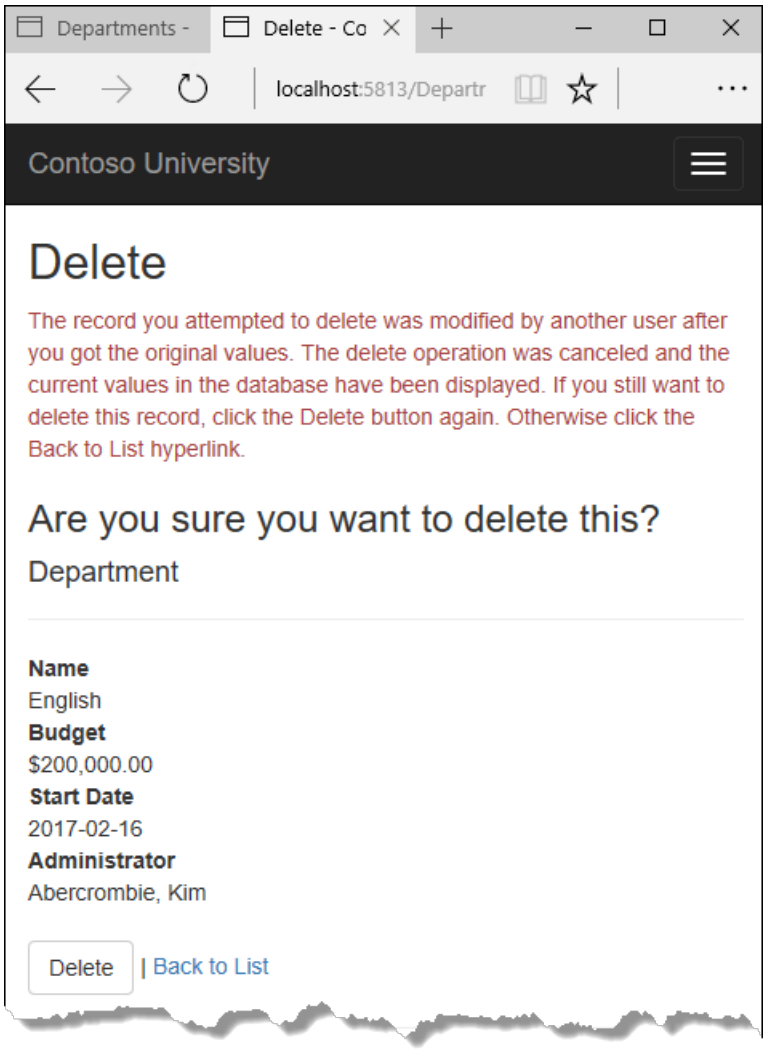
Tutorial: Handle concurrency - ASP.NET MVC with EF Core

9/22/2020 • 18 minutes to read • Edit Online

In earlier tutorials, you learned how to update data. This tutorial shows how to handle conflicts when multiple users update the same entity at the same time.

You'll create web pages that work with the Department entity and handle concurrency errors. The following illustrations show the Edit and Delete pages, including some messages that are displayed if a concurrency conflict occurs.





In this tutorial, you:

- Learn about concurrency conflicts
- Add a tracking property
- Create Departments controller and views
- Update Index view
- Update Edit methods
- Update Edit view
- Test concurrency conflicts
- Update the Delete page
- Update Details and Create views

Prerequisites

- Update related data

Concurrency conflicts

A concurrency conflict occurs when one user displays an entity's data in order to edit it, and then another user updates the same entity's data before the first user's change is written to the database. If you don't enable the detection of such conflicts, whoever updates the database last overwrites the other user's changes. In many applications, this risk is acceptable: if there are few users, or few updates, or if isn't really critical if some changes are overwritten, the cost of programming for concurrency might outweigh the benefit. In that case, you don't have to configure the application to handle concurrency conflicts.

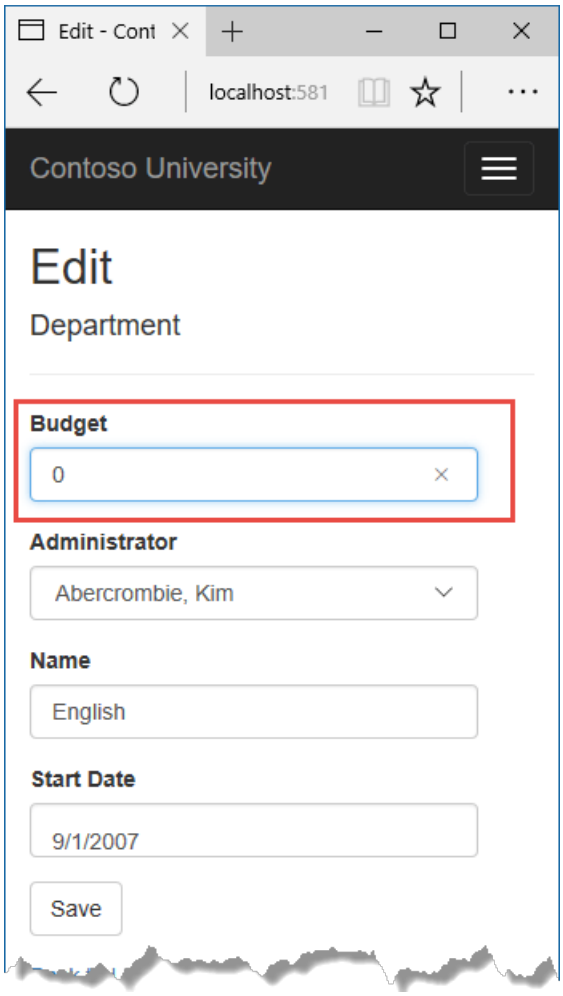
Pessimistic concurrency (locking)

If your application does need to prevent accidental data loss in concurrency scenarios, one way to do that is to use database locks. This is called pessimistic concurrency. For example, before you read a row from a database, you request a lock for read-only or for update access. If you lock a row for update access, no other users are allowed to lock the row either for read-only or update access, because they would get a copy of data that's in the process of being changed. If you lock a row for read-only access, others can also lock it for read-only access but not for update.

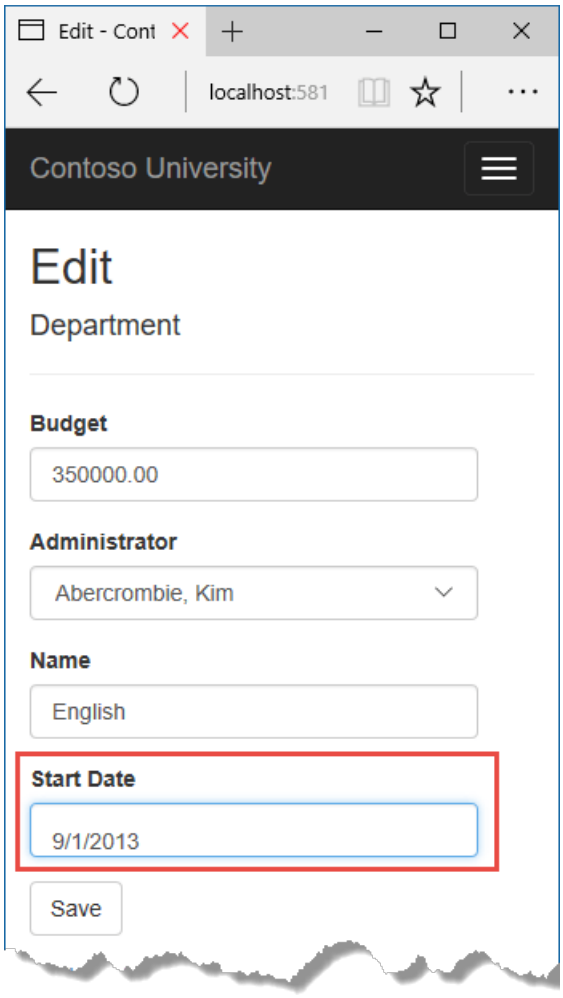
Managing locks has disadvantages. It can be complex to program. It requires significant database management resources, and it can cause performance problems as the number of users of an application increases. For these reasons, not all database management systems support pessimistic concurrency. Entity Framework Core provides no built-in support for it, and this tutorial doesn't show you how to implement it.

Optimistic Concurrency

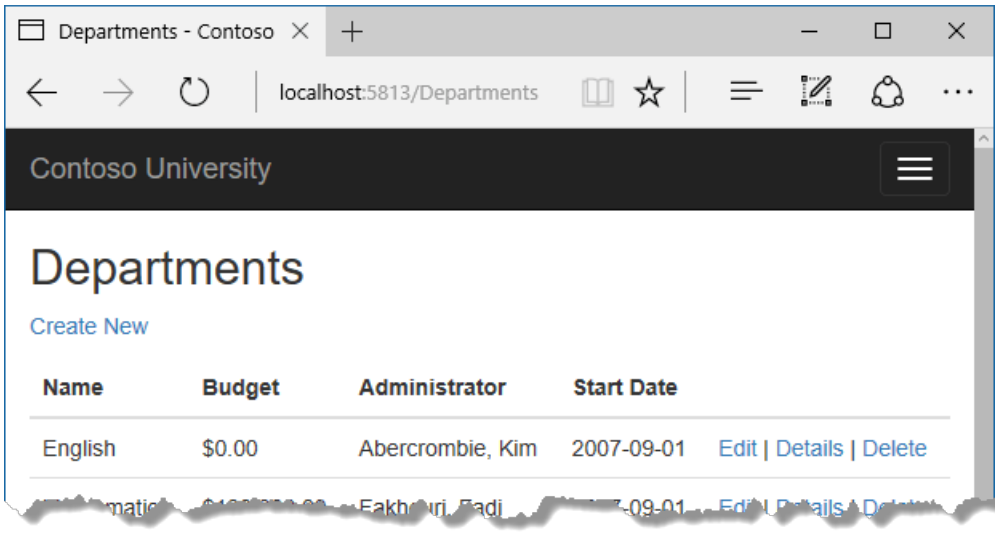
The alternative to pessimistic concurrency is optimistic concurrency. Optimistic concurrency means allowing concurrency conflicts to happen, and then reacting appropriately if they do. For example, Jane visits the Department Edit page and changes the Budget amount for the English department from $350,000.00 to $0.00.



Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.



Jane clicks **Save** first and sees her change when the browser returns to the Index page.



Then John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts.

Some of the options include the following:

- You can keep track of which property a user has modified and update only the corresponding columns in the database.

  In the example scenario, no data would be lost, because different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes -- a start date of 9/1/2013 and a budget of zero dollars. This method of updating can reduce the number of conflicts that could result in data loss, but it can't avoid data loss if competing changes are made to the same

property of an entity. Whether the Entity Framework works this way depends on how you implement your update code. It's often not practical in a web application, because it can require that you maintain large amounts of state in order to keep track of all original property values for an entity as well as new values. Maintaining large amounts of state can affect application performance because it either requires server resources or must be included in the web page itself (for example, in hidden fields) or in a cookie.

- You can let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the restored $350,000.00 value. This is called a *Client Wins* or *Last in Wins* scenario. (All values from the client take precedence over what's in the data store.) As noted in the introduction to this section, if you don't do any coding for concurrency handling, this will happen automatically.

- You can prevent John's change from being updated in the database.

  Typically, you would display an error message, show him the current state of the data, and allow him to reapply his changes if he still wants to make them. This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You'll implement the Store Wins scenario in this tutorial. This method ensures that no changes are overwritten without a user being alerted to what's happening.

Detecting concurrency conflicts

You can resolve conflicts by handling `DbConcurrencyException` exceptions that the Entity Framework throws. In order to know when to throw these exceptions, the Entity Framework must be able to detect conflicts. Therefore, you must configure the database and the data model appropriately. Some options for enabling conflict detection include the following:

- In the database table, include a tracking column that can be used to determine when a row has been changed. You can then configure the Entity Framework to include that column in the Where clause of SQL Update or Delete commands.

  The data type of the tracking column is typically `rowversion`. The `rowversion` value is a sequential number that's incremented each time the row is updated. In an Update or Delete command, the Where clause includes the original value of the tracking column (the original row version) . If the row being updated has been changed by another user, the value in the `rowversion` column is different than the original value, so the Update or Delete statement can't find the row to update because of the Where clause. When the Entity Framework finds that no rows have been updated by the Update or Delete command (that is, when the number of affected rows is zero), it interprets that as a concurrency conflict.

- Configure the Entity Framework to include the original values of every column in the table in the Where clause of Update and Delete commands.

  As in the first option, if anything in the row has changed since the row was first read, the Where clause won't return a row to update, which the Entity Framework interprets as a concurrency conflict. For database tables that have many columns, this approach can result in very large Where clauses, and can require that you maintain large amounts of state. As noted earlier, maintaining large amounts of state can affect application performance. Therefore this approach is generally not recommended, and it isn't the method used in this tutorial.

  If you do want to implement this approach to concurrency, you have to mark all non-primary-key properties in the entity you want to track concurrency for by adding the `ConcurrencyCheck` attribute to them. That change enables the Entity Framework to include all columns in the SQL Where clause of Update and Delete statements.

In the remainder of this tutorial you'll add a `rowversion` tracking property to the Department entity, create a controller and views, and test to verify that everything works correctly.

Add a tracking property

In *Models/Department.cs*, add a tracking property named RowVersion:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
        public byte[] RowVersion { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The `Timestamp` attribute specifies that this column will be included in the Where clause of Update and Delete commands sent to the database. The attribute is called `Timestamp` because previous versions of SQL Server used a SQL `timestamp` data type before the SQL `rowversion` replaced it. The .NET type for `rowversion` is a byte array.

If you prefer to use the fluent API, you can use the `IsConcurrencyToken` method (in *Data/SchoolContext.cs*) to specify the tracking property, as shown in the following example:

```
modelBuilder.Entity<Department>()
    .Property(p => p.RowVersion).IsConcurrencyToken();
```

By adding a property you changed the database model, so you need to do another migration.

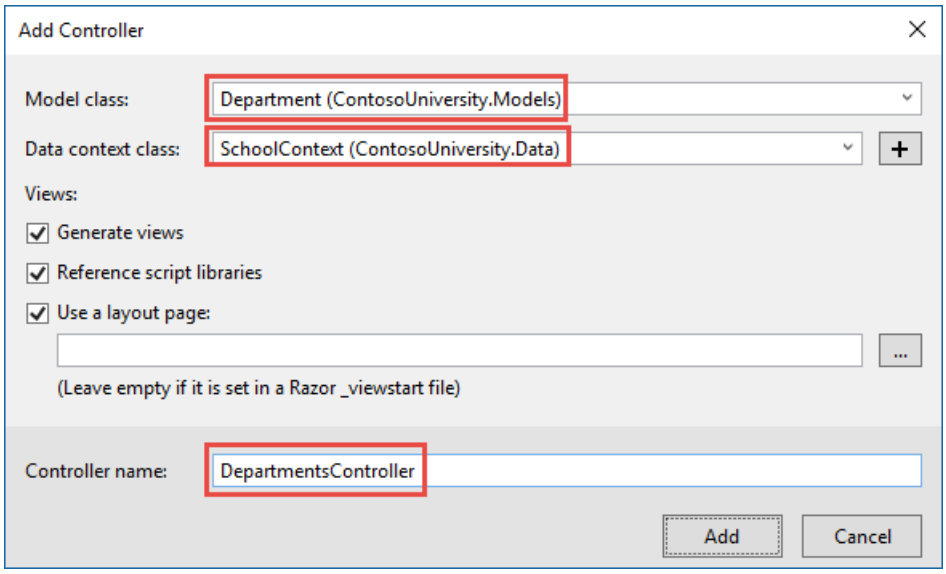
Save your changes and build the project, and then enter the following commands in the command window:

```
dotnet ef migrations add RowVersion
```

```
dotnet ef database update
```

Create Departments controller and views

Scaffold a Departments controller and views as you did earlier for Students, Courses, and Instructors.



In the *DepartmentsController.cs* file, change all four occurrences of "FirstMidName" to "FullName" so that the department administrator drop-down lists will contain the full name of the instructor rather than just the last name.

```
ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID", "FullName", department.InstructorID);
```

Update Index view

The scaffolding engine created a RowVersion column in the Index view, but that field shouldn't be displayed.

Replace the code in *Views/Departments/Index.cshtml* with the following code.

```
@model IEnumerable<ContosoUniversity.Models.Department>

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Name)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Budget)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.StartDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Administrator)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Name)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Budget)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.StartDate)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Administrator.FullName)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.DepartmentID">Edit</a> |
                    <a asp-action="Details" asp-route-id="@item.DepartmentID">Details</a> |
                    <a asp-action="Delete" asp-route-id="@item.DepartmentID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

This changes the heading to "Departments", deletes the RowVersion column, and shows full name instead of first name for the administrator.

Update Edit methods

In both the HttpGet `Edit` method and the `Details` method, add `AsNoTracking`. In the HttpGet `Edit` method, add eager loading for the Administrator.

```
var department = await _context.Departments
    .Include(i => i.Administrator)
    .AsNoTracking()
    .FirstOrDefaultAsync(m => m.DepartmentID == id);
```

Replace the existing code for the HttpPost `Edit` method with the following code:

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int? id, byte[] rowVersion)
{
    if (id == null)
    {
        return NotFound();
    }

    var departmentToUpdate = await _context.Departments.Include(i => i.Administrator).FirstOrDefaultAsync(m =>
m.DepartmentID == id);

    if (departmentToUpdate == null)
    {
        Department deletedDepartment = new Department();
        await TryUpdateModelAsync(deletedDepartment);
        ModelState.AddModelError(string.Empty,
            "Unable to save changes. The department was deleted by another user.");
        ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID", "FullName",
deletedDepartment.InstructorID);
        return View(deletedDepartment);
    }

    _context.Entry(departmentToUpdate).Property("RowVersion").OriginalValue = rowVersion;

    if (await TryUpdateModelAsync<Department>(
        departmentToUpdate,
        "",
        s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
    {
        try
        {
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateConcurrencyException ex)
        {
            var exceptionEntry = ex.Entries.Single();
            var clientValues = (Department)exceptionEntry.Entity;
            var databaseEntry = exceptionEntry.GetDatabaseValues();
            if (databaseEntry == null)
            {
                ModelState.AddModelError(string.Empty,
                    "Unable to save changes. The department was deleted by another user.");
            }
            else
            {
                var databaseValues = (Department)databaseEntry.ToObject();

                if (databaseValues.Name != clientValues.Name)
                {
                    ModelState.AddModelError("Name", $"Current value: {databaseValues.Name}");
                }
                if (databaseValues.Budget != clientValues.Budget)
                {
                    ModelState.AddModelError("Budget", $"Current value: {databaseValues.Budget:c}");
                }
                if (databaseValues.StartDate != clientValues.StartDate)
                {
```

```
                    ModelState.AddModelError("StartDate", $"Current value: {databaseValues.StartDate:d}");
                }
                if (databaseValues.InstructorID != clientValues.InstructorID)
                {
                    Instructor databaseInstructor = await _context.Instructors.FirstOrDefaultAsync(i => i.ID ==
databaseValues.InstructorID);
                    ModelState.AddModelError("InstructorID", $"Current value: {databaseInstructor?.FullName}");
                }

                ModelState.AddModelError(string.Empty, "The record you attempted to edit "
                        + "was modified by another user after you got the original value. The "
                        + "edit operation was canceled and the current values in the database "
                        + "have been displayed. If you still want to edit this record, click "
                        + "the Save button again. Otherwise click the Back to List hyperlink.");
                departmentToUpdate.RowVersion = (byte[])databaseValues.RowVersion;
                ModelState.Remove("RowVersion");
            }
        }
    }
    ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID", "FullName",
departmentToUpdate.InstructorID);
    return View(departmentToUpdate);
}
```

The code begins by trying to read the department to be updated. If the `FirstOrDefaultAsync` method returns null, the department was deleted by another user. In that case the code uses the posted form values to create a department entity so that the Edit page can be redisplayed with an error message. As an alternative, you wouldn't have to re-create the department entity if you display only an error message without redisplaying the department fields.

The view stores the original `RowVersion` value in a hidden field, and this method receives that value in the `rowVersion` parameter. Before you call `SaveChanges`, you have to put that original `RowVersion` property value in the `OriginalValues` collection for the entity.

```
_context.Entry(departmentToUpdate).Property("RowVersion").OriginalValue = rowVersion;
```

Then when the Entity Framework creates a SQL UPDATE command, that command will include a WHERE clause that looks for a row that has the original `RowVersion` value. If no rows are affected by the UPDATE command (no rows have the original `RowVersion` value), the Entity Framework throws a `DbUpdateConcurrencyException` exception.

The code in the catch block for that exception gets the affected Department entity that has the updated values from the `Entries` property on the exception object.

```
var exceptionEntry = ex.Entries.Single();
```

The `Entries` collection will have just one `EntityEntry` object. You can use that object to get the new values entered by the user and the current database values.

```
var clientValues = (Department)exceptionEntry.Entity;
var databaseEntry = exceptionEntry.GetDatabaseValues();
```

The code adds a custom error message for each column that has database values different from what the user entered on the Edit page (only one field is shown here for brevity).

```
var databaseValues = (Department)databaseEntry.ToObject();

if (databaseValues.Name != clientValues.Name)
{
    ModelState.AddModelError("Name", $"Current value: {databaseValues.Name}");
```

Finally, the code sets the `RowVersion` value of the `departmentToUpdate` to the new value retrieved from the database. This new `RowVersion` value will be stored in the hidden field when the Edit page is redisplayed, and the next time the user clicks **Save**, only concurrency errors that happen since the redisplay of the Edit page will be caught.

```
departmentToUpdate.RowVersion = (byte[])databaseValues.RowVersion;
ModelState.Remove("RowVersion");
```

The `ModelState.Remove` statement is required because `ModelState` has the old `RowVersion` value. In the view, the `ModelState` value for a field takes precedence over the model property values when both are present.

Update Edit view

In *Views/Departments/Edit.cshtml*, make the following changes:

- Add a hidden field to save the `RowVersion` property value, immediately following the hidden field for the `DepartmentID` property.
- Add a "Select Administrator" option to the drop-down list.

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Edit">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <input type="hidden" asp-for="DepartmentID" />
            <input type="hidden" asp-for="RowVersion" />
            <div class="form-group">
                <label asp-for="Name" class="control-label"></label>
                <input asp-for="Name" class="form-control" />
                <span asp-validation-for="Name" class="text-danger"></span>
            </div>
            <div class="form-group">

                <select asp-for="InstructorID" class="form-control" asp-items="ViewBag.InstructorID">
                    <option value="">-- Select Administrator --</option>
                </select>
                <span asp-validation-for="InstructorID" class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

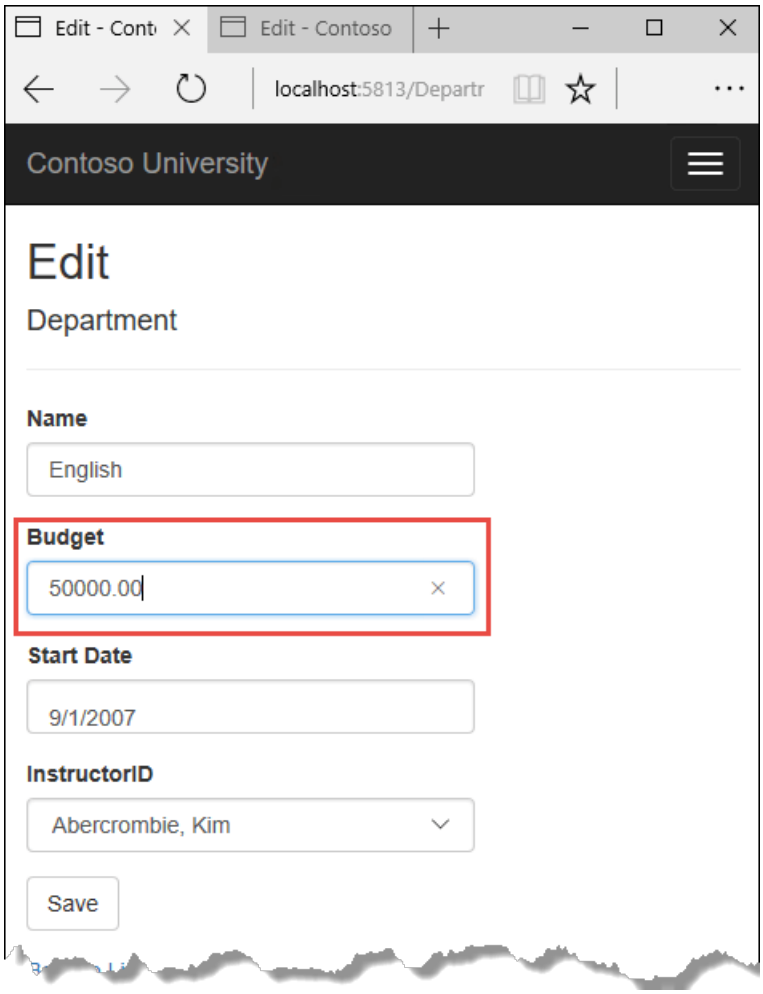
<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Test concurrency conflicts

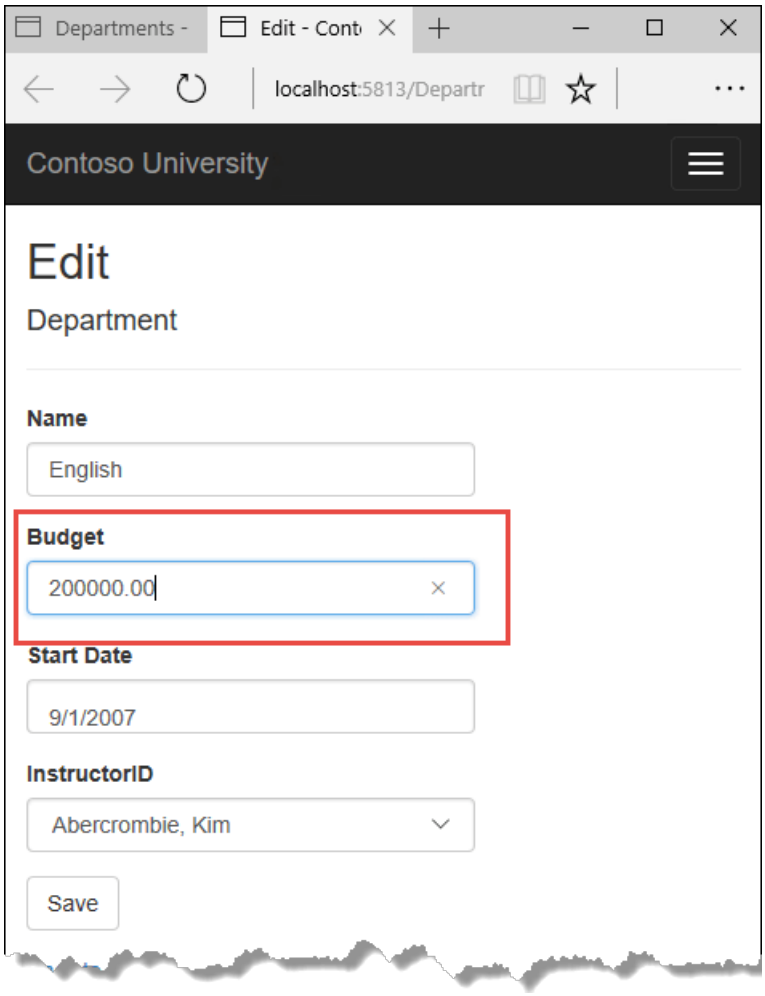
Run the app and go to the Departments Index page. Right-click the **Edit** hyperlink for the English department and select **Open in new tab**, then click the **Edit** hyperlink for the English department. The two browser tabs now display the same information.

Change a field in the first browser tab and click **Save**.

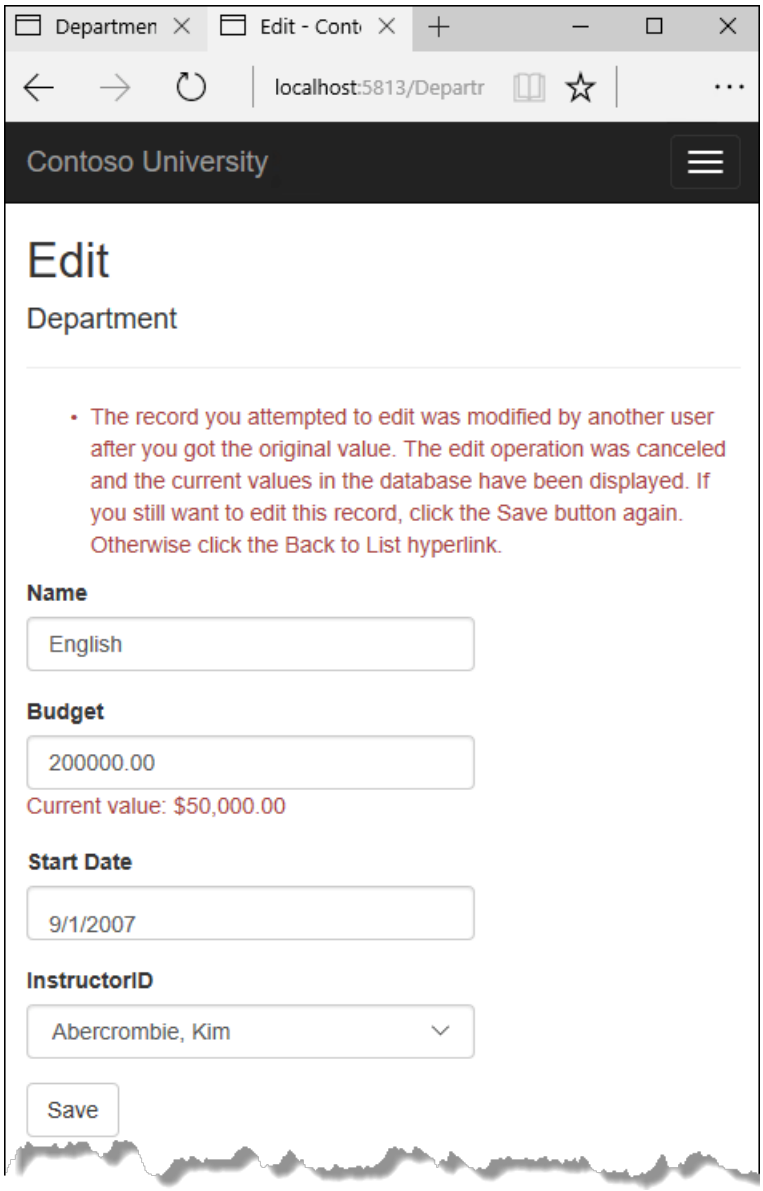


The browser shows the Index page with the changed value.

Change a field in the second browser tab.



Click **Save**. You see an error message:



Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values when the Index page appears.

Update the Delete page

For the Delete page, the Entity Framework detects concurrency conflicts caused by someone else editing the department in a similar manner. When the HttpGet `Delete` method displays the confirmation view, the view includes the original `RowVersion` value in a hidden field. That value is then available to the HttpPost `Delete` method that's called when the user confirms the deletion. When the Entity Framework creates the SQL DELETE command, it includes a WHERE clause with the original `RowVersion` value. If the command results in zero rows affected (meaning the row was changed after the Delete confirmation page was displayed), a concurrency exception is thrown, and the HttpGet `Delete` method is called with an error flag set to true in order to redisplay the confirmation page with an error message. It's also possible that zero rows were affected because the row was deleted by another user, so in that case no error message is displayed.

Update the Delete methods in the Departments controller

In *DepartmentsController.cs*, replace the HttpGet `Delete` method with the following code:

```
public async Task<IActionResult> Delete(int? id, bool? concurrencyError)
{
    if (id == null)
    {
        return NotFound();
    }

    var department = await _context.Departments
        .Include(d => d.Administrator)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.DepartmentID == id);
    if (department == null)
    {
        if (concurrencyError.GetValueOrDefault())
        {
            return RedirectToAction(nameof(Index));
        }
        return NotFound();
    }

    if (concurrencyError.GetValueOrDefault())
    {
        ViewData["ConcurrencyErrorMessage"] = "The record you attempted to delete "
            + "was modified by another user after you got the original values. "
            + "The delete operation was canceled and the current values in the "
            + "database have been displayed. If you still want to delete this "
            + "record, click the Delete button again. Otherwise "
            + "click the Back to List hyperlink.";
    }

    return View(department);
}
```

The method accepts an optional parameter that indicates whether the page is being redisplayed after a concurrency error. If this flag is true and the department specified no longer exists, it was deleted by another user. In that case, the code redirects to the Index page. If this flag is true and the Department does exist, it was changed by another user. In that case, the code sends an error message to the view using `ViewData`.

Replace the code in the HttpPost `Delete` method (named `DeleteConfirmed`) with the following code:

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Delete(Department department)
{
    try
    {
        if (await _context.Departments.AnyAsync(m => m.DepartmentID == department.DepartmentID))
        {
            _context.Departments.Remove(department);
            await _context.SaveChangesAsync();
        }
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateConcurrencyException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { concurrencyError = true, id = department.DepartmentID });
    }
}
```

In the scaffolded code that you just replaced, this method accepted only a record ID:

```
public async Task<IActionResult> DeleteConfirmed(int id)
```

You've changed this parameter to a Department entity instance created by the model binder. This gives EF access to the RowVersion property value in addition to the record key.

```
public async Task<IActionResult> Delete(Department department)
```

You have also changed the action method name from `DeleteConfirmed` to `Delete`. The scaffolded code used the name `DeleteConfirmed` to give the HttpPost method a unique signature. (The CLR requires overloaded methods to have different method parameters.) Now that the signatures are unique, you can stick with the MVC convention and use the same name for the HttpPost and HttpGet delete methods.

If the department is already deleted, the `AnyAsync` method returns false and the application just goes back to the Index method.

If a concurrency error is caught, the code redisplays the Delete confirmation page and provides a flag that indicates it should display a concurrency error message.

Update the Delete view

In *Views/Departments/Delete.cshtml*, replace the scaffolded code with the following code that adds an error message field and hidden fields for the DepartmentID and RowVersion properties. The changes are highlighted.

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<p class="text-danger">@ViewData["ConcurrencyErrorMessage"]</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Budget)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Administrator.FullName)
        </dd>
    </dl>

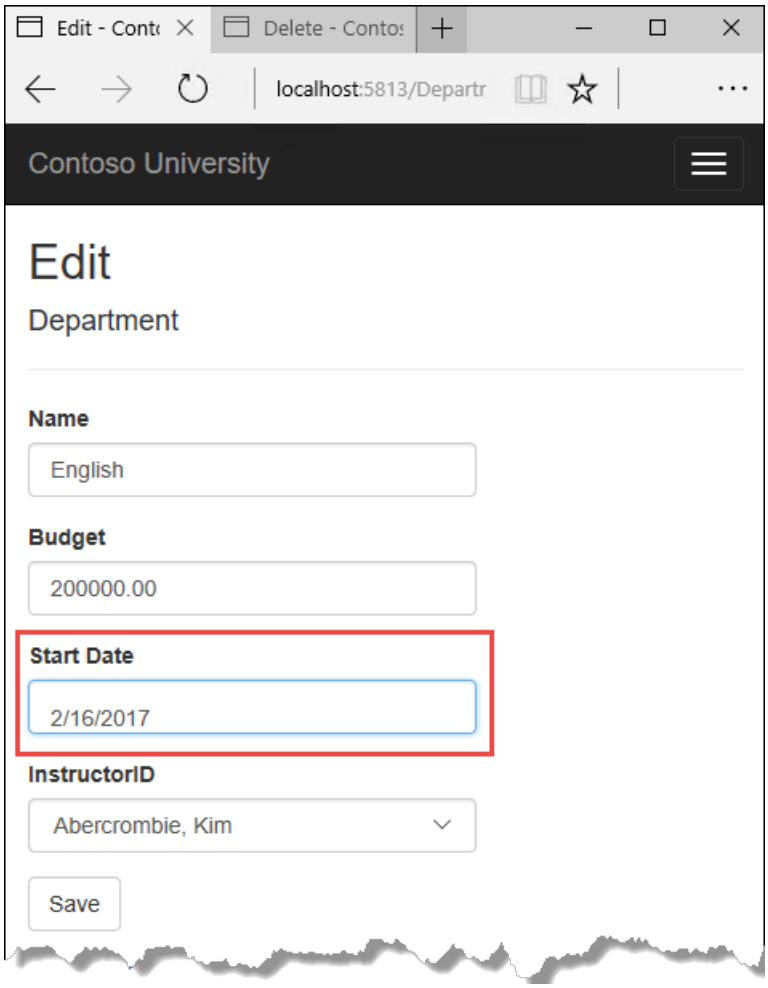
    <form asp-action="Delete">
        <input type="hidden" asp-for="DepartmentID" />
        <input type="hidden" asp-for="RowVersion" />
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-action="Index">Back to List</a>
        </div>
    </form>
</div>
```

This makes the following changes:

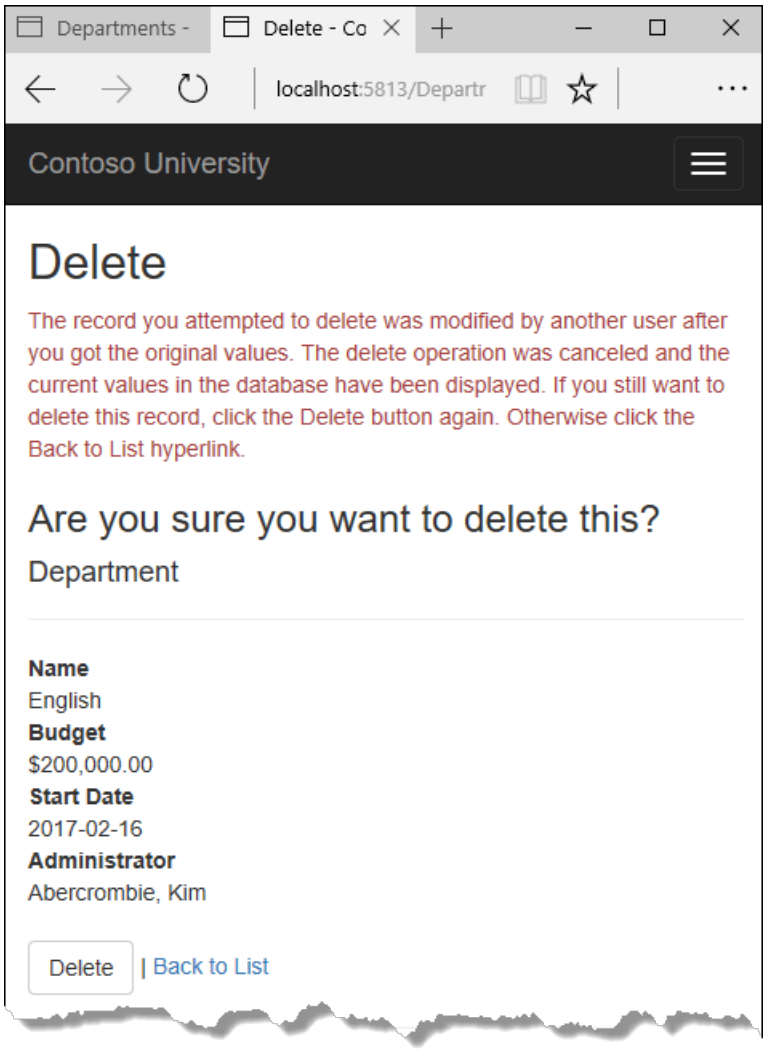
- Adds an error message between the `h2` and `h3` headings.
- Replaces FirstMidName with FullName in the **Administrator** field.
- Removes the RowVersion field.
- Adds a hidden field for the `RowVersion` property.

Run the app and go to the Departments Index page. Right-click the **Delete** hyperlink for the English department and select **Open in new tab**, then in the first tab click the **Edit** hyperlink for the English department.

In the first window, change one of the values, and click **Save**:



In the second tab, click **Delete**. You see the concurrency error message, and the Department values are refreshed with what's currently in the database.



If you click **Delete** again, you're redirected to the Index page, which shows that the department has been deleted.

Update Details and Create views

You can optionally clean up scaffolded code in the Details and Create views.

Replace the code in *Views/Departments/Details.cshtml* to delete the RowVersion column and show the full name of the Administrator.

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Details";
}

<h2>Details</h2>

<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Budget)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Administrator.FullName)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.DepartmentID">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

Replace the code in *Views/Departments/Create.cshtml* to add a Select option to the drop-down list.

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Create">
            <div asp-validation-summary="ModelOnly" class="text-danger"></div>
            <div class="form-group">
                <label asp-for="Name" class="control-label"></label>
                <input asp-for="Name" class="form-control" />
                <span asp-validation-for="Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Budget" class="control-label"></label>
                <input asp-for="Budget" class="form-control" />
                <span asp-validation-for="Budget" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="StartDate" class="control-label"></label>
                <input asp-for="StartDate" class="form-control" />
                <span asp-validation-for="StartDate" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="InstructorID" class="control-label"></label>
                <select asp-for="InstructorID" class="form-control" asp-items="ViewBag.InstructorID">
                    <option value="">-- Select Administrator --</option>
                </select>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Next steps

In this tutorial, you:

- Learned about concurrency conflicts

- Added a tracking property
- Created Departments controller and views
- Updated Index view
- Updated Edit methods
- Updated Edit view
- Tested concurrency conflicts
- Updated the Delete page
- Updated Details and Create views

Advance to the next tutorial to learn how to implement table-per-hierarchy inheritance for the Instructor and Student entities.

Next: Implement table-per-hierarchy inheritance

Tutorial: Implement inheritance - ASP.NET MVC with EF Core

9/22/2020 • 8 minutes to read • Edit Online

In the previous tutorial, you handled concurrency exceptions. This tutorial will show you how to implement inheritance in the data model.

In object-oriented programming, you can use inheritance to facilitate code reuse. In this tutorial, you'll change the `Instructor` and `Student` classes so that they derive from a `Person` base class which contains properties such as `LastName` that are common to both instructors and students. You won't add or change any web pages, but you'll change some of the code and those changes will be automatically reflected in the database.

In this tutorial, you:

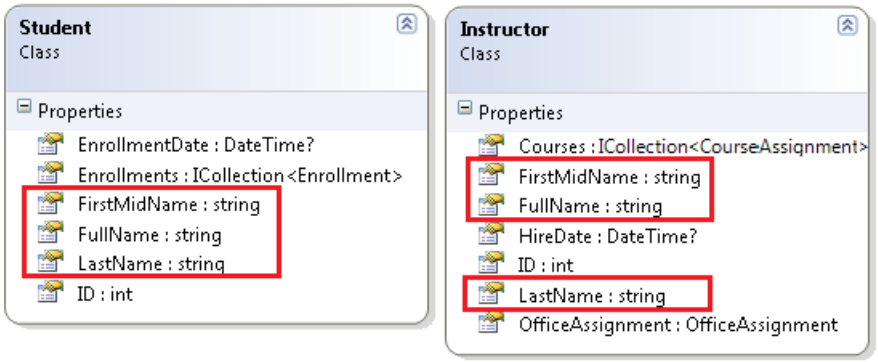
- Map inheritance to database
- Create the Person class
- Update Instructor and Student
- Add Person to the model
- Create and update migrations
- Test the implementation

Prerequisites

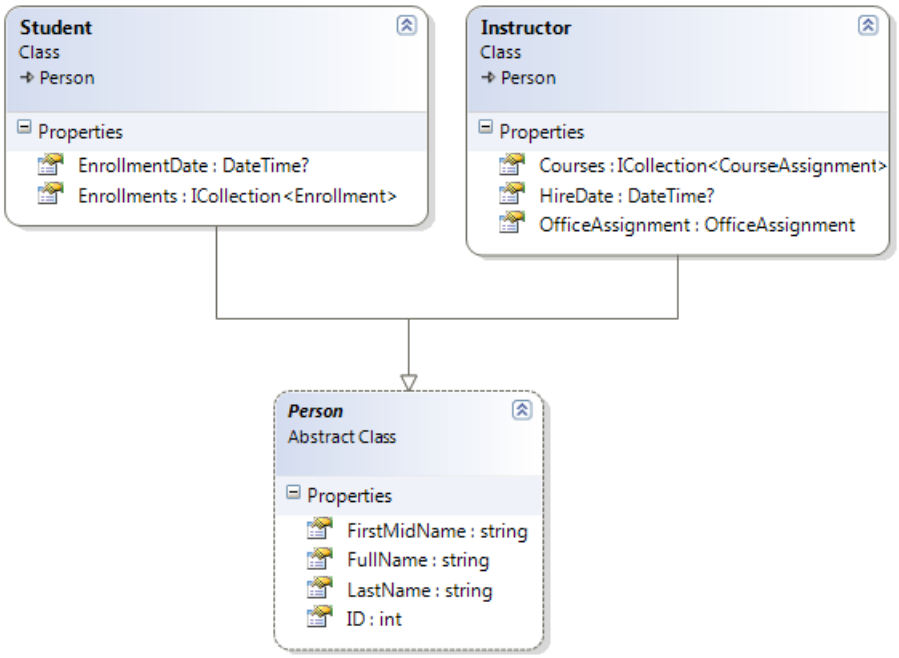
- Handle Concurrency

Map inheritance to database

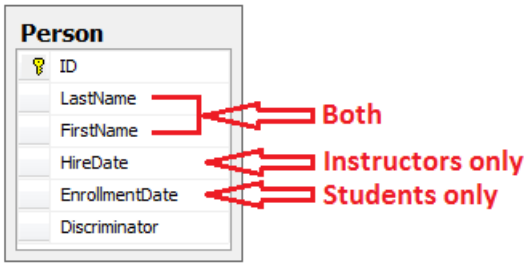
The `Instructor` and `Student` classes in the School data model have several properties that are identical:



Suppose you want to eliminate the redundant code for the properties that are shared by the `Instructor` and `Student` entities. Or you want to write a service that can format names without caring whether the name came from an instructor or a student. You could create a `Person` base class that contains only those shared properties, then make the `Instructor` and `Student` classes inherit from that base class, as shown in the following illustration:



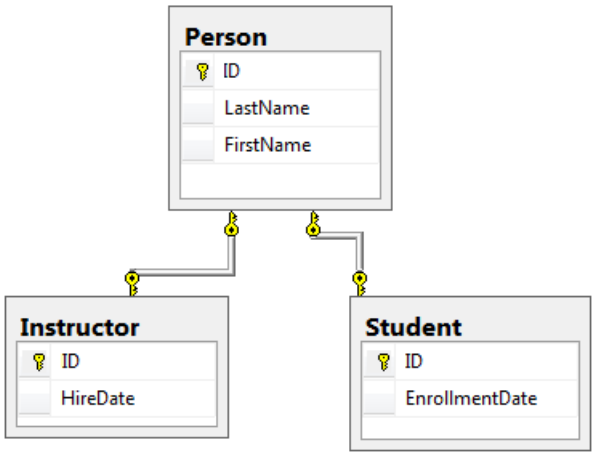
There are several ways this inheritance structure could be represented in the database. You could have a Person table that includes information about both students and instructors in a single table. Some of the columns could apply only to instructors (HireDate), some only to students (EnrollmentDate), some to both (LastName, FirstName). Typically, you'd have a discriminator column to indicate which type each row represents. For example, the discriminator column might have "Instructor" for instructors and "Student" for students.



This pattern of generating an entity inheritance structure from a single database table is called table-per-hierarchy (TPH) inheritance.

An alternative is to make the database look more like the inheritance structure. For example, you could have only the name fields in the Person table and have separate Instructor and Student tables with the date fields.

> **WARNING**
> Table Per Type (TPT) is not supported by EF Core 3.x, however it is has been implemented in EF Core 5.0.



This pattern of making a database table for each entity class is called table per type (TPT) inheritance.

Yet another option is to map all non-abstract types to individual tables. All properties of a class, including inherited properties, map to columns of the corresponding table. This pattern is called Table-per-Concrete Class (TPC) inheritance. If you implemented TPC inheritance for the Person, Student, and Instructor classes as shown earlier, the Student and Instructor tables would look no different after implementing inheritance than they did before.

TPC and TPH inheritance patterns generally deliver better performance than TPT inheritance patterns, because TPT patterns can result in complex join queries.

This tutorial demonstrates how to implement TPH inheritance. TPH is the only inheritance pattern that the Entity Framework Core supports. What you'll do is create a `Person` class, change the `Instructor` and `Student` classes to derive from `Person`, add the new class to the `DbContext`, and create a migration.

> **TIP**
> Consider saving a copy of the project before making the following changes. Then if you run into problems and need to start over, it will be easier to start from the saved project instead of reversing steps done for this tutorial or going back to the beginning of the whole series.

Create the Person class

In the Models folder, create Person.cs and replace the template code with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public abstract class Person
    {
        public int ID { get; set; }

        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }
    }
}
```

Update Instructor and Student

In *Instructor.cs*, derive the Instructor class from the Person class and remove the key and name fields. The code will look like the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Make the same changes in *Student.cs*.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

Add Person to the model

Add the Person entity type to *SchoolContext.cs*. The new lines are highlighted.

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) : base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }
        public DbSet<Person> People { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>().ToTable("CourseAssignment");
            modelBuilder.Entity<Person>().ToTable("Person");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

This is all that the Entity Framework needs in order to configure table-per-hierarchy inheritance. As you'll see, when the database is updated, it will have a Person table in place of the Student and Instructor tables.

Create and update migrations

Save your changes and build the project. Then open the command window in the project folder and enter the following command:

```
dotnet ef migrations add Inheritance
```

Don't run the `database update` command yet. That command will result in lost data because it will drop the Instructor table and rename the Student table to Person. You need to provide custom code to preserve existing data.

Open *Migrations/<timestamp>_Inheritance.cs* and replace the `Up` method with the following code:

```
protected override void Up(MigrationBuilder migrationBuilder)
{
    migrationBuilder.DropForeignKey(
        name: "FK_Enrollment_Student_StudentID",
        table: "Enrollment");

    migrationBuilder.DropIndex(name: "IX_Enrollment_StudentID", table: "Enrollment");

    migrationBuilder.RenameTable(name: "Instructor", newName: "Person");
    migrationBuilder.AddColumn<DateTime>(name: "EnrollmentDate", table: "Person", nullable: true);
    migrationBuilder.AddColumn<string>(name: "Discriminator", table: "Person", nullable: false, maxLength: 128,
defaultValue: "Instructor");
    migrationBuilder.AlterColumn<DateTime>(name: "HireDate", table: "Person", nullable: true);
    migrationBuilder.AddColumn<int>(name: "OldId", table: "Person", nullable: true);

    // Copy existing Student data into new Person table.
    migrationBuilder.Sql("INSERT INTO dbo.Person (LastName, FirstName, HireDate, EnrollmentDate, Discriminator,
OldId) SELECT LastName, FirstName, null AS HireDate, EnrollmentDate, 'Student' AS Discriminator, ID AS OldId
FROM dbo.Student");
    // Fix up existing relationships to match new PK's.
    migrationBuilder.Sql("UPDATE dbo.Enrollment SET StudentId = (SELECT ID FROM dbo.Person WHERE OldId =
Enrollment.StudentId AND Discriminator = 'Student')");

    // Remove temporary key
    migrationBuilder.DropColumn(name: "OldID", table: "Person");

    migrationBuilder.DropTable(
        name: "Student");

    migrationBuilder.CreateIndex(
         name: "IX_Enrollment_StudentID",
         table: "Enrollment",
         column: "StudentID");

    migrationBuilder.AddForeignKey(
        name: "FK_Enrollment_Person_StudentID",
        table: "Enrollment",
        column: "StudentID",
        principalTable: "Person",
        principalColumn: "ID",
        onDelete: ReferentialAction.Cascade);
}
```

This code takes care of the following database update tasks:

- Removes foreign key constraints and indexes that point to the Student table.
- Renames the Instructor table as Person and makes changes needed for it to store Student data:
- Adds nullable EnrollmentDate for students.

- Adds Discriminator column to indicate whether a row is for a student or an instructor.
- Makes HireDate nullable since student rows won't have hire dates.
- Adds a temporary field that will be used to update foreign keys that point to students. When you copy students into the Person table they will get new primary key values.
- Copies data from the Student table into the Person table. This causes students to get assigned new primary key values.
- Fixes foreign key values that point to students.
- Re-creates foreign key constraints and indexes, now pointing them to the Person table.

(If you had used GUID instead of integer as the primary key type, the student primary key values wouldn't have to change, and several of these steps could have been omitted.)

Run the `database update` command:

```
dotnet ef database update
```

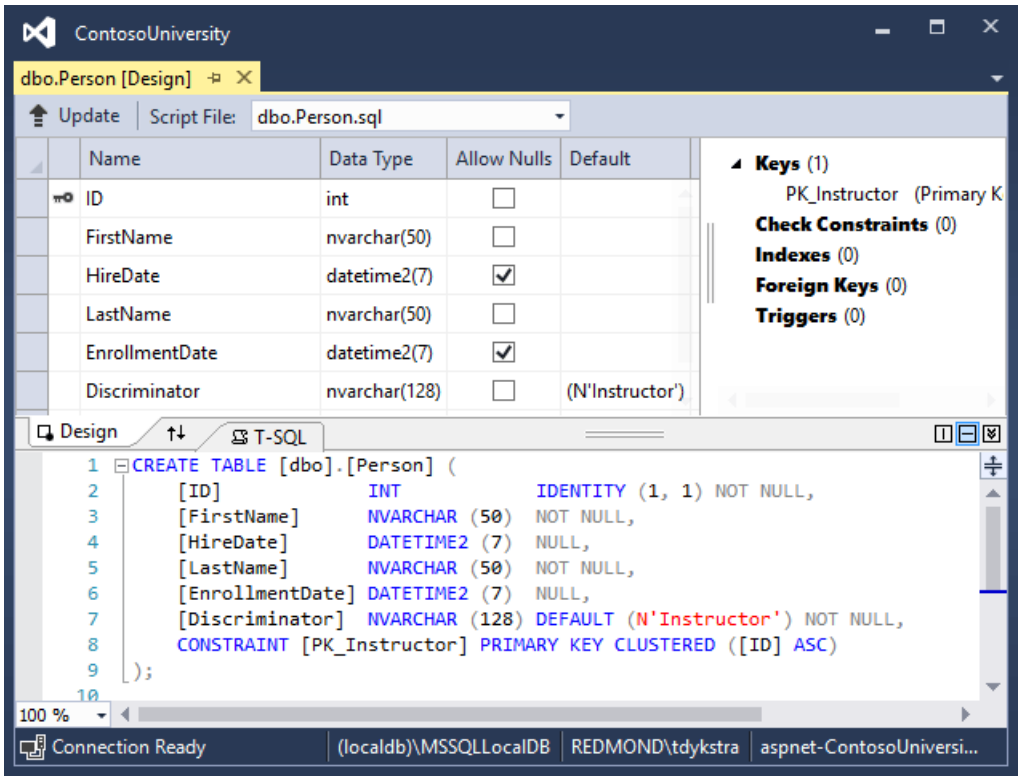
(In a production system you would make corresponding changes to the `Down` method in case you ever had to use that to go back to the previous database version. For this tutorial you won't be using the `Down` method.)

> **NOTE**
> It's possible to get other errors when making schema changes in a database that has existing data. If you get migration errors that you can't resolve, you can either change the database name in the connection string or delete the database. With a new database, there's no data to migrate, and the update-database command is more likely to complete without errors. To delete the database, use SSOX or run the `database drop` CLI command.

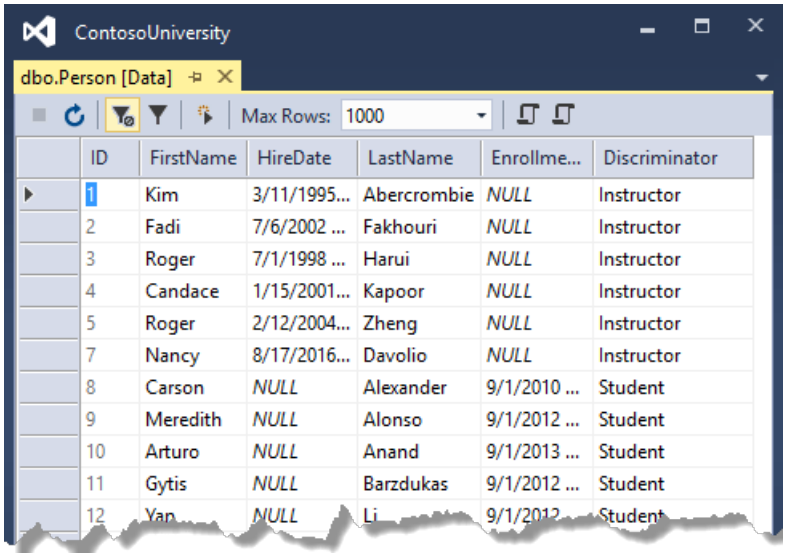
Test the implementation

Run the app and try various pages. Everything works the same as it did before.

In **SQL Server Object Explorer**, expand **Data Connections/SchoolContext** and then **Tables**, and you see that the Student and Instructor tables have been replaced by a Person table. Open the Person table designer and you see that it has all of the columns that used to be in the Student and Instructor tables.



Right-click the Person table, and then click **Show Table Data** to see the discriminator column.



Get the code

Download or view the completed application.

For more information about inheritance in Entity Framework Core, see Inheritance.

Next steps

In this tutorial, you:

- Mapped inheritance to database
- Created the Person class
- Updated Instructor and Student
- Added Person to the model

- Created and update migrations
- Tested the implementation

Advance to the next tutorial to learn how to handle a variety of relatively advanced Entity Framework scenarios.

Next: Advanced topics

Tutorial: Learn about advanced scenarios - ASP.NET MVC with EF Core

9/22/2020 • 13 minutes to read • Edit Online

In the previous tutorial, you implemented table-per-hierarchy inheritance. This tutorial introduces several topics that are useful to be aware of when you go beyond the basics of developing ASP.NET Core web applications that use Entity Framework Core.

In this tutorial, you:

- Perform raw SQL queries
- Call a query to return entities
- Call a query to return other types
- Call an update query
- Examine SQL queries
- Create an abstraction layer
- Learn about Automatic change detection
- Learn about EF Core source code and development plans
- Learn how to use dynamic LINQ to simplify code

Prerequisites

- Implement Inheritance

Perform raw SQL queries

One of the advantages of using the Entity Framework is that it avoids tying your code too closely to a particular method of storing data. It does this by generating SQL queries and commands for you, which also frees you from having to write them yourself. But there are exceptional scenarios when you need to run specific SQL queries that you have manually created. For these scenarios, the Entity Framework Code First API includes methods that enable you to pass SQL commands directly to the database. You have the following options in EF Core 1.0:

- Use the `DbSet.FromSql` method for queries that return entity types. The returned objects must be of the type expected by the `DbSet` object, and they're automatically tracked by the database context unless you turn tracking off.
- Use the `Database.ExecuteSqlCommand` for non-query commands.

If you need to run a query that returns types that aren't entities, you can use ADO.NET with the database connection provided by EF. The returned data isn't tracked by the database context, even if you use this method to retrieve entity types.

As is always true when you execute SQL commands in a web application, you must take precautions to protect your site against SQL injection attacks. One way to do that is to use parameterized queries to make sure that strings submitted by a web page can't be interpreted as SQL commands. In this tutorial you'll use parameterized queries when integrating user input into a query.

Call a query to return entities

The `DbSet<TEntity>` class provides a method that you can use to execute a query that returns an entity of type

`TEntity`. To see how this works you'll change the code in the `Details` method of the Department controller.

In *DepartmentsController.cs*, in the `Details` method, replace the code that retrieves a department with a `FromSql` method call, as shown in the following highlighted code:

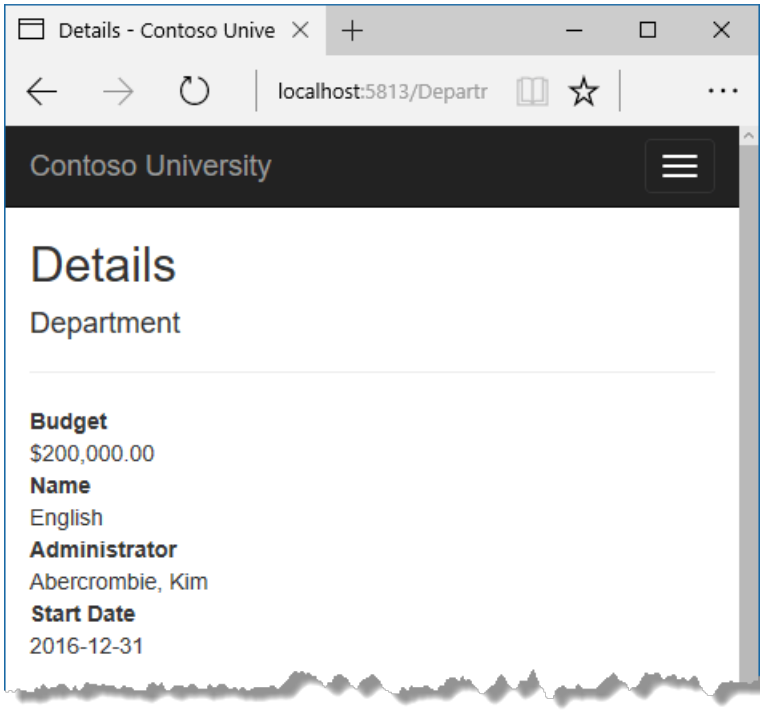
```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    string query = "SELECT * FROM Department WHERE DepartmentID = {0}";
    var department = await _context.Departments
        .FromSql(query, id)
        .Include(d => d.Administrator)
        .AsNoTracking()
        .FirstOrDefaultAsync();

    if (department == null)
    {
        return NotFound();
    }

    return View(department);
}
```

To verify that the new code works correctly, select the **Departments** tab and then **Details** for one of the departments.



Call a query to return other types

Earlier you created a student statistics grid for the About page that showed the number of students for each enrollment date. You got the data from the Students entity set (`_context.Students`) and used LINQ to project the results into a list of `EnrollmentDateGroup` view model objects. Suppose you want to write the SQL itself rather than using LINQ. To do that you need to run a SQL query that returns something other than entity objects. In EF Core 1.0, one way to do that is write ADO.NET code and get the database connection from EF.

In *HomeController.cs*, replace the `About` method with the following code:

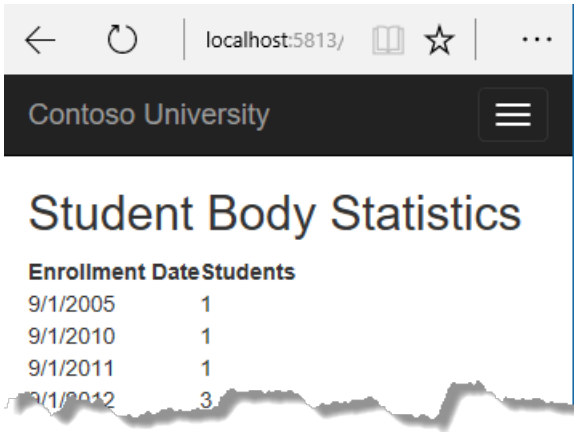
```
public async Task<ActionResult> About()
{
    List<EnrollmentDateGroup> groups = new List<EnrollmentDateGroup>();
    var conn = _context.Database.GetDbConnection();
    try
    {
        await conn.OpenAsync();
        using (var command = conn.CreateCommand())
        {
            string query = "SELECT EnrollmentDate, COUNT(*) AS StudentCount "
                + "FROM Person "
                + "WHERE Discriminator = 'Student' "
                + "GROUP BY EnrollmentDate";
            command.CommandText = query;
            DbDataReader reader = await command.ExecuteReaderAsync();

            if (reader.HasRows)
            {
                while (await reader.ReadAsync())
                {
                    var row = new EnrollmentDateGroup { EnrollmentDate = reader.GetDateTime(0), StudentCount =
reader.GetInt32(1) };
                    groups.Add(row);
                }
            }
            reader.Dispose();
        }
    }
    finally
    {
        conn.Close();
    }
    return View(groups);
}
```

Add a using statement:

```
using System.Data.Common;
```

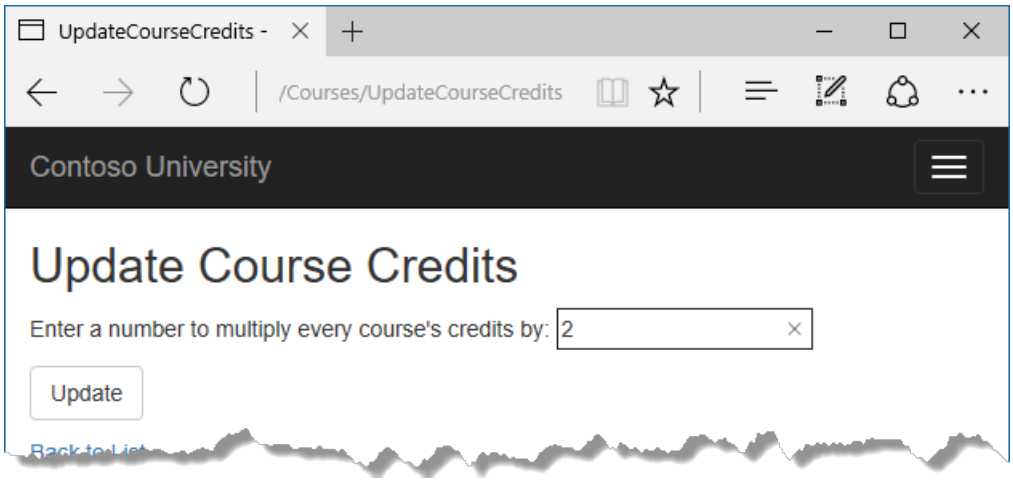
Run the app and go to the About page. It displays the same data it did before.



Call an update query

Suppose Contoso University administrators want to perform global changes in the database, such as changing the number of credits for every course. If the university has a large number of courses, it would be inefficient to retrieve them all as entities and change them individually. In this section you'll implement a web page that enables the user to specify a factor by which to change the number of credits for all courses, and you'll make the change by

executing a SQL UPDATE statement. The web page will look like the following illustration:



In *CoursesController.cs*, add UpdateCourseCredits methods for HttpGet and HttpPost:

```
public IActionResult UpdateCourseCredits()
{
    return View();
}
```

```
[HttpPost]
public async Task<IActionResult> UpdateCourseCredits(int? multiplier)
{
    if (multiplier != null)
    {
        ViewData["RowsAffected"] =
            await _context.Database.ExecuteSqlCommandAsync(
                "UPDATE Course SET Credits = Credits * {0}",
                parameters: multiplier);
    }
    return View();
}
```

When the controller processes an HttpGet request, nothing is returned in `ViewData["RowsAffected"]`, and the view displays an empty text box and a submit button, as shown in the preceding illustration.

When the **Update** button is clicked, the HttpPost method is called, and multiplier has the value entered in the text box. The code then executes the SQL that updates courses and returns the number of affected rows to the view in `ViewData`. When the view gets a `RowsAffected` value, it displays the number of rows updated.

In **Solution Explorer**, right-click the *Views/Courses* folder, and then click **Add > New Item**.

In the **Add New Item** dialog, click **ASP.NET Core** under **Installed** in the left pane, click **Razor View**, and name the new view *UpdateCourseCredits.cshtml*.

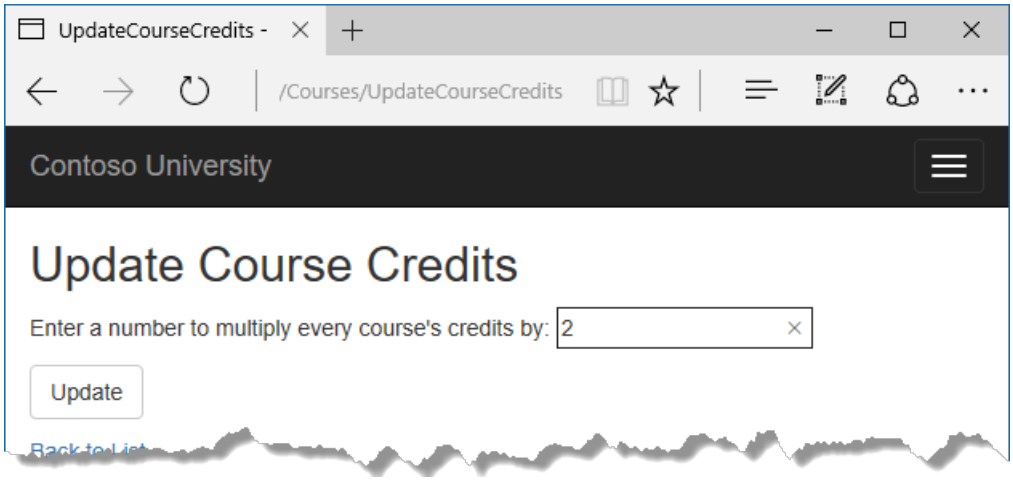
In *Views/Courses/UpdateCourseCredits.cshtml*, replace the template code with the following code:

```
@{
    ViewBag.Title = "UpdateCourseCredits";
}

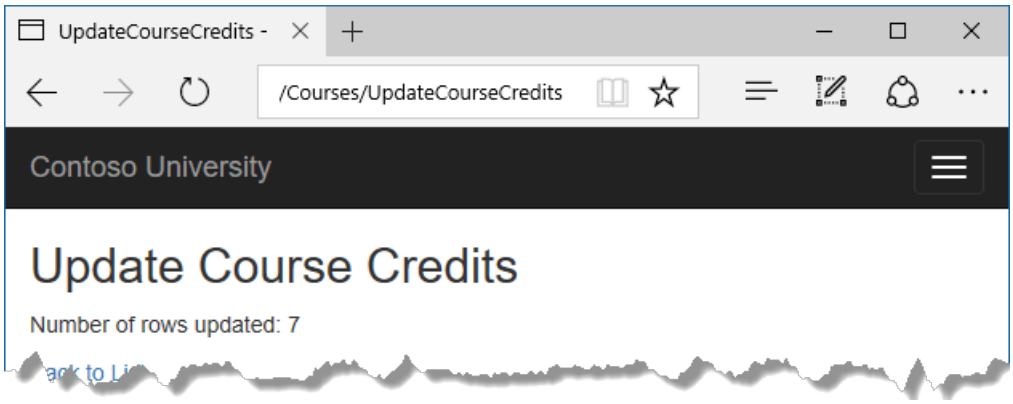
<h2>Update Course Credits</h2>

@if (ViewData["RowsAffected"] == null)
{
    <form asp-action="UpdateCourseCredits">
        <div class="form-actions no-color">
            <p>
                Enter a number to multiply every course's credits by: @Html.TextBox("multiplier")
            </p>
            <p>
                <input type="submit" value="Update" class="btn btn-default" />
            </p>
        </div>
    </form>
}
@if (ViewData["RowsAffected"] != null)
{
    <p>
        Number of rows updated: @ViewData["RowsAffected"]
    </p>
}
<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Run the `UpdateCourseCredits` method by selecting the **Courses** tab, then adding "/UpdateCourseCredits" to the end of the URL in the browser's address bar (for example: `http://localhost:5813/Courses/UpdateCourseCredits`). Enter a number in the text box:



Click **Update**. You see the number of rows affected:



Click **Back to List** to see the list of courses with the revised number of credits.

Note that production code would ensure that updates always result in valid data. The simplified code shown here could multiply the number of credits enough to result in numbers greater than 5. (The `Credits` property has a `[Range(0, 5)]` attribute.) The update query would work but the invalid data could cause unexpected results in other parts of the system that assume the number of credits is 5 or less.

For more information about raw SQL queries, see Raw SQL Queries.

Examine SQL queries

Sometimes it's helpful to be able to see the actual SQL queries that are sent to the database. Built-in logging functionality for ASP.NET Core is automatically used by EF Core to write logs that contain the SQL for queries and updates. In this section you'll see some examples of SQL logging.

Open *StudentsController.cs* and in the `Details` method set a breakpoint on the `if (student == null)` statement.

Run the app in debug mode, and go to the Details page for a student.

Go to the **Output** window showing debug output, and you see the query:

```
Microsoft.EntityFrameworkCore.Database.Command:Information: Executed DbCommand (56ms) [Parameters=
[@__id_0='?'], CommandType='Text', CommandTimeout='30']
SELECT TOP(2) [s].[ID], [s].[Discriminator], [s].[FirstName], [s].[LastName], [s].[EnrollmentDate]
FROM [Person] AS [s]
WHERE ([s].[Discriminator] = N'Student') AND ([s].[ID] = @__id_0)
ORDER BY [s].[ID]
Microsoft.EntityFrameworkCore.Database.Command:Information: Executed DbCommand (122ms) [Parameters=
[@__id_0='?'], CommandType='Text', CommandTimeout='30']
SELECT [s.Enrollments].[EnrollmentID], [s.Enrollments].[CourseID], [s.Enrollments].[Grade], [s.Enrollments].
[StudentID], [e.Course].[CourseID], [e.Course].[Credits], [e.Course].[DepartmentID], [e.Course].[Title]
FROM [Enrollment] AS [s.Enrollments]
INNER JOIN [Course] AS [e.Course] ON [s.Enrollments].[CourseID] = [e.Course].[CourseID]
INNER JOIN (
    SELECT TOP(1) [s0].[ID]
    FROM [Person] AS [s0]
    WHERE ([s0].[Discriminator] = N'Student') AND ([s0].[ID] = @__id_0)
    ORDER BY [s0].[ID]
) AS [t] ON [s.Enrollments].[StudentID] = [t].[ID]
ORDER BY [t].[ID]
```

You'll notice something here that might surprise you: the SQL selects up to 2 rows (`TOP(2)`) from the Person table. The `SingleOrDefaultAsync` method doesn't resolve to 1 row on the server. Here's why:

- If the query would return multiple rows, the method returns null.
- To determine whether the query would return multiple rows, EF has to check if it returns at least 2.

Note that you don't have to use debug mode and stop at a breakpoint to get logging output in the **Output** window. It's just a convenient way to stop the logging at the point you want to look at the output. If you don't do that, logging continues and you have to scroll back to find the parts you're interested in.

Create an abstraction layer

Many developers write code to implement the repository and unit of work patterns as a wrapper around code that works with the Entity Framework. These patterns are intended to create an abstraction layer between the data access layer and the business logic layer of an application. Implementing these patterns can help insulate your application from changes in the data store and can facilitate automated unit testing or test-driven development (TDD). However, writing additional code to implement these patterns isn't always the best choice for applications that use EF, for several reasons:

- The EF context class itself insulates your code from data-store-specific code.
- The EF context class can act as a unit-of-work class for database updates that you do using EF.
- EF includes features for implementing TDD without writing repository code.

For information about how to implement the repository and unit of work patterns, see the Entity Framework 5 version of this tutorial series.

Entity Framework Core implements an in-memory database provider that can be used for testing. For more information, see Test with InMemory.

Automatic change detection

The Entity Framework determines how an entity has changed (and therefore which updates need to be sent to the database) by comparing the current values of an entity with the original values. The original values are stored when the entity is queried or attached. Some of the methods that cause automatic change detection are the following:

- DbContext.SaveChanges
- DbContext.Entry
- ChangeTracker.Entries

If you're tracking a large number of entities and you call one of these methods many times in a loop, you might get significant performance improvements by temporarily turning off automatic change detection using the `ChangeTracker.AutoDetectChangesEnabled` property. For example:

```
_context.ChangeTracker.AutoDetectChangesEnabled = false;
```

EF Core source code and development plans

The Entity Framework Core source is at https://github.com/dotnet/efcore. The EF Core repository contains nightly builds, issue tracking, feature specs, design meeting notes, and the roadmap for future development. You can file or find bugs, and contribute.

Although the source code is open, Entity Framework Core is fully supported as a Microsoft product. The Microsoft Entity Framework team keeps control over which contributions are accepted and tests all code changes to ensure the quality of each release.

Reverse engineer from existing database

To reverse engineer a data model including entity classes from an existing database, use the scaffold-dbcontext command. See the getting-started tutorial.

Use dynamic LINQ to simplify code

The third tutorial in this series shows how to write LINQ code by hard-coding column names in a `switch` statement. With two columns to choose from, this works fine, but if you have many columns the code could get verbose. To solve that problem, you can use the `EF.Property` method to specify the name of the property as a string. To try out this approach, replace the `Index` method in the `StudentsController` with the following code.

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
{
    ViewData["CurrentSort"] = sortOrder;
    ViewData["NameSortParm"] =
        String.IsNullOrEmpty(sortOrder) ? "LastName_desc" : "";
    ViewData["DateSortParm"] =
        sortOrder == "EnrollmentDate" ? "EnrollmentDate_desc" : "EnrollmentDate";

    if (searchString != null)
    {
        pageNumber = 1;
    }
    else
    {
        searchString = currentFilter;
    }

    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;

    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }

    if (string.IsNullOrEmpty(sortOrder))
    {
        sortOrder = "LastName";
    }

    bool descending = false;
    if (sortOrder.EndsWith("_desc"))
    {
        sortOrder = sortOrder.Substring(0, sortOrder.Length - 5);
        descending = true;
    }

    if (descending)
    {
        students = students.OrderByDescending(e => EF.Property<object>(e, sortOrder));
    }
    else
    {
        students = students.OrderBy(e => EF.Property<object>(e, sortOrder));
    }

    int pageSize = 3;
    return View(await PaginatedList<Student>.CreateAsync(students.AsNoTracking(),
        pageNumber ?? 1, pageSize));
}
```

Acknowledgments

Tom Dykstra and Rick Anderson (twitter @RickAndMSFT) wrote this tutorial. Rowan Miller, Diego Vega, and other members of the Entity Framework team assisted with code reviews and helped debug issues that arose while we were writing code for the tutorials. John Parente and Paul Goldman worked on updating the tutorial for ASP.NET Core 2.2.

Troubleshoot common errors

ContosoUniversity.dll used by another process

Error message:

> Cannot open '...bin\Debug\netcoreapp1.0\ContosoUniversity.dll' for writing -- 'The process cannot access the file '...\bin\Debug\netcoreapp1.0\ContosoUniversity.dll' because it is being used by another process.

Solution:

Stop the site in IIS Express. Go to the Windows System Tray, find IIS Express and right-click its icon, select the Contoso University site, and then click **Stop Site**.

Migration scaffolded with no code in Up and Down methods

Possible cause:

The EF CLI commands don't automatically close and save code files. If you have unsaved changes when you run the `migrations add` command, EF won't find your changes.

Solution:

Run the `migrations remove` command, save your code changes and rerun the `migrations add` command.

Errors while running database update

It's possible to get other errors when making schema changes in a database that has existing data. If you get migration errors you can't resolve, you can either change the database name in the connection string or delete the database. With a new database, there's no data to migrate, and the update-database command is much more likely to complete without errors.

The simplest approach is to rename the database in *appsettings.json*. The next time you run `database update`, a new database will be created.

To delete a database in SSOX, right-click the database, click **Delete**, and then in the **Delete Database** dialog box select **Close existing connections** and click **OK**.

To delete a database by using the CLI, run the `database drop` CLI command:

```
dotnet ef database drop
```

Error locating SQL Server instance

Error Message:

> A network-related or instance-specific error occurred while establishing a connection to SQL Server. The server was not found or was not accessible. Verify that the instance name is correct and that SQL Server is configured to allow remote connections. (provider: SQL Network Interfaces, error: 26 - Error Locating Server/Instance Specified)

Solution:

Check the connection string. If you have manually deleted the database file, change the name of the database in the construction string to start over with a new database.

Get the code

Download or view the completed application.

Additional resources

For more information about EF Core, see the Entity Framework Core documentation. A book is also available: Entity Framework Core in Action.

For information on how to deploy a web app, see Host and deploy ASP.NET Core.

For information about other topics related to ASP.NET Core MVC, such as authentication and authorization, see Introduction to ASP.NET Core.

Next steps

In this tutorial, you:

- Performed raw SQL queries
- Called a query to return entities
- Called a query to return other types
- Called an update query
- Examined SQL queries
- Created an abstraction layer
- Learned about Automatic change detection
- Learned about EF Core source code and development plans
- Learned how to use dynamic LINQ to simplify code

This completes this series of tutorials on using the Entity Framework Core in an ASP.NET Core MVC application. This series worked with a new database; an alternative is to reverse engineer a model from an existing database.

Tutorial: EF Core with MVC, existing database

ASP.NET Core fundamentals

9/22/2020 • 17 minutes to read • Edit Online

This article provides an overview of key topics for understanding how to develop ASP.NET Core apps.

The Startup class

The `Startup` class is where:

- Services required by the app are configured.
- The app's request handling pipeline is defined, as a series of middleware components.

Here's a sample `Startup` class:

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddDbContext<RazorPagesMovieContext>(options =>
            options.UseSqlServer(Configuration.GetConnectionString("RazorPagesMovieContext")));

        services.AddControllersWithViews();
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapDefaultControllerRoute();
            endpoints.MapRazorPages();
        });
    }
}
```

For more information, see App startup in ASP.NET Core.

Dependency injection (services)

ASP.NET Core includes a built-in dependency injection (DI) framework that makes configured services available throughout an app. For example, a logging component is a service.

Code to configure (or *register*) services is added to the `Startup.ConfigureServices` method. For example:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<RazorPagesMovieContext>(options =>
        options.UseSqlServer(Configuration.GetConnectionString("RazorPagesMovieContext")));

    services.AddControllersWithViews();
    services.AddRazorPages();
}
```

Services are typically resolved from DI using constructor injection. With constructor injection, a class declares a constructor parameter of either the required type or an interface. The DI framework provides an instance of this service at runtime.

The following example uses constructor injection to resolve a `RazorPagesMovieContext` from DI:

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovieContext context)
    {
        _context = context;
    }

    // ...

    public async Task OnGetAsync()
    {
        Movies = await _context.Movies.ToListAsync();
    }
}
```

If the built-in Inversion of Control (IoC) container doesn't meet all of an app's needs, a third-party IoC container can be used instead.

For more information, see Dependency injection in ASP.NET Core.

Middleware

The request handling pipeline is composed as a series of middleware components. Each component performs operations on an `HttpContext` and either invokes the next middleware in the pipeline or terminates the request.

By convention, a middleware component is added to the pipeline by invoking a `Use...` extension method in the `Startup.Configure` method. For example, to enable rendering of static files, call `UseStaticFiles`.

The following example configures a request handling pipeline:

```
public void Configure(IApplicationBuilder app)
{
    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
        endpoints.MapRazorPages();
    });
}
```

ASP.NET Core includes a rich set of built-in middleware. Custom middleware components can also be written.

For more information, see ASP.NET Core Middleware.

Host

On startup, an ASP.NET Core app builds a *host*. The host encapsulates all of the app's resources, such as:

- An HTTP server implementation
- Middleware components
- Logging
- Dependency injection (DI) services
- Configuration

There are two different hosts:

- .NET Generic Host
- ASP.NET Core Web Host

The .NET Generic Host is recommended. The ASP.NET Core Web Host is available only for backwards compatibility.

The following example creates a .NET Generic Host:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The `CreateDefaultBuilder` and `ConfigureWebHostDefaults` methods configure a host with a set of default options, such as:

- Use Kestrel as the web server and enable IIS integration.
- Load configuration from *appsettings.json*, *appsettings.{Environment Name}.json*, environment variables, command line arguments, and other configuration sources.
- Send logging output to the console and debug providers.

For more information, see .NET Generic Host.

Non-web scenarios

The Generic Host allows other types of apps to use cross-cutting framework extensions, such as logging, dependency injection (DI), configuration, and app lifetime management. For more information, see .NET Generic Host and Background tasks with hosted services in ASP.NET Core.

Servers

An ASP.NET Core app uses an HTTP server implementation to listen for HTTP requests. The server surfaces requests to the app as a set of request features composed into an `HttpContext`.

- Windows
- macOS
- Linux

ASP.NET Core provides the following server implementations:

- *Kestrel* is a cross-platform web server. Kestrel is often run in a reverse proxy configuration using IIS. In ASP.NET Core 2.0 or later, Kestrel can be run as a public-facing edge server exposed directly to the Internet.
- *IIS HTTP Server* is a server for Windows that uses IIS. With this server, the ASP.NET Core app and IIS run in the same process.
- *HTTP.sys* is a server for Windows that isn't used with IIS.

For more information, see Web server implementations in ASP.NET Core.

Configuration

ASP.NET Core provides a configuration framework that gets settings as name-value pairs from an ordered set of configuration providers. Built-in configuration providers are available for a variety of sources, such as *.json* files, *.xml* files, environment variables, and command-line arguments. Write custom configuration providers to support other sources.

By default, ASP.NET Core apps are configured to read from *appsettings.json*, environment variables, the command line, and more. When the app's configuration is loaded, values from environment variables override values from *appsettings.json*.

The preferred way to read related configuration values is using the options pattern. For more information, see Bind hierarchical configuration data using the options pattern.

For managing confidential configuration data such as passwords, ASP.NET Core provides the Secret Manager. For production secrets, we recommend Azure Key Vault.

For more information, see Configuration in ASP.NET Core.

Environments

Execution environments, such as `Development`, `Staging`, and `Production`, are a first-class notion in ASP.NET Core. Specify the environment an app is running in by setting the `ASPNETCORE_ENVIRONMENT` environment variable. ASP.NET Core reads that environment variable at app startup and stores the value in an `IWebHostEnvironment` implementation. This implementation is available anywhere in an app via dependency injection (DI).

The following example configures the app to provide detailed error information when running in the `Development` environment:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapDefaultControllerRoute();
        endpoints.MapRazorPages();
    });
}
```

For more information, see Use multiple environments in ASP.NET Core.

Logging

ASP.NET Core supports a logging API that works with a variety of built-in and third-party logging providers. Available providers include:

- Console
- Debug
- Event Tracing on Windows
- Windows Event Log
- TraceSource
- Azure App Service
- Azure Application Insights

To create logs, resolve an ILogger<TCategoryName> service from dependency injection (DI) and call logging methods such as LogInformation. For example:

```
public class TodoController : ControllerBase
{
    private readonly ILogger _logger;

    public TodoController(ILogger<TodoController> logger)
    {
        _logger = logger;
    }

    [HttpGet("{id}", Name = "GetTodo")]
    public ActionResult<TodoItem> GetById(string id)
    {
        _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);

        // Item lookup code removed.

        if (item == null)
        {
            _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
            return NotFound();
        }

        return item;
    }
}
```

Logging methods such as `LogInformation` support any number of fields. These fields are commonly used to construct a message `string`, but some logging providers send these to a data store as separate fields. This feature makes it possible for logging providers to implement semantic logging, also known as structured logging.

For more information, see Logging in .NET Core and ASP.NET Core.

Routing

A *route* is a URL pattern that is mapped to a handler. The handler is typically a Razor page, an action method in an MVC controller, or a middleware. ASP.NET Core routing gives you control over the URLs used by your app.

For more information, see Routing in ASP.NET Core.

Error handling

ASP.NET Core has built-in features for handling errors, such as:

- A developer exception page
- Custom error pages
- Static status code pages
- Startup exception handling

For more information, see Handle errors in ASP.NET Core.

Make HTTP requests

An implementation of `IHttpClientFactory` is available for creating `HttpClient` instances. The factory:

- Provides a central location for naming and configuring logical `HttpClient` instances. For example, register and configure a *github* client for accessing GitHub. Register and configure a default client for other purposes.
- Supports registration and chaining of multiple delegating handlers to build an outgoing request middleware pipeline. This pattern is similar to ASP.NET Core's inbound middleware pipeline. The pattern provides a mechanism to manage cross-cutting concerns for HTTP requests, including caching, error handling,

serialization, and logging.

- Integrates with *Polly*, a popular third-party library for transient fault handling.
- Manages the pooling and lifetime of underlying `HttpClientHandler` instances to avoid common DNS problems that occur when managing `HttpClient` lifetimes manually.
- Adds a configurable logging experience via ILogger for all requests sent through clients created by the factory.

For more information, see Make HTTP requests using IHttpClientFactory in ASP.NET Core.

Content root

The content root is the base path for:

- The executable hosting the app (*.exe*).
- Compiled assemblies that make up the app (*.dll*).
- Content files used by the app, such as:
  - Razor files (*.cshtml*, *.razor*)
  - Configuration files (*.json*, *.xml*)
  - Data files (*.db*)
- The Web root, typically the *wwwroot* folder.

During development, the content root defaults to the project's root directory. This directory is also the base path for both the app's content files and the Web root. Specify a different content root by setting its path when building the host. For more information, see Content root.

Web root

The web root is the base path for public, static resource files, such as:

- Stylesheets (*.css*)
- JavaScript (*.js*)
- Images (*.png*, *.jpg*)

By default, static files are served only from the web root directory and its sub-directories. The web root path defaults to *{content root}/wwwroot*. Specify a different web root by setting its path when building the host. For more information, see Web root.

Prevent publishing files in *wwwroot* with the <Content> project item in the project file. The following example prevents publishing content in *wwwroot/local* and its sub-directories:

```
<ItemGroup>
  <Content Update="wwwroot\local\**\*.*" CopyToPublishDirectory="Never" />
</ItemGroup>
```

In Razor *.cshtml* files, tilde-slash (`~/`) points to the web root. A path beginning with `~/` is referred to as a *virtual path*.

For more information, see Static files in ASP.NET Core.

This article is an overview of key topics for understanding how to develop ASP.NET Core apps.

The Startup class

The `Startup` class is where:

- Services required by the app are configured.

- The request handling pipeline is defined.

Services are components that are used by the app. For example, a logging component is a service. Code to configure (or *register*) services is added to the `Startup.ConfigureServices` method.

The request handling pipeline is composed as a series of *middleware* components. For example, a middleware might handle requests for static files or redirect HTTP requests to HTTPS. Each middleware performs asynchronous operations on an `HttpContext` and then either invokes the next middleware in the pipeline or terminates the request. Code to configure the request handling pipeline is added to the `Startup.Configure` method.

Here's a sample `Startup` class:

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

        services.AddDbContext<MovieContext>(options =>
                options.UseSqlServer(Configuration.GetConnectionString("MovieDb")));
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseMvc();
    }
}
```

For more information, see App startup in ASP.NET Core.

Dependency injection (services)

ASP.NET Core has a built-in dependency injection (DI) framework that makes configured services available to an app's classes. One way to get an instance of a service in a class is to create a constructor with a parameter of the required type. The parameter can be the service type or an interface. The DI system provides the service at runtime.

Here's a class that uses DI to get an Entity Framework Core context object. The highlighted line is an example of constructor injection:

```
public class IndexModel : PageModel
{
    private readonly RazorPagesMovieContext _context;

    public IndexModel(RazorPagesMovieContext context)
    {
        _context = context;
    }

    // ...

    public async Task OnGetAsync()
    {
        Movies = await _context.Movies.ToListAsync();
    }
}
```

While DI is built in, it's designed to let you plug in a third-party Inversion of Control (IoC) container if you prefer.

For more information, see Dependency injection in ASP.NET Core.

Middleware

The request handling pipeline is composed as a series of middleware components. Each component performs asynchronous operations on an `HttpContext` and then either invokes the next middleware in the pipeline or terminates the request.

By convention, a middleware component is added to the pipeline by invoking its `Use...` extension method in the `Startup.Configure` method. For example, to enable rendering of static files, call `UseStaticFiles`.

The highlighted code in the following example configures the request handling pipeline:

```
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

        services.AddDbContext<MovieContext>(options =>
                options.UseSqlServer(Configuration.GetConnectionString("MovieDb")));
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseMvc();
    }
}
```

ASP.NET Core includes a rich set of built-in middleware, and you can write custom middleware.

For more information, see ASP.NET Core Middleware.

Host

An ASP.NET Core app builds a *host* on startup. The host is an object that encapsulates all of the app's resources, such as:

- An HTTP server implementation
- Middleware components
- Logging
- DI
- Configuration

The main reason for including all of the app's interdependent resources in one object is lifetime management: control over app startup and graceful shutdown.

Two hosts are available: the Web Host and the Generic Host. In ASP.NET Core 2.x, the Generic Host is only for non-web scenarios.

The code to create a host is in `Program.Main`:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

The `CreateDefaultBuilder` method configures a host with commonly used options, such as the following:

- Use Kestrel as the web server and enable IIS integration.
- Load configuration from *appsettings.json*, *appsettings.{Environment Name}.json*, environment variables, command line arguments, and other configuration sources.
- Send logging output to the console and debug providers.

For more information, see ASP.NET Core Web Host.

Non-web scenarios

The Generic Host allows other types of apps to use cross-cutting framework extensions, such as logging, dependency injection (DI), configuration, and app lifetime management. For more information, see .NET Generic Host and Background tasks with hosted services in ASP.NET Core.

Servers

An ASP.NET Core app uses an HTTP server implementation to listen for HTTP requests. The server surfaces requests to the app as a set of request features composed into an `HttpContext`.

- Windows
- macOS
- Linux

ASP.NET Core provides the following server implementations:

- *Kestrel* is a cross-platform web server. Kestrel is often run in a reverse proxy configuration using IIS. Kestrel can be run as a public-facing edge server exposed directly to the Internet.
- *IIS HTTP Server* is a server for windows that uses IIS. With this server, the ASP.NET Core app and IIS run in the same process.
- *HTTP.sys* is a server for Windows that isn't used with IIS.

- Windows
- macOS
- Linux

ASP.NET Core provides the following server implementations:

- *Kestrel* is a cross-platform web server. Kestrel is often run in a reverse proxy configuration using IIS. Kestrel can be run as a public-facing edge server exposed directly to the Internet.
- *HTTP.sys* is a server for Windows that isn't used with IIS.

For more information, see Web server implementations in ASP.NET Core.

Configuration

ASP.NET Core provides a configuration framework that gets settings as name-value pairs from an ordered set of configuration providers. There are built-in configuration providers for a variety of sources, such as *.json* files, *.xml* files, environment variables, and command-line arguments. You can also write custom configuration providers.

For example, you could specify that configuration comes from *appsettings.json* and environment variables. Then when the value of *ConnectionString* is requested, the framework looks first in the *appsettings.json* file. If the value is found there but also in an environment variable, the value from the environment variable would take precedence.

For managing confidential configuration data such as passwords, ASP.NET Core provides a Secret Manager tool. For production secrets, we recommend Azure Key Vault.

For more information, see Configuration in ASP.NET Core.

Options

Where possible, ASP.NET Core follows the *options pattern* for storing and retrieving configuration values. The options pattern uses classes to represent groups of related settings.

For example, the following code sets WebSockets options:

```
var options = new WebSocketOptions
{
   KeepAliveInterval = TimeSpan.FromSeconds(120),
   ReceiveBufferSize = 4096
};

app.UseWebSockets(options);
```

For more information, see Options pattern in ASP.NET Core.

Environments

Execution environments, such as *Development*, *Staging*, and *Production*, are a first-class notion in ASP.NET Core. You can specify the environment an app is running in by setting the `ASPNETCORE_ENVIRONMENT` environment variable. ASP.NET Core reads that environment variable at app startup and stores the value in an `IHostingEnvironment` implementation. The environment object is available anywhere in the app via DI.

The following sample code from the `Startup` class configures the app to provide detailed error information only when it runs in development:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseMvc();
}
```

For more information, see Use multiple environments in ASP.NET Core.

Logging

ASP.NET Core supports a logging API that works with a variety of built-in and third-party logging providers. Available providers include the following:

- Console
- Debug
- Event Tracing on Windows
- Windows Event Log
- TraceSource
- Azure App Service
- Azure Application Insights

Write logs from anywhere in an app's code by getting an `ILogger` object from DI and calling log methods.

Here's sample code that uses an `ILogger` object, with constructor injection and the logging method calls highlighted.

```
public class TodoController : ControllerBase
{
    private readonly ILogger _logger;

    public TodoController(ILogger<TodoController> logger)
    {
        _logger = logger;
    }

    [HttpGet("{id}", Name = "GetTodo")]
    public ActionResult<TodoItem> GetById(string id)
    {
        _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);
        // Item lookup code removed.
        if (item == null)
        {
            _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
            return NotFound();
        }
        return item;
    }
}
```

The `ILogger` interface lets you pass any number of fields to the logging provider. The fields are commonly used to construct a message string, but the provider can also send them as separate fields to a data store. This feature makes it possible for logging providers to implement semantic logging, also known as structured logging.

For more information, see Logging in .NET Core and ASP.NET Core.

Routing

A *route* is a URL pattern that is mapped to a handler. The handler is typically a Razor page, an action method in an MVC controller, or a middleware. ASP.NET Core routing gives you control over the URLs used by your app.

For more information, see Routing in ASP.NET Core.

Error handling

ASP.NET Core has built-in features for handling errors, such as:

- A developer exception page

- Custom error pages
- Static status code pages
- Startup exception handling

For more information, see Handle errors in ASP.NET Core.

Make HTTP requests

An implementation of `IHttpClientFactory` is available for creating `HttpClient` instances. The factory:

- Provides a central location for naming and configuring logical `HttpClient` instances. For example, a *github* client can be registered and configured to access GitHub. A default client can be registered for other purposes.
- Supports registration and chaining of multiple delegating handlers to build an outgoing request middleware pipeline. This pattern is similar to the inbound middleware pipeline in ASP.NET Core. The pattern provides a mechanism to manage cross-cutting concerns around HTTP requests, including caching, error handling, serialization, and logging.
- Integrates with *Polly*, a popular third-party library for transient fault handling.
- Manages the pooling and lifetime of underlying `HttpClientHandler` instances to avoid common DNS problems that occur when manually managing `HttpClient` lifetimes.
- Adds a configurable logging experience (via `ILogger`) for all requests sent through clients created by the factory.

For more information, see Make HTTP requests using IHttpClientFactory in ASP.NET Core.

Content root

The content root is the base path to the:

- Executable hosting the app (*.exe*).
- Compiled assemblies that make up the app (*.dll*).
- Non-code content files used by the app, such as:
  - Razor files (*.cshtml*, *.razor*)
  - Configuration files (*.json*, *.xml*)
  - Data files (*.db*)
- Web root, typically the published *wwwroot* folder.

During development:

- The content root defaults to the project's root directory.
- The project's root directory is used to create the:
  - Path to the app's non-code content files in the project's root directory.
  - Web root, typically the *wwwroot* folder in the project's root directory.

An alternative content root path can be specified when building the host. For more information, see ASP.NET Core Web Host.

Web root

The web root is the base path to public, non-code, static resource files, such as:

- Stylesheets (*.css*)
- JavaScript (*.js*)
- Images (*.png*, *.jpg*)

Static files are only served by default from the web root directory (and sub-directories).

The web root path defaults to *{content root}/wwwroot*, but a different web root can be specified when building the host. For more information, see Web root.

Prevent publishing files in *wwwroot* with the <Content> project item in the project file. The following example prevents publishing content in the *wwwroot/local* directory and sub-directories:

```
<ItemGroup>
  <Content Update="wwwroot\local\**\*.*" CopyToPublishDirectory="Never" />
</ItemGroup>
```

In Razor (*.cshtml*) files, the tilde-slash (`~/`) points to the web root. A path beginning with `~/` is referred to as a *virtual path*.

For more information, see Static files in ASP.NET Core.

App startup in ASP.NET Core

9/22/2020 • 13 minutes to read • Edit Online

By Rick Anderson, Tom Dykstra, and Steve Smith

The `Startup` class configures services and the app's request pipeline.

The Startup class

ASP.NET Core apps use a `Startup` class, which is named `Startup` by convention. The `Startup` class:

- Optionally includes a ConfigureServices method to configure the app's *services*. A service is a reusable component that provides app functionality. Services are *registered* in `ConfigureServices` and consumed across the app via dependency injection (DI) or ApplicationServices.
- Includes a Configure method to create the app's request processing pipeline.

`ConfigureServices` and `Configure` are called by the ASP.NET Core runtime when the app starts:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

The preceding sample is for Razor Pages; the MVC version is similar.

The `Startup` class is specified when the app's host is built. The `Startup` class is typically specified by calling the WebHostBuilderExtensions.UseStartup<TStartup> method on the host builder:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The host provides services that are available to the `Startup` class constructor. The app adds additional services via `ConfigureServices`. Both the host and app services are available in `Configure` and throughout the app.

Only the following service types can be injected into the `Startup` constructor when using the Generic Host (IHostBuilder):

- IWebHostEnvironment
- IHostEnvironment
- IConfiguration

```
public class Startup
{
    private readonly IWebHostEnvironment _env;

    public Startup(IConfiguration configuration, IWebHostEnvironment env)
    {
        Configuration = configuration;
        _env = env;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        if (_env.IsDevelopment())
        {
        }
        else
        {
        }
    }
}
```

Most services are not available until the `Configure` method is called.

Multiple Startup

When the app defines separate `Startup` classes for different environments (for example, `StartupDevelopment`), the appropriate `Startup` class is selected at runtime. The class whose name suffix matches the current environment is prioritized. If the app is run in the Development environment and includes both a `Startup`

class and a `StartupDevelopment` class, the `StartupDevelopment` class is used. For more information, see Use multiple environments.

See The host for more information on the host. For information on handling errors during startup, see Startup exception handling.

The ConfigureServices method

The ConfigureServices method is:

- Optional.
- Called by the host before the `Configure` method to configure the app's services.
- Where configuration options are set by convention.

The host may configure some services before `Startup` methods are called. For more information, see The host.

For features that require substantial setup, there are `Add{Service}` extension methods on IServiceCollection. For example, **Add**DbContext, **Add**DefaultIdentity, **Add**EntityFrameworkStores, and **Add**RazorPages:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {

        services.AddDbContext<ApplicationDbContext>(options =>
            options.UseSqlServer(
                Configuration.GetConnectionString("DefaultConnection")));
        services.AddDefaultIdentity<IdentityUser>(
            options => options.SignIn.RequireConfirmedAccount = true)
            .AddEntityFrameworkStores<ApplicationDbContext>();

        services.AddRazorPages();
    }
```

Adding services to the service container makes them available within the app and in the `Configure` method. The services are resolved via dependency injection or from ApplicationServices.

The Configure method

The Configure method is used to specify how the app responds to HTTP requests. The request pipeline is configured by adding middleware components to an IApplicationBuilder instance. `IApplicationBuilder` is available to the `Configure` method, but it isn't registered in the service container. Hosting creates an `IApplicationBuilder` and passes it directly to `Configure`.

The ASP.NET Core templates configure the pipeline with support for:

- Developer Exception Page
- Exception handler
- HTTP Strict Transport Security (HSTS)
- HTTPS redirection

- Static files
- ASP.NET Core MVC and Razor Pages

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

The preceding sample is for Razor Pages; the MVC version is similar.

Each `Use` extension method adds one or more middleware components to the request pipeline. For instance, UseStaticFiles configures middleware to serve static files.

Each middleware component in the request pipeline is responsible for invoking the next component in the pipeline or short-circuiting the chain, if appropriate.

Additional services, such as `IWebHostEnvironment`, `ILoggerFactory`, or anything defined in `ConfigureServices`, can be specified in the `Configure` method signature. These services are injected if they're available.

For more information on how to use `IApplicationBuilder` and the order of middleware processing, see ASP.NET Core Middleware.

Configure services without Startup

To configure services and the request processing pipeline without using a `Startup` class, call `ConfigureServices` and `Configure` convenience methods on the host builder. Multiple calls to `ConfigureServices` append to one another. If multiple `Configure` method calls exist, the last `Configure` call is

used.

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.ConfigureServices(services =>
                {
                    services.AddControllersWithViews();
                })
                .Configure(app =>
                {
                    var loggerFactory = app.ApplicationServices
                        .GetRequiredService<ILoggerFactory>();
                    var logger = loggerFactory.CreateLogger<Program>();
                    var env = app.ApplicationServices.GetRequiredService<IWebHostEnvironment>();
                    var config = app.ApplicationServices.GetRequiredService<IConfiguration>();

                    logger.LogInformation("Logged in Configure");

                    if (env.IsDevelopment())
                    {
                        app.UseDeveloperExceptionPage();
                    }
                    else
                    {
                        app.UseExceptionHandler("/Home/Error");
                        app.UseHsts();
                    }

                    var configValue = config["MyConfigKey"];
                });
            });
        });
}
```

Extend Startup with startup filters

Use IStartupFilter:

- To configure middleware at the beginning or end of an app's Configure middleware pipeline without an explicit call to `Use{Middleware}`. `IStartupFilter` is used by ASP.NET Core to add defaults to the beginning of the pipeline without having to make the app author explicitly register the default middleware. `IStartupFilter` allows a different component call `Use{Middleware}` on behalf of the app author.
- To create a pipeline of `Configure` methods. IStartupFilter.Configure can set a middleware to run before or after middleware added by libraries.

`IStartupFilter` implements Configure, which receives and returns an `Action<IApplicationBuilder>`. An IApplicationBuilder defines a class to configure an app's request pipeline. For more information, see Create a middleware pipeline with IApplicationBuilder.

Each `IStartupFilter` can add one or more middlewares in the request pipeline. The filters are invoked in the

order they were added to the service container. Filters may add middleware before or after passing control to the next filter, thus they append to the beginning or end of the app pipeline.

The following example demonstrates how to register a middleware with `IStartupFilter`. The `RequestSetOptionsMiddleware` middleware sets an options value from a query string parameter:

```
public class RequestSetOptionsMiddleware
{
    private readonly RequestDelegate _next;

    public RequestSetOptionsMiddleware( RequestDelegate next )
    {
        _next = next;
    }

    // Test with https://localhost:5001/Privacy/?option=Hello
    public async Task Invoke(HttpContext httpContext)
    {
        var option = httpContext.Request.Query["option"];

        if (!string.IsNullOrWhiteSpace(option))
        {
            httpContext.Items["option"] = WebUtility.HtmlEncode(option);
        }

        await _next(httpContext);
    }
}
```

The `RequestSetOptionsMiddleware` is configured in the `RequestSetOptionsStartupFilter` class:

```
public class RequestSetOptionsStartupFilter : IStartupFilter
{
    public Action<IApplicationBuilder> Configure(Action<IApplicationBuilder> next)
    {
        return builder =>
        {
            builder.UseMiddleware<RequestSetOptionsMiddleware>();
            next(builder);
        };
    }
}
```

The `IStartupFilter` is registered in the service container in ConfigureServices.

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
           .ConfigureAppConfiguration((hostingContext, config) =>
           {
           })
         .ConfigureWebHostDefaults(webBuilder =>
         {
             webBuilder.UseStartup<Startup>();
         })
        .ConfigureServices(services =>
        {
            services.AddTransient<IStartupFilter,
                      RequestSetOptionsStartupFilter>();
        });
}
```

When a query string parameter for `option` is provided, the middleware processes the value assignment before the ASP.NET Core middleware renders the response.

Middleware execution order is set by the order of `IStartupFilter` registrations:

- Multiple `IStartupFilter` implementations may interact with the same objects. If ordering is important, order their `IStartupFilter` service registrations to match the order that their middlewares should run.
- Libraries may add middleware with one or more `IStartupFilter` implementations that run before or after other app middleware registered with `IStartupFilter`. To invoke an `IStartupFilter` middleware before a middleware added by a library's `IStartupFilter`:
  - Position the service registration before the library is added to the service container.
  - To invoke afterward, position the service registration after the library is added.

Add configuration at startup from an external assembly

An IHostingStartup implementation allows adding enhancements to an app at startup from an external assembly outside of the app's `Startup` class. For more information, see Use hosting startup assemblies in ASP.NET Core.

The Startup class

ASP.NET Core apps use a `Startup` class, which is named `Startup` by convention. The `Startup` class:

- Optionally includes a ConfigureServices method to configure the app's *services*. A service is a reusable component that provides app functionality. Services are *registered* in `ConfigureServices` and consumed

across the app via dependency injection (DI) or ApplicationServices.

- Includes a Configure method to create the app's request processing pipeline.

`ConfigureServices` and `Configure` are called by the ASP.NET Core runtime when the app starts:

```
public class Startup
{
    // Use this method to add services to the container.
    public void ConfigureServices(IServiceCollection services)
    {
        ...
    }

    // Use this method to configure the HTTP request pipeline.
    public void Configure(IApplicationBuilder app)
    {
        ...
    }
}
```

The `Startup` class is specified when the app's host is built. The `Startup` class is typically specified by calling the WebHostBuilderExtensions.UseStartup<TStartup> method on the host builder:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

The host provides services that are available to the `Startup` class constructor. The app adds additional services via `ConfigureServices`. Both the host and app services are then available in `Configure` and throughout the app.

A common use of dependency injection into the `Startup` class is to inject:

- IHostingEnvironment to configure services by environment.
- IConfiguration to read configuration.
- ILoggerFactory to create a logger in `Startup.ConfigureServices`.

```
public class Startup
{
    private readonly IHostingEnvironment _env;
    private readonly IConfiguration _config;
    private readonly ILoggerFactory _loggerFactory;

    public Startup(IHostingEnvironment env, IConfiguration config,
        ILoggerFactory loggerFactory)
    {
        _env = env;
        _config = config;
        _loggerFactory = loggerFactory;
    }

    public void ConfigureServices(IServiceCollection services)
    {
        var logger = _loggerFactory.CreateLogger<Startup>();

        if (_env.IsDevelopment())
        {
            // Development service configuration

            logger.LogInformation("Development environment");
        }
        else
        {
            // Non-development service configuration

            logger.LogInformation("Environment: {EnvironmentName}", _env.EnvironmentName);
        }

        // Configuration is available during startup.
        // Examples:
        //   _config["key"]
        //   _config["subsection:suboption1"]
    }
}
```

Most services are not available until the `Configure` method is called.

Multiple Startup

When the app defines separate `Startup` classes for different environments (for example, `StartupDevelopment`), the appropriate `Startup` class is selected at runtime. The class whose name suffix matches the current environment is prioritized. If the app is run in the Development environment and includes both a `Startup` class and a `StartupDevelopment` class, the `StartupDevelopment` class is used. For more information, see Use multiple environments.

See The host for more information on the host. For information on handling errors during startup, see Startup exception handling.

The ConfigureServices method

The ConfigureServices method is:

- Optional.
- Called by the host before the `Configure` method to configure the app's services.
- Where configuration options are set by convention.

The host may configure some services before `Startup` methods are called. For more information, see The host.

For features that require substantial setup, there are `Add{Service}` extension methods on IServiceCollection. For example, **Add**DbContext, **Add**DefaultIdentity, **Add**EntityFrameworkStores, and **Add**RazorPages:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>()
        .AddDefaultUI(UIFramework.Bootstrap4)
        .AddEntityFrameworkStores<ApplicationDbContext>();

    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    // Add application services.
    services.AddTransient<IEmailSender, AuthMessageSender>();
    services.AddTransient<ISmsSender, AuthMessageSender>();
}
```

Adding services to the service container makes them available within the app and in the `Configure` method. The services are resolved via dependency injection or from ApplicationServices.

See SetCompatibilityVersion for more information on `SetCompatibilityVersion`.

The Configure method

The Configure method is used to specify how the app responds to HTTP requests. The request pipeline is configured by adding middleware components to an IApplicationBuilder instance. `IApplicationBuilder` is available to the `Configure` method, but it isn't registered in the service container. Hosting creates an `IApplicationBuilder` and passes it directly to `Configure`.

The ASP.NET Core templates configure the pipeline with support for:

- Developer Exception Page
- Exception handler
- HTTP Strict Transport Security (HSTS)
- HTTPS redirection
- Static files
- ASP.NET Core MVC and Razor Pages
- General Data Protection Regulation (GDPR)

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();

    app.UseMvc();
}
```

Each `Use` extension method adds one or more middleware components to the request pipeline. For instance, UseStaticFiles configures middleware to serve static files.

Each middleware component in the request pipeline is responsible for invoking the next component in the pipeline or short-circuiting the chain, if appropriate.

Additional services, such as `IHostingEnvironment` and `ILoggerFactory`, or anything defined in `ConfigureServices`, can be specified in the `Configure` method signature. These services are injected if they're available.

For more information on how to use `IApplicationBuilder` and the order of middleware processing, see ASP.NET Core Middleware.

Configure services without Startup

To configure services and the request processing pipeline without using a `Startup` class, call `ConfigureServices` and `Configure` convenience methods on the host builder. Multiple calls to `ConfigureServices` append to one another. If multiple `Configure` method calls exist, the last `Configure` call is used.

```
public class Program
{
    public static IHostingEnvironment HostingEnvironment { get; set; }
    public static IConfiguration Configuration { get; set; }

    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
            })
            .ConfigureServices(services =>
            {
                ...
            })
            .Configure(app =>
            {
                var loggerFactory = app.ApplicationServices
                    .GetRequiredService<ILoggerFactory>();
                var logger = loggerFactory.CreateLogger<Program>();
                var env = app.ApplicationServices.GetRequiredService<IHostingEnvironment>();
                var config = app.ApplicationServices.GetRequiredService<IConfiguration>();

                logger.LogInformation("Logged in Configure");

                if (env.IsDevelopment())
                {
                    ...
                }
                else
                {
                    ...
                }

                var configValue = config["subsection:suboption1"];

                ...
            });
}
```

Extend Startup with startup filters

Use IStartupFilter:

- To configure middleware at the beginning or end of an app's Configure middleware pipeline without an explicit call to `Use{Middleware}`. `IStartupFilter` is used by ASP.NET Core to add defaults to the beginning of the pipeline without having to make the app author explicitly register the default middleware. `IStartupFilter` allows a different component call `Use{Middleware}` on behalf of the app author.
- To create a pipeline of `Configure` methods. IStartupFilter.Configure can set a middleware to run before or after middleware added by libraries.

`IStartupFilter` implements Configure, which receives and returns an `Action<IApplicationBuilder>`. An IApplicationBuilder defines a class to configure an app's request pipeline. For more information, see Create a middleware pipeline with IApplicationBuilder.

Each `IStartupFilter` can add one or more middlewares in the request pipeline. The filters are invoked in the order they were added to the service container. Filters may add middleware before or after passing control to the next filter, thus they append to the beginning or end of the app pipeline.

The following example demonstrates how to register a middleware with `IStartupFilter`. The `RequestSetOptionsMiddleware` middleware sets an options value from a query string parameter:

```
public class RequestSetOptionsMiddleware
{
    private readonly RequestDelegate _next;
    private IOptions<AppOptions> _injectedOptions;

    public RequestSetOptionsMiddleware(
        RequestDelegate next, IOptions<AppOptions> injectedOptions)
    {
        _next = next;
        _injectedOptions = injectedOptions;
    }

    public async Task Invoke(HttpContext httpContext)
    {
        Console.WriteLine("RequestSetOptionsMiddleware.Invoke");

        var option = httpContext.Request.Query["option"];

        if (!string.IsNullOrWhiteSpace(option))
        {
            _injectedOptions.Value.Option = WebUtility.HtmlEncode(option);
        }

        await _next(httpContext);
    }
}
```

The `RequestSetOptionsMiddleware` is configured in the `RequestSetOptionsStartupFilter` class:

```
public class RequestSetOptionsStartupFilter : IStartupFilter
{
    public Action<IApplicationBuilder> Configure(Action<IApplicationBuilder> next)
    {
        return builder =>
        {
            builder.UseMiddleware<RequestSetOptionsMiddleware>();
            next(builder);
        };
    }
}
```

The `IStartupFilter` is registered in the service container in ConfigureServices.

```
WebHost.CreateDefaultBuilder(args)
    .ConfigureServices(services =>
    {
        services.AddTransient<IStartupFilter,
            RequestSetOptionsStartupFilter>();
    })
    .UseStartup<Startup>()
    .Build();
```

When a query string parameter for `option` is provided, the middleware processes the value assignment before the ASP.NET Core middleware renders the response.

Middleware execution order is set by the order of `IStartupFilter` registrations:

- Multiple `IStartupFilter` implementations may interact with the same objects. If ordering is important,

order their `IStartupFilter` service registrations to match the order that their middlewares should run.

- Libraries may add middleware with one or more `IStartupFilter` implementations that run before or after other app middleware registered with `IStartupFilter`. To invoke an `IStartupFilter` middleware before a middleware added by a library's `IStartupFilter`:
  - Position the service registration before the library is added to the service container.
  - To invoke afterward, position the service registration after the library is added.

Add configuration at startup from an external assembly

An IHostingStartup implementation allows adding enhancements to an app at startup from an external assembly outside of the app's `Startup` class. For more information, see Use hosting startup assemblies in ASP.NET Core.

Dependency injection in ASP.NET Core

9/22/2020 • 40 minutes to read • Edit Online

By Kirk Larkin, Steve Smith, Scott Addie, and Brandon Dahler

ASP.NET Core supports the dependency injection (DI) software design pattern, which is a technique for achieving Inversion of Control (IoC) between classes and their dependencies.

For more information specific to dependency injection within MVC controllers, see Dependency injection into controllers in ASP.NET Core.

For more information on dependency injection of options, see Options pattern in ASP.NET Core.

View or download sample code (how to download)

Overview of dependency injection

A *dependency* is an object that another object depends on. Examine the following `MyDependency` class with a `WriteMessage` method that other classes depend on:

```
public class MyDependency
{
    public void WriteMessage(string message)
    {
        Console.WriteLine($"MyDependency.WriteMessage called. Message:
{message}");
    }
}
```

A class can create an instance of the `MyDependency` class to make use of its `WriteMessage` method. In the following example, the `MyDependency` class is a dependency of the `IndexModel` class:

```
public class IndexModel : PageModel
{
    private readonly MyDependency _dependency = new MyDependency();

    public void OnGet()
    {
        _dependency.WriteMessage("IndexModel.OnGet created this message.");
    }
}
```

The class creates and directly depends on the `MyDependency` class. Code dependencies, such as in the previous example, are problematic and should be avoided for the following reasons:

- To replace `MyDependency` with a different implementation, the `IndexModel` class must be modified.
- If `MyDependency` has dependencies, they must also be configured by the `IndexModel` class. In a large project with multiple classes depending on

`MyDependency`, the configuration code becomes scattered across the app.

- This implementation is difficult to unit test. The app should use a mock or stub `MyDependency` class, which isn't possible with this approach.

Dependency injection addresses these problems through:

- The use of an interface or base class to abstract the dependency implementation.
- Registration of the dependency in a service container. ASP.NET Core provides a built-in service container, IServiceProvider. Services are typically registered in the app's `Startup.ConfigureServices` method.
- *Injection* of the service into the constructor of the class where it's used. The framework takes on the responsibility of creating an instance of the dependency and disposing of it when it's no longer needed.

In the sample app, the `IMyDependency` interface defines the `WriteMessage` method:

```
public interface IMyDependency
{
    void WriteMessage(string message);
}
```

This interface is implemented by a concrete type, `MyDependency`:

```
public class MyDependency : IMyDependency
{
    public void WriteMessage(string message)
    {
        Console.WriteLine($"MyDependency.WriteMessage Message: {message}");
    }
}
```

The sample app registers the `IMyDependency` service with the concrete type `MyDependency`. The AddScoped method registers the service with a scoped lifetime, the lifetime of a single request. Service lifetimes are described later in this topic.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddScoped<IMyDependency, MyDependency>();

    services.AddRazorPages();
}
```

In the sample app, the `IMyDependency` service is requested and used to call the `WriteMessage` method:

```
public class Index2Model : PageModel
{
    private readonly IMyDependency _myDependency;

    public Index2Model(IMyDependency myDependency)
    {
        _myDependency = myDependency;
    }

    public void OnGet()
    {
        _myDependency.WriteMessage("Index2Model.OnGet");
    }
}
```

By using the DI pattern, the controller:

- Doesn't use the concrete type `MyDependency`, only the `IMyDependency` interface it implements. That makes it easy to change the implementation that the controller uses without modifying the controller.
- Doesn't create an instance of `MyDependency`, it's created by the DI container.

The implementation of the `IMyDependency` interface can be improved by using the built-in logging API:

```
public class MyDependency2 : IMyDependency
{
    private readonly ILogger<MyDependency2> _logger;

    public MyDependency2(ILogger<MyDependency2> logger)
    {
        _logger = logger;
    }

    public void WriteMessage(string message)
    {
        _logger.LogInformation( $"MyDependency2.WriteMessage Message: {message}");
    }
}
```

The updated `ConfigureServices` method registers the new `IMyDependency` implementation:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddScoped<IMyDependency, MyDependency2>();

    services.AddRazorPages();
}
```

`MyDependency2` depends on ILogger<TCategoryName>, which it requests in the constructor. `ILogger<TCategoryName>` is a framework-provided service.

It's not unusual to use dependency injection in a chained fashion. Each requested dependency in turn requests its own dependencies. The container resolves the dependencies in the graph and returns the fully resolved service. The collective set of dependencies that must be resolved is typically referred to as a *dependency tree*, *dependency graph*, or *object graph*.

The container resolves `ILogger<TCategoryName>` by taking advantage of (generic) open types, eliminating the need to register every (generic) constructed type.

In dependency injection terminology, a service:

- Is typically an object that provides a service to other objects, such as the `IMyDependency` service.
- Is not related to a web service, although the service may use a web service.

The framework provides a robust logging system. The `IMyDependency` implementations shown in the preceding examples were written to demonstrate basic DI, not to implement logging. Most apps shouldn't need to write loggers. The following code demonstrates using the default logging, which doesn't require any services to be registered in `ConfigureServices`:

```
public class AboutModel : PageModel
{
    private readonly ILogger _logger;

    public AboutModel(ILogger<AboutModel> logger)
    {
        _logger = logger;
    }

    public string Message { get; set; }

    public void OnGet()
    {
        Message = $"About page visited at {DateTime.UtcNow.ToLongTimeString()}";
        _logger.LogInformation(Message);
    }
}
```

Using the preceding code, there is no need to update `ConfigureServices`, because logging is provided by the framework.

Services injected into Startup

Services can be injected into the `Startup` constructor and the `Startup.Configure` method.

Only the following services can be injected into the `Startup` constructor when using the Generic Host (IHostBuilder):

- IWebHostEnvironment
- IHostEnvironment
- IConfiguration

Any service registered with the DI container can be injected into the `Startup.Configure` method:

```
public void Configure(IApplicationBuilder app, ILogger<Startup> logger)
{
    ...
}
```

For more information, see App startup in ASP.NET Core and Access configuration in Startup.

Register groups of services with extension methods

The ASP.NET Core framework uses a convention for registering a group of related services. The convention is to use a single `Add{GROUP_NAME}` extension method to register all of the services required by a framework feature. For example, the <Microsoft.Extensions.DependencyInjection.MvcServiceCollectionExtensions.AddControllers> extension method registers the services required for MVC controllers.

The following code is generated by the Razor Pages template using individual user accounts and shows how to add additional services to the container using the extension methods AddDbContext and AddDefaultIdentity:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<ApplicationDbContext>(options =>
        options.UseSqlServer(
            Configuration.GetConnectionString("DefaultConnection")));
    services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
        .AddEntityFrameworkStores<ApplicationDbContext>();
    services.AddRazorPages();
}
```

Consider the following `ConfigureServices` method, which registers services and configures options:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<PositionOptions>(
        Configuration.GetSection(PositionOptions.Position));
    services.Configure<ColorOptions>(
        Configuration.GetSection(ColorOptions.Color));

    services.AddScoped<IMyDependency, MyDependency>();
    services.AddScoped<IMyDependency2, MyDependency2>();

    services.AddRazorPages();
}
```

Related groups of registrations can be moved to an extension method to register services. For example, the configuration services are added to the following class:

```
using ConfigSample.Options;
using Microsoft.Extensions.Configuration;

namespace Microsoft.Extensions.DependencyInjection
{
    public static class MyConfigServiceCollectionExtensions
    {
        public static IServiceCollection AddConfig(
             this IServiceCollection services, IConfiguration config)
        {
            services.Configure<PositionOptions>(
                config.GetSection(PositionOptions.Position));
            services.Configure<ColorOptions>(
                config.GetSection(ColorOptions.Color));

            return services;
        }
    }
}
```

The remaining services are registered in a similar class. The following `ConfigureServices` method uses the new extension methods to register the services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddConfig(Configuration)
            .AddMyDependencyGroup();

    services.AddRazorPages();
}
```

Note: Each `services.Add{GROUP_NAME}` extension method adds and potentially configures services. For example, AddControllersWithViews adds the services MVC controllers with views require, and AddRazorPages adds the services Razor Pages requires. We recommended that apps follow this naming convention. Place extension methods in the Microsoft.Extensions.DependencyInjection namespace to encapsulate groups of service registrations.

Service lifetimes

Services can be registered with one of the following lifetimes:

- Transient
- Scoped
- Singleton

The following sections describe each of the preceding lifetimes. Choose an appropriate lifetime for each registered service.

Transient

Transient lifetime services are created each time they're requested from the service container. This lifetime works best for lightweight, stateless services. Register transient services with AddTransient.

In apps that process requests, transient services are disposed at the end of the request.

Scoped

Scoped lifetime services are created once per client request (connection). Register scoped services with AddScoped.

In apps that process requests, scoped services are disposed at the end of the request.

When using Entity Framework Core, the AddDbContext extension method registers `DbContext` types with a scoped lifetime by default.

Do ***not*** resolve a scoped service from a singleton. It may cause the service to have incorrect state when processing subsequent requests. It's fine to:

- Resolve a singleton service from a scoped or transient service.
- Resolve a scoped service from another scoped or transient service.

By default, in the development environment, resolving a service from another service with a longer lifetime throws an exception. For more information, see Scope validation.

To use scoped services in middleware, use one of the following approaches:

- Inject the service into the middleware's `Invoke` or `InvokeAsync` method. Using constructor injection throws a runtime exception because it forces the scoped service to behave like a singleton. The sample in the Lifetime and registration options section demonstrates the `InvokeAsync` approach.
- Use Factory-based middleware. Middleware registered using this approach is activated per client request (connection), which allows scoped services to be injected into the middleware's `InvokeAsync` method.

For more information, see Write custom ASP.NET Core middleware.

Singleton

Singleton lifetime services are created either:

- The first time they're requested.
- By the developer, when providing an implementation instance directly to the container. This approach is rarely needed.

Every subsequent request uses the same instance. If the app requires singleton behavior, allow the service container to manage the service's lifetime. Don't implement the singleton design pattern and provide code to dispose of the singleton. Services should never be disposed by code that resolved the service from the container. If a type or factory is registered as a singleton, the container disposes the singleton automatically.

Register singleton services with AddSingleton. Singleton services must be thread safe and are often used in stateless services.

In apps that process requests, singleton services are disposed when the ServiceProvider is disposed on application shutdown. Because memory is not released until the app is shut down, consider memory use with a singleton service.

> **WARNING**
> Do ***not*** resolve a scoped service from a singleton. It may cause the service to have incorrect state when processing subsequent requests. It's fine to resolve a singleton service from a scoped or transient service.

Service registration methods

The framework provides service registration extension methods that are useful in specific scenarios:

METHOD	AUTOMATIC OBJECT DISPOSAL	MULTIPLE IMPLEMENTATIONS	PASS ARGS
`Add{LIFETIME}<{SERVICE}, {IMPLEMENTATION}>()` Example: `services.AddSingleton<IMyDep, MyDep>();`	Yes	Yes	No
`Add{LIFETIME}<{SERVICE}>(sp => new {IMPLEMENTATION})` Examples: `services.AddSingleton<IMyDep>(sp => new MyDep());` `services.AddSingleton<IMyDep>(sp => new MyDep(99));`	Yes	Yes	Yes
`Add{LIFETIME}<{IMPLEMENTATION}>()` Example: `services.AddSingleton<MyDep>();`	Yes	No	No
`AddSingleton<{SERVICE}>(new {IMPLEMENTATION})` Examples: `services.AddSingleton<IMyDep>(new MyDep());` `services.AddSingleton<IMyDep>(new MyDep(99));`	No	Yes	Yes
`AddSingleton(new {IMPLEMENTATION})` Examples: `services.AddSingleton(new MyDep());` `services.AddSingleton(new MyDep(99));`	No	No	Yes

For more information on type disposal, see the Disposal of services section. It's common to use multiple implementations when mocking types for testing.

The framework also provides `TryAdd{LIFETIME}` extension methods, which register the service only if there isn't already an implementation registered.

In the following example, the call to `AddSingleton` registers `MyDependency` as an implementation for `IMyDependency`. The call to `TryAddSingleton` has no effect because `IMyDependency` already has a registered implementation:

```
services.AddSingleton<IMyDependency, MyDependency>();
// The following line has no effect:
services.TryAddSingleton<IMyDependency, DifferentDependency>();
```

For more information, see:

- TryAdd
- TryAddTransient
- TryAddScoped
- TryAddSingleton

The TryAddEnumerable(ServiceDescriptor) methods register the service only if there isn't already an implementation *of the same type*. Multiple services are resolved via `IEnumerable<{SERVICE}>`. When registering services, the developer should add an instance if one of the same type hasn't already been added. Generally, library authors use `TryAddEnumerable` to avoid registering multiple copies of an implementation in the container.

In the following example, the first call to `TryAddEnumerable` registers `MyDependency` as an implementation for `IMyDependency1`. The second call registers `MyDependency` for `IMyDependency2`. The third call has no effect because `IMyDependency1` already has a registered implementation of `MyDependency`:

```
public interface IMyDependency1 { }
public interface IMyDependency2 { }

public class MyDependency : IMyDependency1, IMyDependency2 { }

services.TryAddEnumerable(ServiceDescriptor.Singleton<IMyDependency1,
MyDependency>());
services.TryAddEnumerable(ServiceDescriptor.Singleton<IMyDependency2,
MyDependency>());
services.TryAddEnumerable(ServiceDescriptor.Singleton<IMyDependency1,
MyDependency>());
```

Service registration is generally order independent except when registering multiple implementations of the same type.

`IServiceCollection` is a collection of ServiceDescriptor objects. The following example shows how to register a service by creating and adding a `ServiceDescriptor`:

```
var myKey = Configuration["MyKey"];
var descriptor = new ServiceDescriptor(
    typeof(IMyDependency),
    sp => new MyDependency5(myKey),
    ServiceLifetime.Transient);

services.Add(descriptor);
```

The built-in `Add{LIFETIME}` methods use the same approach. For example, see the AddScoped source code.

Constructor injection behavior

Services can be resolved by using:

- IServiceProvider

- ActivatorUtilities:
  - Creates objects that aren't registered in the container.
  - Used with framework features, such as Tag Helpers, MVC controllers, and model binders.

Constructors can accept arguments that aren't provided by dependency injection, but the arguments must assign default values.

When services are resolved by `IServiceProvider` or `ActivatorUtilities`, constructor injection requires a *public* constructor.

When services are resolved by `ActivatorUtilities`, constructor injection requires that only one applicable constructor exists. Constructor overloads are supported, but only one overload can exist whose arguments can all be fulfilled by dependency injection.

Entity Framework contexts

By default, Entity Framework contexts are added to the service container using the scoped lifetime because web app database operations are normally scoped to the client request. To use a different lifetime, specify the lifetime by using an AddDbContext overload. Services of a given lifetime shouldn't use a database context with a lifetime that's shorter than the service's lifetime.

Lifetime and registration options

To demonstrate the difference between service lifetimes and their registration options, consider the following interfaces that represent a task as an operation with an identifier, `OperationId`. Depending on how the lifetime of an operation's service is configured for the following interfaces, the container provides either the same or different instances of the service when requested by a class:

```
public interface IOperation
{
    string OperationId { get; }
}

public interface IOperationTransient : IOperation { }
public interface IOperationScoped : IOperation { }
public interface IOperationSingleton : IOperation { }
```

The following `Operation` class implements all of the preceding interfaces. The `Operation` constructor generates a GUID and stores the last 4 characters in the `OperationId` property:

```
public class Operation : IOperationTransient, IOperationScoped,
IOperationSingleton
{
    public Operation()
    {
        OperationId = Guid.NewGuid().ToString()[^4..];
    }

    public string OperationId { get; }
}
```

The `Startup.ConfigureServices` method creates multiple registrations of the

`Operation` class according to the named lifetimes:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddTransient<IOperationTransient, Operation>();
    services.AddScoped<IOperationScoped, Operation>();
    services.AddSingleton<IOperationSingleton, Operation>();

    services.AddRazorPages();
}
```

The sample app demonstrates object lifetimes both within and between requests. The `IndexModel` and the middleware request each kind of `IOperation` type and log the `OperationId` for each:

```
public class IndexModel : PageModel
{
    private readonly ILogger _logger;
    private readonly IOperationTransient _transientOperation;
    private readonly IOperationSingleton _singletonOperation;
    private readonly IOperationScoped _scopedOperation;

    public IndexModel(ILogger<IndexModel> logger,
                      IOperationTransient transientOperation,
                      IOperationScoped scopedOperation,
                      IOperationSingleton singletonOperation)
    {
        _logger = logger;
        _transientOperation = transientOperation;
        _scopedOperation    = scopedOperation;
        _singletonOperation = singletonOperation;
    }

    public void  OnGet()
    {
        _logger.LogInformation("Transient: " + _transientOperation.OperationId);
        _logger.LogInformation("Scoped: "    + _scopedOperation.OperationId);
        _logger.LogInformation("Singleton: " + _singletonOperation.OperationId);
    }
}
```

Similar to the `IndexModel`, the middleware resolves the same services:

```
public class MyMiddleware
{
    private readonly RequestDelegate _next;
    private readonly ILogger _logger;

    private readonly IOperationTransient _transientOperation;
    private readonly IOperationSingleton _singletonOperation;

    public MyMiddleware(RequestDelegate next, ILogger<MyMiddleware> logger,
        IOperationTransient transientOperation,
        IOperationSingleton singletonOperation)
    {
        _logger = logger;
        _transientOperation = transientOperation;
        _singletonOperation = singletonOperation;
        _next = next;
    }

    public async Task InvokeAsync(HttpContext context,
        IOperationScoped scopedOperation)
    {
        _logger.LogInformation("Transient: " + _transientOperation.OperationId);
        _logger.LogInformation("Scoped: "    + scopedOperation.OperationId);
        _logger.LogInformation("Singleton: " + _singletonOperation.OperationId);

        await _next(context);
    }
}

public static class MyMiddlewareExtensions
{
    public static IApplicationBuilder UseMyMiddleware(this IApplicationBuilder
builder)
    {
        return builder.UseMiddleware<MyMiddleware>();
    }
}
```

Scoped services must be resolved in the `InvokeAsync` method:

```
public async Task InvokeAsync(HttpContext context,
    IOperationScoped scopedOperation)
{
    _logger.LogInformation("Transient: " + _transientOperation.OperationId);
    _logger.LogInformation("Scoped: "    + scopedOperation.OperationId);
    _logger.LogInformation("Singleton: " + _singletonOperation.OperationId);

    await _next(context);
}
```

The logger output shows:

- *Transient* objects are always different. The transient `OperationId` value is different in the `IndexModel` and in the middleware.
- *Scoped* objects are the same for each request but different across each request.
- *Singleton* objects are the same for every request.

To reduce the logging output, set "Logging:LogLevel:Microsoft:Error" in the *appsettings.Development.json* file:

```
{
  "MyKey": "MyKey from appsettings.Developement.json",
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "System": "Debug",
      "Microsoft": "Error"
    }
  }
}
```

Call services from main

Create an IServiceScope with IServiceScopeFactory.CreateScope to resolve a scoped service within the app's scope. This approach is useful to access a scoped service at startup to run initialization tasks.

The following example shows how to access the scoped `IMyDependency` service and call its `WriteMessage` method in `Program.Main`:

```
public class Program
{
    public static void Main(string[] args)
    {
        var host = CreateHostBuilder(args).Build();

        using (var serviceScope = host.Services.CreateScope())
        {
            var services = serviceScope.ServiceProvider;

            try
            {
                var myDependency = services.GetRequiredService<IMyDependency>();
                myDependency.WriteMessage("Call services from main");
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();
                logger.LogError(ex, "An error occurred.");
            }
        }

        host.Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

Scope validation

When the app runs in the Development environment and calls CreateDefaultBuilder to build the host, the default service provider performs checks to verify that:

- Scoped services aren't resolved from the root service provider.
- Scoped services aren't injected into singletons.

The root service provider is created when BuildServiceProvider is called. The root service provider's lifetime corresponds to the app's lifetime when the provider starts with the app and is disposed when the app shuts down.

Scoped services are disposed by the container that created them. If a scoped service is created in the root container, the service's lifetime is effectively promoted to singleton because it's only disposed by the root container when the app shuts down. Validating service scopes catches these situations when `BuildServiceProvider` is called.

For more information, see Scope validation.

Request Services

The services available within an ASP.NET Core request are exposed through the HttpContext.RequestServices collection. When services are requested from inside of a request, the services and their dependencies are resolved from the `RequestServices` collection.

The framework creates a scope per request and `RequestServices` exposes the scoped service provider. All scoped services are valid for as long as the request is active.

> **NOTE**
>
> Prefer requesting dependencies as constructor parameters to resolving services from the `RequestServices` collection. This results in classes that are easier to test.

Design services for dependency injection

When designing services for dependency injection:

- Avoid stateful, static classes and members. Avoid creating global state by designing apps to use singleton services instead.
- Avoid direct instantiation of dependent classes within services. Direct instantiation couples the code to a particular implementation.
- Make services small, well-factored, and easily tested.

If a class has a lot of injected dependencies, it might be a sign that the class has too many responsibilities and violates the Single Responsibility Principle (SRP). Attempt to refactor the class by moving some of its responsibilities into new classes. Keep in mind that Razor Pages page model classes and MVC controller classes should focus on UI concerns.

Disposal of services

The container calls Dispose for the IDisposable types it creates. Services resolved from the container should never be disposed by the developer. If a type or factory is registered as a singleton, the container disposes the singleton automatically.

In the following example, the services are created by the service container and disposed automatically:

```
public class Service1 : IDisposable
{
    private bool _disposed;

    public void Write(string message)
    {
```

```
        Console.WriteLine($"Service1: {message}");
    }

    public void Dispose()
    {
        if (_disposed)
            return;

        Console.WriteLine("Service1.Dispose");
        _disposed = true;
    }
}

public class Service2 : IDisposable
{
    private bool _disposed;

    public void Write(string message)
    {
        Console.WriteLine($"Service2: {message}");
    }

    public void Dispose()
    {
        if (_disposed)
            return;

        Console.WriteLine("Service2.Dispose");
        _disposed = true;
    }
}

public interface IService3
{
    public void Write(string message);
}

public class Service3 : IService3, IDisposable
{
    private bool _disposed;

    public Service3(string myKey)
    {
        MyKey = myKey;
    }

    public string MyKey { get; }

    public void Write(string message)
    {
        Console.WriteLine($"Service3: {message}, MyKey = {MyKey}");
    }

    public void Dispose()
    {
        if (_disposed)
            return;

        Console.WriteLine("Service3.Dispose");
        _disposed = true;
    }
}
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddScoped<Service1>();
    services.AddSingleton<Service2>();

    var myKey = Configuration["MyKey"];
    services.AddSingleton<IService3>(sp => new Service3(myKey));

    services.AddRazorPages();
}
```

```
public class IndexModel : PageModel
{
    private readonly Service1 _service1;
    private readonly Service2 _service2;
    private readonly IService3 _service3;

    public IndexModel(Service1 service1, Service2 service2, IService3 service3)
    {
        _service1 = service1;
        _service2 = service2;
        _service3 = service3;
    }

    public void OnGet()
    {
        _service1.Write("IndexModel.OnGet");
        _service2.Write("IndexModel.OnGet");
        _service3.Write("IndexModel.OnGet");
    }
}
```

The debug console shows the following output after each refresh of the Index page:

```
Service1: IndexModel.OnGet
Service2: IndexModel.OnGet
Service3: IndexModel.OnGet
Service1.Dispose
```

Services not created by the service container

Consider the following code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton(new Service1());
    services.AddSingleton(new Service2());

    services.AddRazorPages();
}
```

In the preceding code:

- The service instances aren't created by the service container.
- The framework doesn't dispose of the services automatically.
- The developer is responsible for disposing the services.

IDisposable guidance for Transient and shared instances

Transient, limited lifetime

Scenario

The app requires an IDisposable instance with a transient lifetime for either of the following scenarios:

- The instance is resolved in the root scope (root container).
- The instance should be disposed before the scope ends.

Solution

Use the factory pattern to create an instance outside of the parent scope. In this situation, the app would generally have a `Create` method that calls the final type's constructor directly. If the final type has other dependencies, the factory can:

- Receive an IServiceProvider in its constructor.
- Use ActivatorUtilities.CreateInstance to instantiate the instance outside of the container, while using the container for its dependencies.

Shared instance, limited lifetime

Scenario

The app requires a shared IDisposable instance across multiple services, but the IDisposable instance should have a limited lifetime.

Solution

Register the instance with a scoped lifetime. Use IServiceScopeFactory.CreateScope to create a new IServiceScope. Use the scope's IServiceProvider to get required services. Dispose the scope when it's no longer needed.

General IDisposable guidelines

- Don't register IDisposable instances with a transient lifetime. Use the factory pattern instead.
- Don't resolve IDisposable instances with a transient or scoped lifetime in the root scope. The only exception to this is if the app creates/recreates and disposes IServiceProvider, but this isn't an ideal pattern.
- Receiving an IDisposable dependency via DI doesn't require that the receiver implement IDisposable itself. The receiver of the IDisposable dependency shouldn't call Dispose on that dependency.
- Use scopes to control the lifetimes of services. Scopes aren't hierarchical, and there's no special connection among scopes.

Default service container replacement

The built-in service container is designed to serve the needs of the framework and most consumer apps. We recommend using the built-in container unless you need a specific feature that it doesn't support, such as:

- Property injection
- Injection based on name
- Child containers
- Custom lifetime management
- `Func<T>` support for lazy initialization
- Convention-based registration

The following third-party containers can be used with ASP.NET Core apps:

- Autofac

- Dryloc
- Grace
- LightInject
- Lamar
- Stashbox
- Unity

Thread safety

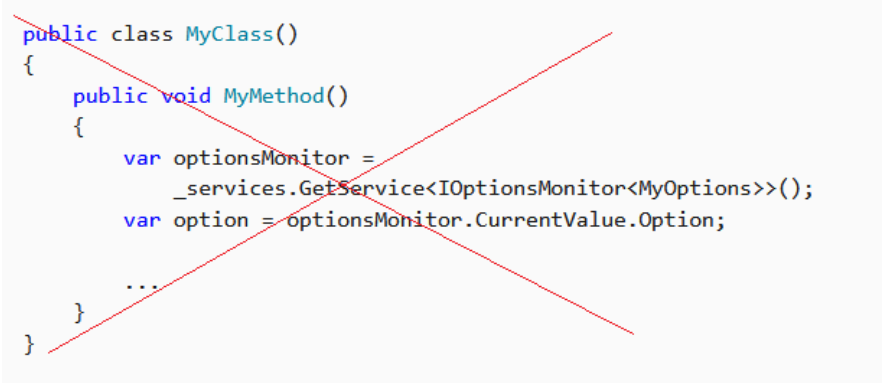
Create thread-safe singleton services. If a singleton service has a dependency on a transient service, the transient service may also require thread safety depending on how it's used by the singleton.

The factory method of single service, such as the second argument to AddSingleton<TService>(IServiceCollection, Func<IServiceProvider,TService>), doesn't need to be thread-safe. Like a type (`static`) constructor, it's guaranteed to be called only once by a single thread.

Recommendations

- `async/await` and `Task` based service resolution isn't supported. Because C# doesn't support asynchronous constructors, use asynchronous methods after synchronously resolving the service.
- Avoid storing data and configuration directly in the service container. For example, a user's shopping cart shouldn't typically be added to the service container. Configuration should use the options pattern. Similarly, avoid "data holder" objects that only exist to allow access to another object. It's better to request the actual item via DI.
- Avoid static access to services. For example, avoid capturing IApplicationBuilder.ApplicationServices as a static field or property for use elsewhere.
- Keep DI factories fast and synchronous.
- Avoid using the *service locator pattern*. For example, don't invoke GetService to obtain a service instance when you can use DI instead:

  Incorrect:



```
public class MyClass()
{
    public void MyMethod()
    {
        var optionsMonitor =
            _services.GetService<IOptionsMonitor<MyOptions>>();
        var option = optionsMonitor.CurrentValue.Option;

        ...
    }
}
```

  Correct:

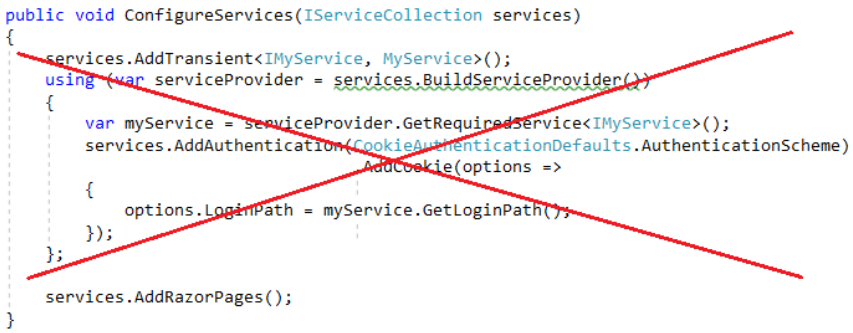
```
public class MyClass
{
    private readonly IOptionsMonitor<MyOptions> _optionsMonitor;

    public MyClass(IOptionsMonitor<MyOptions> optionsMonitor)
    {
        _optionsMonitor = optionsMonitor;
    }

    public void MyMethod()
    {
        var option = _optionsMonitor.CurrentValue.Option;

        ...
    }
}
```

- Another service locator variation to avoid is injecting a factory that resolves dependencies at runtime. Both of these practices mix Inversion of Control strategies.
- Avoid static access to `HttpContext` (for example, IHttpContextAccessor.HttpContext).
- Avoid calls to BuildServiceProvider in `ConfigureServices`. Calling `BuildServiceProvider` typically happens when the developer wants to resolve a service in `ConfigureServices`. For example, consider the case where the `LoginPath` is loaded from configuration. Avoid the following approach:



In the preceding image, selecting the green wavy line under `services.BuildServiceProvider` shows the following ASP0000 warning:

> ASP0000 Calling 'BuildServiceProvider' from application code results in an additional copy of singleton services being created. Consider alternatives such as dependency injecting services as parameters to 'Configure'.

Calling `BuildServiceProvider` creates a second container, which can create torn singletons and cause references to object graphs across multiple containers.

A correct way to get `LoginPath` is to use the options pattern's built-in support for DI:

```
public void ConfigureServices(IServiceCollection services)
{

services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationSchem
e)
        .AddCookie();

    services.AddOptions<CookieAuthenticationOptions>(
                        CookieAuthenticationDefaults.AuthenticationScheme)
        .Configure<IMyService>((options, myService) =>
        {
            options.LoginPath = myService.GetLoginPath();
        });

    services.AddRazorPages();
}
```

- Disposable transient services are captured by the container for disposal. This can turn into a memory leak if resolved from the top level container.
- Enable scope validation to make sure the app doesn't have singletons that capture scoped services. For more information, see Scope validation.

Like all sets of recommendations, you may encounter situations where ignoring a recommendation is required. Exceptions are rare, mostly special cases within the framework itself.

DI is an *alternative* to static/global object access patterns. You may not be able to realize the benefits of DI if you mix it with static object access.

Recommended patterns for multi-tenancy in DI

Orchard Core is an application framework for building modular, multi-tenant applications on ASP.NET Core. For more information, see the Orchard Core Documentation.

See the Orchard Core samples for examples of how to build modular and multi-tenant apps using just the Orchard Core Framework without any of its CMS-specific features.

Framework-provided services

The `Startup.ConfigureServices` method registers services that the app uses, including platform features, such as Entity Framework Core and ASP.NET Core MVC. Initially, the `IServiceCollection` provided to `ConfigureServices` has services defined by the framework depending on how the host was configured. For apps based on the ASP.NET Core templates, the framework registers more than 250 services.

The following table lists a small sample of these framework-registered services:

SERVICE TYPE	LIFETIME
Microsoft.AspNetCore.Hosting.Builder.IApplicationBuilderFactory	Transient
IHostApplicationLifetime	Singleton
IWebHostEnvironment	Singleton

SERVICE TYPE	LIFETIME
Microsoft.AspNetCore.Hosting.IStartup	Singleton
Microsoft.AspNetCore.Hosting.IStartupFilter	Transient
Microsoft.AspNetCore.Hosting.Server.IServer	Singleton
Microsoft.AspNetCore.Http.IHttpContextFactory	Transient
Microsoft.Extensions.Logging.ILogger<TCategoryName>	Singleton
Microsoft.Extensions.Logging.ILoggerFactory	Singleton
Microsoft.Extensions.ObjectPool.ObjectPoolProvider	Singleton
Microsoft.Extensions.Options.IConfigureOptions<TOptions>	Transient
Microsoft.Extensions.Options.IOptions<TOptions>	Singleton
System.Diagnostics.DiagnosticSource	Singleton
System.Diagnostics.DiagnosticListener	Singleton

By Steve Smith, Scott Addie, and Brandon Dahler

ASP.NET Core supports the dependency injection (DI) software design pattern, which is a technique for achieving Inversion of Control (IoC) between classes and their dependencies.

For more information specific to dependency injection within MVC controllers, see Dependency injection into controllers in ASP.NET Core.

View or download sample code (how to download)

Overview of dependency injection

A *dependency* is any object that another object requires. Examine the following `MyDependency` class with a `WriteMessage` method that other classes in an app depend upon:

```
public class MyDependency
{
    public MyDependency()
    {
    }

    public Task WriteMessage(string message)
    {
        Console.WriteLine(
            $"MyDependency.WriteMessage called. Message: {message}");

        return Task.FromResult(0);
    }
}
```

An instance of the `MyDependency` class can be created to make the `WriteMessage` method available to a class. The `MyDependency` class is a dependency of the `IndexModel` class:

```
public class IndexModel : PageModel
{
    MyDependency _dependency = new MyDependency();

    public async Task OnGetAsync()
    {
        await _dependency.WriteMessage(
            "IndexModel.OnGetAsync created this message.");
    }
}
```

The class creates and directly depends on the `MyDependency` instance. Code dependencies (such as the previous example) are problematic and should be avoided for the following reasons:

- To replace `MyDependency` with a different implementation, the class must be modified.
- If `MyDependency` has dependencies, they must be configured by the class. In a large project with multiple classes depending on `MyDependency`, the configuration code becomes scattered across the app.
- This implementation is difficult to unit test. The app should use a mock or stub `MyDependency` class, which isn't possible with this approach.

Dependency injection addresses these problems through:

- The use of an interface or base class to abstract the dependency implementation.
- Registration of the dependency in a service container. ASP.NET Core provides a built-in service container, IServiceProvider. Services are registered in the app's `Startup.ConfigureServices` method.
- *Injection* of the service into the constructor of the class where it's used. The

framework takes on the responsibility of creating an instance of the dependency and disposing of it when it's no longer needed.

In the sample app, the `IMyDependency` interface defines a method that the service provides to the app:

```
public interface IMyDependency
{
    Task WriteMessage(string message);
}
```

This interface is implemented by a concrete type, `MyDependency`:

```
public class MyDependency : IMyDependency
{
    private readonly ILogger<MyDependency> _logger;

    public MyDependency(ILogger<MyDependency> logger)
    {
        _logger = logger;
    }

    public Task WriteMessage(string message)
    {
        _logger.LogInformation(
            "MyDependency.WriteMessage called. Message: {Message}",
            message);

        return Task.FromResult(0);
    }
}
```

`MyDependency` requests an ILogger<TCategoryName> in its constructor. It's not unusual to use dependency injection in a chained fashion. Each requested dependency in turn requests its own dependencies. The container resolves the dependencies in the graph and returns the fully resolved service. The collective set of dependencies that must be resolved is typically referred to as a *dependency tree*, *dependency graph*, or *object graph*.

`IMyDependency` and `ILogger<TCategoryName>` must be registered in the service container. `IMyDependency` is registered in `Startup.ConfigureServices`. `ILogger<TCategoryName>` is registered by the logging abstractions infrastructure, so it's a framework-provided service registered by default by the framework.

The container resolves `ILogger<TCategoryName>` by taking advantage of (generic) open types, eliminating the need to register every (generic) constructed type:

```
services.AddSingleton(typeof(ILogger<>), typeof(Logger<>));
```

In the sample app, the `IMyDependency` service is registered with the concrete type `MyDependency`. The registration scopes the service lifetime to the lifetime of a single request. Service lifetimes are described later in this topic.

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddScoped<IMyDependency, MyDependency>();
    services.AddTransient<IOperationTransient, Operation>();
    services.AddScoped<IOperationScoped, Operation>();
    services.AddSingleton<IOperationSingleton, Operation>();
    services.AddSingleton<IOperationSingletonInstance>(new Operation(Guid.Empty));

    // OperationService depends on each of the other Operation types.
    services.AddTransient<OperationService, OperationService>();
}
```

NOTE

Each `services.Add{SERVICE_NAME}` extension method adds (and potentially configures) services. For example, `services.AddMvc()` adds the services Razor Pages and MVC require. We recommended that apps follow this convention. Place extension methods in the Microsoft.Extensions.DependencyInjection namespace to encapsulate groups of service registrations.

If the service's constructor requires a built in type, such as a `string`, the type can be injected by using configuration or the options pattern:

```
public class MyDependency : IMyDependency
{
    public MyDependency(IConfiguration config)
    {
        var myStringValue = config["MyStringKey"];

        // Use myStringValue
    }

    ...
}
```

An instance of the service is requested via the constructor of a class where the service is used and assigned to a private field. The field is used to access the service as necessary throughout the class.

In the sample app, the `IMyDependency` instance is requested and used to call the service's `WriteMessage` method:

```
public class IndexModel : PageModel
{
    private readonly IMyDependency _myDependency;

    public IndexModel(
        IMyDependency myDependency,
        OperationService operationService,
        IOperationTransient transientOperation,
        IOperationScoped scopedOperation,
        IOperationSingleton singletonOperation,
        IOperationSingletonInstance singletonInstanceOperation)
    {
        _myDependency = myDependency;
        OperationService = operationService;
        TransientOperation = transientOperation;
        ScopedOperation = scopedOperation;
        SingletonOperation = singletonOperation;
        SingletonInstanceOperation = singletonInstanceOperation;
    }

    public OperationService OperationService { get; }
    public IOperationTransient TransientOperation { get; }
    public IOperationScoped ScopedOperation { get; }
    public IOperationSingleton SingletonOperation { get; }
    public IOperationSingletonInstance SingletonInstanceOperation { get; }

    public async Task OnGetAsync()
    {
        await _myDependency.WriteMessage(
            "IndexModel.OnGetAsync created this message.");
    }
}
```

Services injected into Startup

Only the following service types can be injected into the `Startup` constructor when using the Generic Host (IHostBuilder):

- `IWebHostEnvironment`
- IHostEnvironment
- IConfiguration

Services can be injected into `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IOptions<MyOptions> options)
{
    ...
}
```

For more information, see App startup in ASP.NET Core.

Framework-provided services

The `Startup.ConfigureServices` method is responsible for defining the services that the app uses, including platform features, such as Entity Framework Core and ASP.NET Core MVC. Initially, the `IServiceCollection` provided to `ConfigureServices` has services defined by the framework depending on how the host was configured. It's not uncommon for an app based on an ASP.NET Core template to have hundreds of services registered by the framework. A small sample of framework-registered

services is listed in the following table.

SERVICE TYPE	LIFETIME
Microsoft.AspNetCore.Hosting.Builder.IApplicationBuilderFactory	Transient
Microsoft.AspNetCore.Hosting.IApplicationLifetime	Singleton
Microsoft.AspNetCore.Hosting.IHostingEnvironment	Singleton
Microsoft.AspNetCore.Hosting.IStartup	Singleton
Microsoft.AspNetCore.Hosting.IStartupFilter	Transient
Microsoft.AspNetCore.Hosting.Server.IServer	Singleton
Microsoft.AspNetCore.Http.IHttpContextFactory	Transient
Microsoft.Extensions.Logging.ILogger<TCategoryName>	Singleton
Microsoft.Extensions.Logging.ILoggerFactory	Singleton
Microsoft.Extensions.ObjectPool.ObjectPoolProvider	Singleton
Microsoft.Extensions.Options.IConfigureOptions<TOptions>	Transient
Microsoft.Extensions.Options.IOptions<TOptions>	Singleton
System.Diagnostics.DiagnosticSource	Singleton
System.Diagnostics.DiagnosticListener	Singleton

Register additional services with extension methods

When a service collection extension method is available to register a service (and its dependent services, if required), the convention is to use a single `Add{SERVICE_NAME}` extension method to register all of the services required by that service. The following code is an example of how to add additional services to the container using the extension methods AddDbContext<TContext> and AddIdentityCore:

```
public void ConfigureServices(IServiceCollection services)
{
    ...

    services.AddDbContext<ApplicationDbContext>(options =>

options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection")));

    services.AddIdentity<ApplicationUser, IdentityRole>()
        .AddEntityFrameworkStores<ApplicationDbContext>()
        .AddDefaultTokenProviders();

    ...
}
```

For more information, see the ServiceCollection class in the API documentation.

Service lifetimes

Choose an appropriate lifetime for each registered service. ASP.NET Core services can be configured with the following lifetimes:

Transient

Transient lifetime services (AddTransient) are created each time they're requested from the service container. This lifetime works best for lightweight, stateless services.

In apps that process requests, transient services are disposed at the end of the request.

Scoped

Scoped lifetime services (AddScoped) are created once per client request (connection).

In apps that process requests, scoped services are disposed at the end of the request.

> **WARNING**
>
> When using a scoped service in a middleware, inject the service into the `Invoke` or `InvokeAsync` method. Don't inject via constructor injection because it forces the service to behave like a singleton. For more information, see Write custom ASP.NET Core middleware.

Singleton

Singleton lifetime services (AddSingleton) are created the first time they're requested (or when `Startup.ConfigureServices` is run and an instance is specified with the service registration). Every subsequent request uses the same instance. If the app requires singleton behavior, allowing the service container to manage the service's lifetime is recommended. Don't implement the singleton design pattern and provide user code to manage the object's lifetime in the class.

In apps that process requests, singleton services are disposed when the ServiceProvider is disposed at app shutdown.

> **WARNING**
>
> It's dangerous to resolve a scoped service from a singleton. It may cause the service to have incorrect state when processing subsequent requests.

Service registration methods

Service registration extension methods offer overloads that are useful in specific scenarios.

METHOD	AUTOMATIC OBJECT DISPOSAL	MULTIPLE IMPLEMENTATIONS	PASS ARGS
`Add{LIFETIME}<{SERVICE}, {IMPLEMENTATION}>()` Example: `services.AddSingleton<IMyDep, MyDep>();`	Yes	Yes	No
`Add{LIFETIME}<{SERVICE}>(sp => new {IMPLEMENTATION})` Examples: `services.AddSingleton<IMyDep>(sp => new MyDep());` `services.AddSingleton<IMyDep>(sp => new MyDep("A string!"));`	Yes	Yes	Yes
`Add{LIFETIME}<{IMPLEMENTATION}>()` Example: `services.AddSingleton<MyDep>();`	Yes	No	No
`AddSingleton<{SERVICE}>(new {IMPLEMENTATION})` Examples: `services.AddSingleton<IMyDep>(new MyDep());` `services.AddSingleton<IMyDep>(new MyDep("A string!"));`	No	Yes	Yes
`AddSingleton(new {IMPLEMENTATION})` Examples: `services.AddSingleton(new MyDep());` `services.AddSingleton(new MyDep("A string!"));`	No	No	Yes

For more information on type disposal, see the Disposal of services section. A common scenario for multiple implementations is mocking types for testing.

`TryAdd{LIFETIME}` methods only register the service if there isn't already an implementation registered.

In the following example, the first line registers `MyDependency` for `IMyDependency`. The second line has no effect because `IMyDependency` already has a registered implementation:

```
services.AddSingleton<IMyDependency, MyDependency>();
// The following line has no effect:
services.TryAddSingleton<IMyDependency, DifferentDependency>();
```

For more information, see:

- TryAdd
- TryAddTransient
- TryAddScoped
- TryAddSingleton

TryAddEnumerable(ServiceDescriptor) methods only register the service if there isn't already an implementation *of the same type*. Multiple services are resolved via `IEnumerable<{SERVICE}>`. When registering services, the developer only wants to add an instance if one of the same type hasn't already been added. Generally, this method is used by library authors to avoid registering two copies of an instance in the container.

In the following example, the first line registers `MyDep` for `IMyDep1`. The second line registers `MyDep` for `IMyDep2`. The third line has no effect because `IMyDep1` already has a registered implementation of `MyDep`:

```
public interface IMyDep1 {}
public interface IMyDep2 {}

public class MyDep : IMyDep1, IMyDep2 {}

services.TryAddEnumerable(ServiceDescriptor.Singleton<IMyDep1, MyDep>());
services.TryAddEnumerable(ServiceDescriptor.Singleton<IMyDep2, MyDep>());
// Two registrations of MyDep for IMyDep1 is avoided by the following line:
services.TryAddEnumerable(ServiceDescriptor.Singleton<IMyDep1, MyDep>());
```

Constructor injection behavior

Services can be resolved by two mechanisms:

- IServiceProvider
- ActivatorUtilities: Permits object creation without service registration in the dependency injection container. `ActivatorUtilities` is used with user-facing abstractions, such as Tag Helpers, MVC controllers, and model binders.

Constructors can accept arguments that aren't provided by dependency injection, but the arguments must assign default values.

When services are resolved by `IServiceProvider` or `ActivatorUtilities`, constructor injection requires a *public* constructor.

When services are resolved by `ActivatorUtilities`, constructor injection requires that only one applicable constructor exists. Constructor overloads are supported, but only one overload can exist whose arguments can all be fulfilled by dependency injection.

Entity Framework contexts

Entity Framework contexts are usually added to the service container using the scoped lifetime because web app database operations are normally scoped to the client request. The default lifetime is scoped if a lifetime isn't specified by an

AddDbContext<TContext> overload when registering the database context. Services of a given lifetime shouldn't use a database context with a shorter lifetime than the service.

Lifetime and registration options

To demonstrate the difference between the lifetime and registration options, consider the following interfaces that represent tasks as an operation with a unique identifier, `OperationId`. Depending on how the lifetime of an operations service is configured for the following interfaces, the container provides either the same or a different instance of the service when requested by a class:

```
public interface IOperation
{
    Guid OperationId { get; }
}

public interface IOperationTransient : IOperation
{
}

public interface IOperationScoped : IOperation
{
}

public interface IOperationSingleton : IOperation
{
}

public interface IOperationSingletonInstance : IOperation
{
}
```

The interfaces are implemented in the `Operation` class. The `Operation` constructor generates a GUID if one isn't supplied:

```
public class Operation : IOperationTransient,
    IOperationScoped,
    IOperationSingleton,
    IOperationSingletonInstance
{
    public Operation() : this(Guid.NewGuid())
    {
    }

    public Operation(Guid id)
    {
        OperationId = id;
    }

    public Guid OperationId { get; private set; }
}
```

An `OperationService` is registered that depends on each of the other `Operation` types. When `OperationService` is requested via dependency injection, it receives either a new instance of each service or an existing instance based on the lifetime of the dependent service.

- When transient services are created when requested from the container, the `OperationId` of the `IOperationTransient` service is different than the `OperationId`

of the `OperationService`. `OperationService` receives a new instance of the `IOperationTransient` class. The new instance yields a different `OperationId`.

- When scoped services are created per client request, the `OperationId` of the `IOperationScoped` service is the same as that of `OperationService` within a client request. Across client requests, both services share a different `OperationId` value.
- When singleton and singleton-instance services are created once and used across all client requests and all services, the `OperationId` is constant across all service requests.

```
public class OperationService
{
    public OperationService(
        IOperationTransient transientOperation,
        IOperationScoped scopedOperation,
        IOperationSingleton singletonOperation,
        IOperationSingletonInstance instanceOperation)
    {
        TransientOperation = transientOperation;
        ScopedOperation = scopedOperation;
        SingletonOperation = singletonOperation;
        SingletonInstanceOperation = instanceOperation;
    }

    public IOperationTransient TransientOperation { get; }
    public IOperationScoped ScopedOperation { get; }
    public IOperationSingleton SingletonOperation { get; }
    public IOperationSingletonInstance SingletonInstanceOperation { get; }
}
```

In `Startup.ConfigureServices`, each type is added to the container according to its named lifetime:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc().SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

    services.AddScoped<IMyDependency, MyDependency>();
    services.AddTransient<IOperationTransient, Operation>();
    services.AddScoped<IOperationScoped, Operation>();
    services.AddSingleton<IOperationSingleton, Operation>();
    services.AddSingleton<IOperationSingletonInstance>(new Operation(Guid.Empty));

    // OperationService depends on each of the other Operation types.
    services.AddTransient<OperationService, OperationService>();
}
```

The `IOperationSingletonInstance` service is using a specific instance with a known ID of `Guid.Empty`. It's clear when this type is in use (its GUID is all zeroes).

The sample app demonstrates object lifetimes within and between individual requests. The sample app's `IndexModel` requests each kind of `IOperation` type and the `OperationService`. The page then displays all of the page model class's and service's `OperationId` values through property assignments:

```
public class IndexModel : PageModel
{
    private readonly IMyDependency _myDependency;

    public IndexModel(
        IMyDependency myDependency,
        OperationService operationService,
        IOperationTransient transientOperation,
        IOperationScoped scopedOperation,
        IOperationSingleton singletonOperation,
        IOperationSingletonInstance singletonInstanceOperation)
    {
        _myDependency = myDependency;
        OperationService = operationService;
        TransientOperation = transientOperation;
        ScopedOperation = scopedOperation;
        SingletonOperation = singletonOperation;
        SingletonInstanceOperation = singletonInstanceOperation;
    }

    public OperationService OperationService { get; }
    public IOperationTransient TransientOperation { get; }
    public IOperationScoped ScopedOperation { get; }
    public IOperationSingleton SingletonOperation { get; }
    public IOperationSingletonInstance SingletonInstanceOperation { get; }

    public async Task OnGetAsync()
    {
        await _myDependency.WriteMessage(
            "IndexModel.OnGetAsync created this message.");
    }
}
```

Two following output shows the results of two requests:

First request:

Controller operations:

Transient: d233e165-f417-469b-a866-1cf1935d2518
Scoped: 5d997e2d-55f5-4a64-8388-51c4e3a1ad19
Singleton: 01271bc1-9e31-48e7-8f7c-7261b040ded9
Instance: 00000000-0000-0000-0000-000000000000

`OperationService` operations:

Transient: c6b049eb-1318-4e31-90f1-eb2dd849ff64
Scoped: 5d997e2d-55f5-4a64-8388-51c4e3a1ad19
Singleton: 01271bc1-9e31-48e7-8f7c-7261b040ded9
Instance: 00000000-0000-0000-0000-000000000000

Second request:

Controller operations:

Transient: b63bd538-0a37-4ff1-90ba-081c5138dda0
Scoped: 31e820c5-4834-4d22-83fc-a60118acb9f4
Singleton: 01271bc1-9e31-48e7-8f7c-7261b040ded9
Instance: 00000000-0000-0000-0000-000000000000

`OperationService` operations:

Transient: c4cbacb8-36a2-436d-81c8-8c1b78808aaf

Scoped: 31e820c5-4834-4d22-83fc-a60118acb9f4
Singleton: 01271bc1-9e31-48e7-8f7c-7261b040ded9
Instance: 00000000-0000-0000-0000-000000000000

Observe which of the `OperationId` values vary within a request and between requests:

- *Transient* objects are always different. The transient `OperationId` value for both the first and second client requests are different for both `OperationService` operations and across client requests. A new instance is provided to each service request and client request.
- *Scoped* objects are the same within a client request but different across client requests.
- *Singleton* objects are the same for every object and every request regardless of whether an `Operation` instance is provided in `Startup.ConfigureServices`.

Call services from main

Create an IServiceScope with IServiceScopeFactory.CreateScope to resolve a scoped service within the app's scope. This approach is useful to access a scoped service at startup to run initialization tasks. The following example shows how to obtain a context for the `MyScopedService` in `Program.Main`:

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Logging;

public class Program
{
    public static async Task Main(string[] args)
    {
        var host = CreateWebHostBuilder(args).Build();

        using (var serviceScope = host.Services.CreateScope())
        {
            var services = serviceScope.ServiceProvider;

            try
            {
                var serviceContext = services.GetRequiredService<MyScopedService>
();
                // Use the context here
            }
            catch (Exception ex)
            {
                var logger = services.GetRequiredService<ILogger<Program>>();
                logger.LogError(ex, "An error occurred.");
            }
        }

        await host.RunAsync();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

Scope validation

When the app is running in the Development environment, the default service provider performs checks to verify that:

- Scoped services aren't directly or indirectly resolved from the root service provider.
- Scoped services aren't directly or indirectly injected into singletons.

The root service provider is created when BuildServiceProvider is called. The root service provider's lifetime corresponds to the app/server's lifetime when the provider starts with the app and is disposed when the app shuts down.

Scoped services are disposed by the container that created them. If a scoped service is created in the root container, the service's lifetime is effectively promoted to singleton because it's only disposed by the root container when app/server is shut down. Validating service scopes catches these situations when `BuildServiceProvider` is called.

For more information, see ASP.NET Core Web Host.

Request Services

The services available within an ASP.NET Core request from `HttpContext` are exposed through the HttpContext.RequestServices collection.

Request Services represent the services configured and requested as part of the app. When the objects specify dependencies, these are satisfied by the types found in `RequestServices`, not `ApplicationServices`.

Generally, the app shouldn't use these properties directly. Instead, request the types that classes require via class constructors and allow the framework inject the dependencies. This yields classes that are easier to test.

> **NOTE**
>
> Prefer requesting dependencies as constructor parameters to accessing the `RequestServices` collection.

Design services for dependency injection

Best practices are to:

- Design services to use dependency injection to obtain their dependencies.
- Avoid stateful, static classes and members. Design apps to use singleton services instead, which avoid creating global state.
- Avoid direct instantiation of dependent classes within services. Direct instantiation couples the code to a particular implementation.
- Make app classes small, well-factored, and easily tested.

If a class seems to have too many injected dependencies, this is generally a sign that the class has too many responsibilities and is violating the Single Responsibility Principle (SRP). Attempt to refactor the class by moving some of its responsibilities into a new class. Keep in mind that Razor Pages page model classes and MVC controller classes should focus on UI concerns. Business rules and data access implementation details should be kept in classes appropriate to these separate

concerns.

Disposal of services

The container calls Dispose for the IDisposable types it creates. If an instance is added to the container by user code, it isn't disposed automatically.

In the following example, the services are created by the service container and disposed automatically:

```
public class Service1 : IDisposable {}
public class Service2 : IDisposable {}

public interface IService3 {}
public class Service3 : IService3, IDisposable {}

public void ConfigureServices(IServiceCollection services)
{
    services.AddScoped<Service1>();
    services.AddSingleton<Service2>();
    services.AddSingleton<IService3>(sp => new Service3());
}
```

In the following example:

- The service instances aren't created by the service container.
- The intended service lifetimes aren't known by the framework.
- The framework doesn't dispose of the services automatically.
- If the services aren't explicitly disposed in developer code, they persist until the app shuts down.

```
public class Service1 : IDisposable {}
public class Service2 : IDisposable {}

public void ConfigureServices(IServiceCollection services)
{
    services.AddSingleton<Service1>(new Service1());
    services.AddSingleton(new Service2());
}
```

IDisposable guidance for Transient and shared instances

Transient, limited lifetime

Scenario

The app requires an IDisposable instance with a transient lifetime for either of the following scenarios:

- The instance is resolved in the root scope.
- The instance should be disposed before the scope ends.

Solution

Use the factory pattern to create an instance outside of the parent scope. In this situation, the app would generally have a `Create` method that calls the final type's constructor directly. If the final type has other dependencies, the factory can:

- Receive an IServiceProvider in its constructor.
- Use ActivatorUtilities.CreateInstance to instantiate the instance outside the container, while using the container for its dependencies.

Shared Instance, limited lifetime

Scenario

The app requires a shared IDisposable instance across multiple services, but the IDisposable should have a limited lifetime.

Solution

Register the instance with a Scoped lifetime. Use IServiceScopeFactory.CreateScope to start and create a new IServiceScope. Use the scope's IServiceProvider to get required services. Dispose the scope when the lifetime should end.

General Guidelines

- Don't register IDisposable instances with a Transient scope. Use the factory pattern instead.
- Don't resolve Transient or Scoped IDisposable instances in the root scope. The only general exception is when the app creates/recreates and disposes the IServiceProvider, which isn't an ideal pattern.
- Receiving an IDisposable dependency via DI doesn't require that the receiver implement IDisposable itself. The receiver of the IDisposable dependency shouldn't call Dispose on that dependency.
- Scopes should be used to control lifetimes of services. Scopes aren't hierarchical, and there's no special connection among scopes.

Default service container replacement

The built-in service container is designed to serve the needs of the framework and most consumer apps. We recommend using the built-in container unless you need a specific feature that the built-in container doesn't support, such as:

- Property injection
- Injection based on name
- Child containers
- Custom lifetime management
- `Func<T>` support for lazy initialization
- Convention-based registration

The following third-party containers can be used with ASP.NET Core apps:

- Autofac
- Dryloc
- Grace
- LightInject
- Lamar
- Stashbox
- Unity

Thread safety

Create thread-safe singleton services. If a singleton service has a dependency on a transient service, the transient service may also require thread safety depending how it's used by the singleton.

The factory method of single service, such as the second argument to AddSingleton<TService>(IServiceCollection, Func<IServiceProvider,TService>),

doesn't need to be thread-safe. Like a type (`static`) constructor, it's guaranteed to be called once by a single thread.

Recommendations

- `async/await` and `Task` based service resolution is not supported. C# does not support asynchronous constructors; therefore, the recommended pattern is to use asynchronous methods after synchronously resolving the service.
- Avoid storing data and configuration directly in the service container. For example, a user's shopping cart shouldn't typically be added to the service container. Configuration should use the options pattern. Similarly, avoid "data holder" objects that only exist to allow access to some other object. It's better to request the actual item via DI.
- Avoid static access to services. For example, avoid statically-typing IApplicationBuilder.ApplicationServices for use elsewhere.
- Avoid using the *service locator pattern*, which mixes Inversion of Control strategies.
  - Don't invoke GetService to obtain a service instance when you can use DI instead:

    Incorrect:

    ```
    public class MyClass()

      public void MyMethod()
      {
          var optionsMonitor =
              _services.GetService<IOptionsMonitor<MyOptions>>();
          var option = optionsMonitor.CurrentValue.Option;

          ...
      }
    ```

    Correct:

    ```
    public class MyClass
    {
        private readonly IOptionsMonitor<MyOptions> _optionsMonitor;

        public MyClass(IOptionsMonitor<MyOptions> optionsMonitor)
        {
            _optionsMonitor = optionsMonitor;
        }

        public void MyMethod()
        {
            var option = _optionsMonitor.CurrentValue.Option;

            ...
        }
    }
    ```

- Avoid injecting a factory that resolves dependencies at runtime using GetService.
- Avoid static access to `HttpContext` (for example,

IHttpContextAccessor.HttpContext).

Like all sets of recommendations, you may encounter situations where ignoring a recommendation is required. Exceptions are rare, mostly special cases within the framework itself.

DI is an *alternative* to static/global object access patterns. You may not be able to realize the benefits of DI if you mix it with static object access.

ASP.NET Core Middleware

9/22/2020 • 22 minutes to read • Edit Online

By Rick Anderson and Steve Smith

Middleware is software that's assembled into an app pipeline to handle requests and responses. Each component:

- Chooses whether to pass the request to the next component in the pipeline.
- Can perform work before and after the next component in the pipeline.

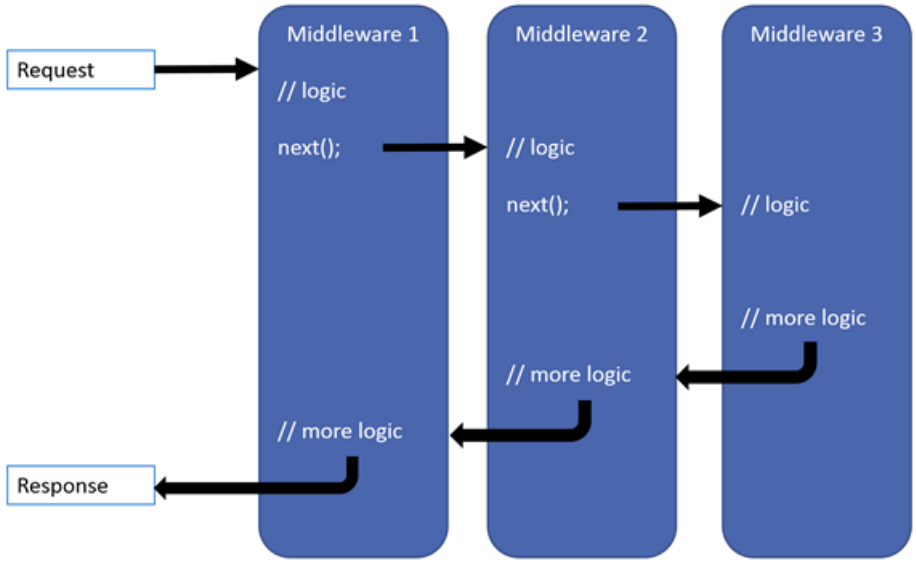
Request delegates are used to build the request pipeline. The request delegates handle each HTTP request.

Request delegates are configured using Run, Map, and Use extension methods. An individual request delegate can be specified in-line as an anonymous method (called in-line middleware), or it can be defined in a reusable class. These reusable classes and in-line anonymous methods are *middleware*, also called *middleware components*. Each middleware component in the request pipeline is responsible for invoking the next component in the pipeline or short-circuiting the pipeline. When a middleware short-circuits, it's called a *terminal middleware* because it prevents further middleware from processing the request.

Migrate HTTP handlers and modules to ASP.NET Core middleware explains the difference between request pipelines in ASP.NET Core and ASP.NET 4.x and provides additional middleware samples.

Create a middleware pipeline with IApplicationBuilder

The ASP.NET Core request pipeline consists of a sequence of request delegates, called one after the other. The following diagram demonstrates the concept. The thread of execution follows the black arrows.



Each delegate can perform operations before and after the next delegate. Exception-handling delegates should be called early in the pipeline, so they can catch exceptions that occur in later stages of the pipeline.

The simplest possible ASP.NET Core app sets up a single request delegate that handles all requests. This

case doesn't include an actual request pipeline. Instead, a single anonymous function is called in response to every HTTP request.

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello, World!");
        });
    }
}
```

Chain multiple request delegates together with Use. The `next` parameter represents the next delegate in the pipeline. You can short-circuit the pipeline by *not* calling the *next* parameter. You can typically perform actions both before and after the next delegate, as the following example demonstrates:

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.Use(async (context, next) =>
        {
            // Do work that doesn't write to the Response.
            await next.Invoke();
            // Do logging or other work that doesn't write to the Response.
        });

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from 2nd delegate.");
        });
    }
}
```

When a delegate doesn't pass a request to the next delegate, it's called *short-circuiting the request pipeline*. Short-circuiting is often desirable because it avoids unnecessary work. For example, Static File Middleware can act as a *terminal middleware* by processing a request for a static file and short-circuiting the rest of the pipeline. Middleware added to the pipeline before the middleware that terminates further processing still processes code after their `next.Invoke` statements. However, see the following warning about attempting to write to a response that has already been sent.

> **WARNING**
>
> Don't call `next.Invoke` after the response has been sent to the client. Changes to HttpResponse after the response has started throw an exception. For example, setting headers and a status code throw an exception. Writing to the response body after calling `next`:
>
> - May cause a protocol violation. For example, writing more than the stated `Content-Length`.
> - May corrupt the body format. For example, writing an HTML footer to a CSS file.
>
> HasStarted is a useful hint to indicate if headers have been sent or the body has been written to.

Run delegates don't receive a `next` parameter. The first `Run` delegate is always terminal and terminates the pipeline. `Run` is a convention. Some middleware components may expose `Run[Middleware]` methods that run at the end of the pipeline:

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.Use(async (context, next) =>
        {
            // Do work that doesn't write to the Response.
            await next.Invoke();
            // Do logging or other work that doesn't write to the Response.
        });

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from 2nd delegate.");
        });
    }
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

In the preceding example, the `Run` delegate writes `"Hello from 2nd delegate."` to the response and then terminates the pipeline. If another `Use` or `Run` delegate is added after the `Run` delegate, it's not called.

Middleware order

The following diagram shows the complete request processing pipeline for ASP.NET Core MVC and Razor Pages apps. You can see how, in a typical app, existing middlewares are ordered and where custom middlewares are added. You have full control over how to reorder existing middlewares or inject new custom middlewares as necessary for your scenarios.

The **Endpoint** middleware in the preceding diagram executes the filter pipeline for the corresponding app type—MVC or Razor Pages.

The order that middleware components are added in the `Startup.Configure` method defines the order in which the middleware components are invoked on requests and the reverse order for the response. The order is **critical** for security, performance, and functionality.

The following `Startup.Configure` method adds security-related middleware components in the recommended order:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    // app.UseCookiePolicy();

    app.UseRouting();
    // app.UseRequestLocalization();
    // app.UseCors();

    app.UseAuthentication();
    app.UseAuthorization();
    // app.UseSession();
    // app.UseResponseCaching();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
        endpoints.MapControllerRoute(
            name: "default",
            pattern: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

In the preceding code:

- Middleware that is not added when creating a new web app with individual users accounts is commented out.
- Not every middleware needs to go in this exact order, but many do. For example:
  - `UseCors`, `UseAuthentication`, and `UseAuthorization` must go in the order shown.
  - `UseCors` currently must go before `UseResponseCaching` due to this bug.

The following `Startup.Configure` method adds middleware components for common app scenarios:

1. Exception/error handling
   - When the app runs in the Development environment:
     - Developer Exception Page Middleware (UseDeveloperExceptionPage) reports app runtime errors.
     - Database Error Page Middleware reports database runtime errors.
   - When the app runs in the Production environment:
     - Exception Handler Middleware (UseExceptionHandler) catches exceptions thrown in the following middlewares.
     - HTTP Strict Transport Security Protocol (HSTS) Middleware (UseHsts) adds the `Strict-Transport-Security` header.
2. HTTPS Redirection Middleware (UseHttpsRedirection) redirects HTTP requests to HTTPS.
3. Static File Middleware (UseStaticFiles) returns static files and short-circuits further request processing.
4. Cookie Policy Middleware (UseCookiePolicy) conforms the app to the EU General Data Protection Regulation (GDPR) regulations.

5. Routing Middleware (UseRouting) to route requests.
6. Authentication Middleware (UseAuthentication) attempts to authenticate the user before they're allowed access to secure resources.
7. Authorization Middleware (UseAuthorization) authorizes a user to access secure resources.
8. Session Middleware (UseSession) establishes and maintains session state. If the app uses session state, call Session Middleware after Cookie Policy Middleware and before MVC Middleware.
9. Endpoint Routing Middleware (UseEndpoints with MapRazorPages) to add Razor Pages endpoints to the request pipeline.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();
    app.UseRouting();
    app.UseAuthentication();
    app.UseAuthorization();
    app.UseSession();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

In the preceding example code, each middleware extension method is exposed on IApplicationBuilder through the Microsoft.AspNetCore.Builder namespace.

UseExceptionHandler is the first middleware component added to the pipeline. Therefore, the Exception Handler Middleware catches any exceptions that occur in later calls.

Static File Middleware is called early in the pipeline so that it can handle requests and short-circuit without going through the remaining components. The Static File Middleware provides **no** authorization checks. Any files served by Static File Middleware, including those under *wwwroot*, are publicly available. For an approach to secure static files, see Static files in ASP.NET Core.

If the request isn't handled by the Static File Middleware, it's passed on to the Authentication Middleware (UseAuthentication), which performs authentication. Authentication doesn't short-circuit unauthenticated requests. Although Authentication Middleware authenticates requests, authorization (and rejection) occurs only after MVC selects a specific Razor Page or MVC controller and action.

The following example demonstrates a middleware order where requests for static files are handled by Static File Middleware before Response Compression Middleware. Static files aren't compressed with this middleware order. The Razor Pages responses can be compressed.

```
public void Configure(IApplicationBuilder app)
{
    // Static files aren't compressed by Static File Middleware.
    app.UseStaticFiles();

    app.UseResponseCompression();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

For Single Page Applications (SPAs), the SPA middleware UseSpaStaticFiles usually comes last in the middleware pipeline. The SPA middleware comes last:

- To allow all other middlewares to respond to matching requests first.
- To allow SPAs with client-side routing to run for all routes that are unrecognized by the server app.

For more details on SPAs, see the guides for the React and Angular project templates.

Forwarded Headers Middleware order

Forwarded Headers Middleware should run before other middleware. This ordering ensures that the middleware relying on forwarded headers information can consume the header values for processing. To run Forwarded Headers Middleware after diagnostics and error handling middleware, see Forwarded Headers Middleware order.

Branch the middleware pipeline

Map extensions are used as a convention for branching the pipeline. `Map` branches the request pipeline based on matches of the given request path. If the request path starts with the given path, the branch is executed.

```
public class Startup
{
    private static void HandleMapTest1(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            await context.Response.WriteAsync("Map Test 1");
        });
    }

    private static void HandleMapTest2(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            await context.Response.WriteAsync("Map Test 2");
        });
    }

    public void Configure(IApplicationBuilder app)
    {
        app.Map("/map1", HandleMapTest1);

        app.Map("/map2", HandleMapTest2);

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from non-Map delegate. <p>");
        });
    }
}
```

The following table shows the requests and responses from `http://localhost:1234` using the previous code.

REQUEST	RESPONSE
localhost:1234	Hello from non-Map delegate.
localhost:1234/map1	Map Test 1
localhost:1234/map2	Map Test 2
localhost:1234/map3	Hello from non-Map delegate.

When `Map` is used, the matched path segments are removed from `HttpRequest.Path` and appended to `HttpRequest.PathBase` for each request.

`Map` supports nesting, for example:

```
app.Map("/level1", level1App => {
    level1App.Map("/level2a", level2AApp => {
        // "/level1/level2a" processing
    });
    level1App.Map("/level2b", level2BApp => {
        // "/level1/level2b" processing
    });
});
```

`Map` can also match multiple segments at once:

```
public class Startup
{
    private static void HandleMultiSeg(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            await context.Response.WriteAsync("Map multiple segments.");
        });
    }

    public void Configure(IApplicationBuilder app)
    {
        app.Map("/map1/seg1", HandleMultiSeg);

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from non-Map delegate.");
        });
    }
}
```

MapWhen branches the request pipeline based on the result of the given predicate. Any predicate of type `Func<HttpContext, bool>` can be used to map requests to a new branch of the pipeline. In the following example, a predicate is used to detect the presence of a query string variable `branch`:

```
public class Startup
{
    private static void HandleBranch(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            var branchVer = context.Request.Query["branch"];
            await context.Response.WriteAsync($"Branch used = {branchVer}");
        });
    }

    public void Configure(IApplicationBuilder app)
    {
        app.MapWhen(context => context.Request.Query.ContainsKey("branch"),
                               HandleBranch);

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from non-Map delegate. <p>");
        });
    }
}
```

The following table shows the requests and responses from `http://localhost:1234` using the previous code:

REQUEST	RESPONSE
localhost:1234	Hello from non-Map delegate.
localhost:1234/?branch=master	Branch used = master

UseWhen also branches the request pipeline based on the result of the given predicate. Unlike with `MapWhen`, this branch is rejoined to the main pipeline if it doesn't short-circuit or contain a terminal middleware:

```
public class Startup
{
    private readonly ILogger<Startup> _logger;

    public Startup(ILogger<Startup> logger)
    {
        _logger = logger;
    }

    private void HandleBranchAndRejoin(IApplicationBuilder app)
    {
        app.Use(async (context, next) =>
        {
            var branchVer = context.Request.Query["branch"];
            _logger.LogInformation("Branch used = {branchVer}", branchVer);

            // Do work that doesn't write to the Response.
            await next();
            // Do other work that doesn't write to the Response.
        });
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseWhen(context => context.Request.Query.ContainsKey("branch"),
                               HandleBranchAndRejoin);

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from main pipeline.");
        });
    }
}
```

In the preceding example, a response of "Hello from main pipeline." is written for all requests. If the request includes a query string variable `branch`, its value is logged before the main pipeline is rejoined.

Built-in middleware

ASP.NET Core ships with the following middleware components. The *Order* column provides notes on middleware placement in the request processing pipeline and under what conditions the middleware may terminate request processing. When a middleware short-circuits the request processing pipeline and prevents further downstream middleware from processing a request, it's called a *terminal middleware*. For more information on short-circuiting, see the Create a middleware pipeline with IApplicationBuilder section.

MIDDLEWARE	DESCRIPTION	ORDER
Authentication	Provides authentication support.	Before `HttpContext.User` is needed. Terminal for OAuth callbacks.
Authorization	Provides authorization support.	Immediately after the Authentication Middleware.
Cookie Policy	Tracks consent from users for storing personal information and enforces minimum standards for cookie fields, such as `secure` and `SameSite`.	Before middleware that issues cookies. Examples: Authentication, Session, MVC (TempData).

MIDDLEWARE	DESCRIPTION	ORDER
CORS	Configures Cross-Origin Resource Sharing.	Before components that use CORS. `UseCors` currently must go before `UseResponseCaching` due to this bug.
Diagnostics	Several separate middlewares that provide a developer exception page, exception handling, status code pages, and the default web page for new apps.	Before components that generate errors. Terminal for exceptions or serving the default web page for new apps.
Forwarded Headers	Forwards proxied headers onto the current request.	Before components that consume the updated fields. Examples: scheme, host, client IP, method.
Health Check	Checks the health of an ASP.NET Core app and its dependencies, such as checking database availability.	Terminal if a request matches a health check endpoint.
Header Propagation	Propagates HTTP headers from the incoming request to the outgoing HTTP Client requests.	
HTTP Method Override	Allows an incoming POST request to override the method.	Before components that consume the updated method.
HTTPS Redirection	Redirect all HTTP requests to HTTPS.	Before components that consume the URL.
HTTP Strict Transport Security (HSTS)	Security enhancement middleware that adds a special response header.	Before responses are sent and after components that modify requests. Examples: Forwarded Headers, URL Rewriting.
MVC	Processes requests with MVC/Razor Pages.	Terminal if a request matches a route.
OWIN	Interop with OWIN-based apps, servers, and middleware.	Terminal if the OWIN Middleware fully processes the request.
Response Caching	Provides support for caching responses.	Before components that require caching. `UseCORS` must come before `UseResponseCaching`.
Response Compression	Provides support for compressing responses.	Before components that require compression.
Request Localization	Provides localization support.	Before localization sensitive components.
Endpoint Routing	Defines and constrains request routes.	Terminal for matching routes.

MIDDLEWARE	DESCRIPTION	ORDER
SPA	Handles all requests from this point in the middleware chain by returning the default page for the Single Page Application (SPA)	Late in the chain, so that other middleware for serving static files, MVC actions, etc., takes precedence.
Session	Provides support for managing user sessions.	Before components that require Session.
Static Files	Provides support for serving static files and directory browsing.	Terminal if a request matches a file.
URL Rewrite	Provides support for rewriting URLs and redirecting requests.	Before components that consume the URL.
WebSockets	Enables the WebSockets protocol.	Before components that are required to accept WebSocket requests.

By Rick Anderson and Steve Smith

Middleware is software that's assembled into an app pipeline to handle requests and responses. Each component:

- Chooses whether to pass the request to the next component in the pipeline.
- Can perform work before and after the next component in the pipeline.

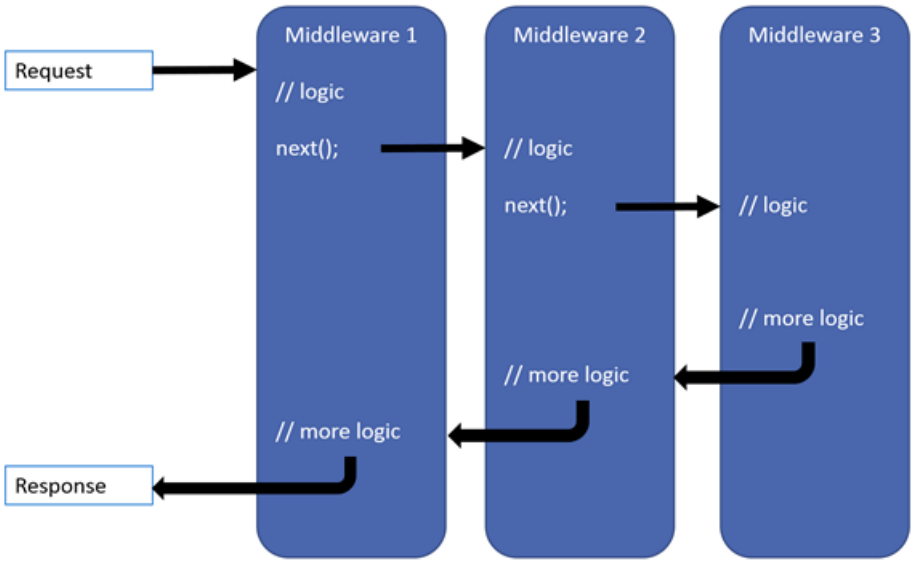
Request delegates are used to build the request pipeline. The request delegates handle each HTTP request.

Request delegates are configured using Run, Map, and Use extension methods. An individual request delegate can be specified in-line as an anonymous method (called in-line middleware), or it can be defined in a reusable class. These reusable classes and in-line anonymous methods are *middleware*, also called *middleware components*. Each middleware component in the request pipeline is responsible for invoking the next component in the pipeline or short-circuiting the pipeline. When a middleware short-circuits, it's called a *terminal middleware* because it prevents further middleware from processing the request.

Migrate HTTP handlers and modules to ASP.NET Core middleware explains the difference between request pipelines in ASP.NET Core and ASP.NET 4.x and provides additional middleware samples.

Create a middleware pipeline with IApplicationBuilder

The ASP.NET Core request pipeline consists of a sequence of request delegates, called one after the other. The following diagram demonstrates the concept. The thread of execution follows the black arrows.



Each delegate can perform operations before and after the next delegate. Exception-handling delegates should be called early in the pipeline, so they can catch exceptions that occur in later stages of the pipeline.

The simplest possible ASP.NET Core app sets up a single request delegate that handles all requests. This case doesn't include an actual request pipeline. Instead, a single anonymous function is called in response to every HTTP request.

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello, World!");
        });
    }
}
```

The first Run delegate terminates the pipeline.

Chain multiple request delegates together with Use. The `next` parameter represents the next delegate in the pipeline. You can short-circuit the pipeline by *not* calling the *next* parameter. You can typically perform actions both before and after the next delegate, as the following example demonstrates:

```
public class Startup
{
    public void Configure(IApplicationBuilder app)
    {
        app.Use(async (context, next) =>
        {
            // Do work that doesn't write to the Response.
            await next.Invoke();
            // Do logging or other work that doesn't write to the Response.
        });

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from 2nd delegate.");
        });
    }
}
```

When a delegate doesn't pass a request to the next delegate, it's called *short-circuiting the request pipeline*. Short-circuiting is often desirable because it avoids unnecessary work. For example, Static File Middleware can act as a *terminal middleware* by processing a request for a static file and short-circuiting the rest of the pipeline. Middleware added to the pipeline before the middleware that terminates further processing still processes code after their `next.Invoke` statements. However, see the following warning about attempting to write to a response that has already been sent.

WARNING

Don't call `next.Invoke` after the response has been sent to the client. Changes to HttpResponse after the response has started throw an exception. For example, changes such as setting headers and a status code throw an exception. Writing to the response body after calling `next`:

- May cause a protocol violation. For example, writing more than the stated `Content-Length`.
- May corrupt the body format. For example, writing an HTML footer to a CSS file.

HasStarted is a useful hint to indicate if headers have been sent or the body has been written to.

Middleware order

The order that middleware components are added in the `Startup.Configure` method defines the order in which the middleware components are invoked on requests and the reverse order for the response. The order is **critical** for security, performance, and functionality.

The following `Startup.Configure` method adds security related middleware components in the recommended order:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();

    // app.UseRequestLocalization();
    // app.UseCors();

    app.UseAuthentication();
    // app.UseSession();

    app.UseMvc(routes =>
    {
        routes.MapRoute(
            name: "default",
            template: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

In the preceding code:

- Middleware that is not added when creating a new web app with individual users accounts is commented out.
- Not every middleware needs to go in this exact order, but many do. For example, `UseCors` and `UseAuthentication` must go in the order shown.

The following `Startup.Configure` method adds middleware components for common app scenarios:

1. Exception/error handling
   - When the app runs in the Development environment:
     - Developer Exception Page Middleware (UseDeveloperExceptionPage) reports app runtime errors.
     - Database Error Page Middleware (`Microsoft.AspNetCore.Builder.DatabaseErrorPageExtensions.UseDatabaseErrorPage`) reports database runtime errors.
   - When the app runs in the Production environment:
     - Exception Handler Middleware (UseExceptionHandler) catches exceptions thrown in the following middlewares.
     - HTTP Strict Transport Security Protocol (HSTS) Middleware (UseHsts) adds the `Strict-Transport-Security` header.
2. HTTPS Redirection Middleware (UseHttpsRedirection) redirects HTTP requests to HTTPS.
3. Static File Middleware (UseStaticFiles) returns static files and short-circuits further request processing.
4. Cookie Policy Middleware (UseCookiePolicy) conforms the app to the EU General Data Protection Regulation (GDPR) regulations.
5. Authentication Middleware (UseAuthentication) attempts to authenticate the user before they're allowed access to secure resources.

6. Session Middleware (UseSession) establishes and maintains session state. If the app uses session state, call Session Middleware after Cookie Policy Middleware and before MVC Middleware.
7. MVC (UseMvc) to add MVC to the request pipeline.

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
        app.UseDatabaseErrorPage();
    }
    else
    {
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();
    app.UseCookiePolicy();
    app.UseAuthentication();
    app.UseSession();
    app.UseMvc();
}
```

In the preceding example code, each middleware extension method is exposed on IApplicationBuilder through the Microsoft.AspNetCore.Builder namespace.

UseExceptionHandler is the first middleware component added to the pipeline. Therefore, the Exception Handler Middleware catches any exceptions that occur in later calls.

Static File Middleware is called early in the pipeline so that it can handle requests and short-circuit without going through the remaining components. The Static File Middleware provides **no** authorization checks. Any files served by Static File Middleware, including those under *wwwroot*, are publicly available. For an approach to secure static files, see Static files in ASP.NET Core.

If the request isn't handled by the Static File Middleware, it's passed on to the Authentication Middleware (UseAuthentication), which performs authentication. Authentication doesn't short-circuit unauthenticated requests. Although Authentication Middleware authenticates requests, authorization (and rejection) occurs only after MVC selects a specific Razor Page or MVC controller and action.

The following example demonstrates a middleware order where requests for static files are handled by Static File Middleware before Response Compression Middleware. Static files aren't compressed with this middleware order. The MVC responses from UseMvcWithDefaultRoute can be compressed.

```
public void Configure(IApplicationBuilder app)
{
    // Static files aren't compressed by Static File Middleware.
    app.UseStaticFiles();

    app.UseResponseCompression();

    app.UseMvcWithDefaultRoute();
}
```

Use, Run, and Map

Configure the HTTP pipeline using Use, Run, and Map. The `Use` method can short-circuit the pipeline (that is, if it doesn't call a `next` request delegate). `Run` is a convention, and some middleware

components may expose `Run[Middleware]` methods that run at the end of the pipeline.

Map extensions are used as a convention for branching the pipeline. `Map` branches the request pipeline based on matches of the given request path. If the request path starts with the given path, the branch is executed.

```
public class Startup
{
    private static void HandleMapTest1(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            await context.Response.WriteAsync("Map Test 1");
        });
    }

    private static void HandleMapTest2(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            await context.Response.WriteAsync("Map Test 2");
        });
    }

    public void Configure(IApplicationBuilder app)
    {
        app.Map("/map1", HandleMapTest1);

        app.Map("/map2", HandleMapTest2);

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from non-Map delegate. <p>");
        });
    }
}
```

The following table shows the requests and responses from `http://localhost:1234` using the previous code.

REQUEST	RESPONSE
localhost:1234	Hello from non-Map delegate.
localhost:1234/map1	Map Test 1
localhost:1234/map2	Map Test 2
localhost:1234/map3	Hello from non-Map delegate.

When `Map` is used, the matched path segments are removed from `HttpRequest.Path` and appended to `HttpRequest.PathBase` for each request.

MapWhen branches the request pipeline based on the result of the given predicate. Any predicate of type `Func<HttpContext, bool>` can be used to map requests to a new branch of the pipeline. In the following example, a predicate is used to detect the presence of a query string variable `branch`:

```
public class Startup
{
    private static void HandleBranch(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            var branchVer = context.Request.Query["branch"];
            await context.Response.WriteAsync($"Branch used = {branchVer}");
        });
    }

    public void Configure(IApplicationBuilder app)
    {
        app.MapWhen(context => context.Request.Query.ContainsKey("branch"),
                               HandleBranch);

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from non-Map delegate. <p>");
        });
    }
}
```

The following table shows the requests and responses from `http://localhost:1234` using the previous code.

REQUEST	RESPONSE
localhost:1234	Hello from non-Map delegate.
localhost:1234/?branch=master	Branch used = master

`Map` supports nesting, for example:

```
app.Map("/level1", level1App => {
    level1App.Map("/level2a", level2AApp => {
        // "/level1/level2a" processing
    });
    level1App.Map("/level2b", level2BApp => {
        // "/level1/level2b" processing
    });
});
```

`Map` can also match multiple segments at once:

```
public class Startup
{
    private static void HandleMultiSeg(IApplicationBuilder app)
    {
        app.Run(async context =>
        {
            await context.Response.WriteAsync("Map multiple segments.");
        });
    }

    public void Configure(IApplicationBuilder app)
    {
        app.Map("/map1/seg1", HandleMultiSeg);

        app.Run(async context =>
        {
            await context.Response.WriteAsync("Hello from non-Map delegate.");
        });
    }
}
```

Built-in middleware

ASP.NET Core ships with the following middleware components. The *Order* column provides notes on middleware placement in the request processing pipeline and under what conditions the middleware may terminate request processing. When a middleware short-circuits the request processing pipeline and prevents further downstream middleware from processing a request, it's called a *terminal middleware*. For more information on short-circuiting, see the Create a middleware pipeline with IApplicationBuilder section.

MIDDLEWARE	DESCRIPTION	ORDER
Authentication	Provides authentication support.	Before `HttpContext.User` is needed. Terminal for OAuth callbacks.
Cookie Policy	Tracks consent from users for storing personal information and enforces minimum standards for cookie fields, such as `secure` and `SameSite`.	Before middleware that issues cookies. Examples: Authentication, Session, MVC (TempData).
CORS	Configures Cross-Origin Resource Sharing.	Before components that use CORS.
Diagnostics	Several separate middlewares that provide a developer exception page, exception handling, status code pages, and the default web page for new apps.	Before components that generate errors. Terminal for exceptions or serving the default web page for new apps.
Forwarded Headers	Forwards proxied headers onto the current request.	Before components that consume the updated fields. Examples: scheme, host, client IP, method.

MIDDLEWARE	DESCRIPTION	ORDER
Health Check	Checks the health of an ASP.NET Core app and its dependencies, such as checking database availability.	Terminal if a request matches a health check endpoint.
HTTP Method Override	Allows an incoming POST request to override the method.	Before components that consume the updated method.
HTTPS Redirection	Redirect all HTTP requests to HTTPS.	Before components that consume the URL.
HTTP Strict Transport Security (HSTS)	Security enhancement middleware that adds a special response header.	Before responses are sent and after components that modify requests. Examples: Forwarded Headers, URL Rewriting.
MVC	Processes requests with MVC/Razor Pages.	Terminal if a request matches a route.
OWIN	Interop with OWIN-based apps, servers, and middleware.	Terminal if the OWIN Middleware fully processes the request.
Response Caching	Provides support for caching responses.	Before components that require caching.
Response Compression	Provides support for compressing responses.	Before components that require compression.
Request Localization	Provides localization support.	Before localization sensitive components.
Endpoint Routing	Defines and constrains request routes.	Terminal for matching routes.
Session	Provides support for managing user sessions.	Before components that require Session.
Static Files	Provides support for serving static files and directory browsing.	Terminal if a request matches a file.
URL Rewrite	Provides support for rewriting URLs and redirecting requests.	Before components that consume the URL.
WebSockets	Enables the WebSockets protocol.	Before components that are required to accept WebSocket requests.

.NET Generic Host

9/22/2020 • 32 minutes to read • Edit Online

The ASP.NET Core templates create a .NET Core Generic Host, HostBuilder.

Host definition

A *host* is an object that encapsulates an app's resources, such as:

- Dependency injection (DI)
- Logging
- Configuration
- `IHostedService` implementations

When a host starts, it calls IHostedService.StartAsync on each implementation of IHostedService registered in the service container's collection of hosted services. In a web app, one of the `IHostedService` implementations is a web service that starts an HTTP server implementation.

The main reason for including all of the app's interdependent resources in one object is lifetime management: control over app startup and graceful shutdown.

Set up a host

The host is typically configured, built, and run by code in the `Program` class. The `Main` method:

- Calls a `CreateHostBuilder` method to create and configure a builder object.
- Calls `Build` and `Run` methods on the builder object.

The ASP.NET Core web templates generate the following code to create a Generic Host:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code creates a Generic Host using non-HTTP workload. The `IHostedService` implementation is added to the DI container:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureServices((hostContext, services) =>
            {
               services.AddHostedService<Worker>();
            });
}
```

For an HTTP workload, the `Main` method is the same but `CreateHostBuilder` calls `ConfigureWebHostDefaults`:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

The preceding code is generated by the ASP.NET Core templates.

If the app uses Entity Framework Core, don't change the name or signature of the `CreateHostBuilder` method. The Entity Framework Core tools expect to find a `CreateHostBuilder` method that configures the host without running the app. For more information, see Design-time DbContext Creation.

Default builder settings

The CreateDefaultBuilder method:

- Sets the content root to the path returned by GetCurrentDirectory.
- Loads host configuration from:
  - Environment variables prefixed with `DOTNET_`.
  - Command-line arguments.
- Loads app configuration from:
  - *appsettings.json*.
  - *appsettings.{Environment}.json*.
  - Secret Manager when the app runs in the `Development` environment.
  - Environment variables.
  - Command-line arguments.
- Adds the following logging providers:
  - Console
  - Debug
  - EventSource
  - EventLog (only when running on Windows)
- Enables scope validation and dependency validation when the environment is Development.

The `ConfigureWebHostDefaults` method:

- Loads host configuration from environment variables prefixed with `ASPNETCORE_`.
- Sets Kestrel server as the web server and configures it using the app's hosting configuration providers. For

the Kestrel server's default options, see Kestrel web server implementation in ASP.NET Core.

- Adds Host Filtering middleware.
- Adds Forwarded Headers middleware if `ASPNETCORE_FORWARDEDHEADERS_ENABLED` equals `true`.
- Enables IIS integration. For the IIS default options, see Host ASP.NET Core on Windows with IIS.

The Settings for all app types and Settings for web apps sections later in this article show how to override default builder settings.

Framework-provided services

The following services are registered automatically:

- IHostApplicationLifetime
- IHostLifetime
- IHostEnvironment / IWebHostEnvironment

For more information on framework-provided services, see Dependency injection in ASP.NET Core.

IHostApplicationLifetime

Inject the IHostApplicationLifetime (formerly `IApplicationLifetime`) service into any class to handle post-startup and graceful shutdown tasks. Three properties on the interface are cancellation tokens used to register app start and app stop event handler methods. The interface also includes a `StopApplication` method.

The following example is an `IHostedService` implementation that registers `IHostApplicationLifetime` events:

```
internal class LifetimeEventsHostedService : IHostedService
{
    private readonly ILogger _logger;
    private readonly IHostApplicationLifetime _appLifetime;

    public LifetimeEventsHostedService(
        ILogger<LifetimeEventsHostedService> logger,
        IHostApplicationLifetime appLifetime)
    {
        _logger = logger;
        _appLifetime = appLifetime;
    }

    public Task StartAsync(CancellationToken cancellationToken)
    {
        _appLifetime.ApplicationStarted.Register(OnStarted);
        _appLifetime.ApplicationStopping.Register(OnStopping);
        _appLifetime.ApplicationStopped.Register(OnStopped);

        return Task.CompletedTask;
    }

    public Task StopAsync(CancellationToken cancellationToken)
    {
        return Task.CompletedTask;
    }

    private void OnStarted()
    {
        _logger.LogInformation("OnStarted has been called.");

        // Perform post-startup activities here
    }

    private void OnStopping()
    {
        _logger.LogInformation("OnStopping has been called.");

        // Perform on-stopping activities here
    }

    private void OnStopped()
    {
        _logger.LogInformation("OnStopped has been called.");

        // Perform post-stopped activities here
    }
}
```

IHostLifetime

The IHostLifetime implementation controls when the host starts and when it stops. The last implementation registered is used.

`Microsoft.Extensions.Hosting.Internal.ConsoleLifetime` is the default `IHostLifetime` implementation. `ConsoleLifetime`:

- Listens for `Ctrl+C`/SIGINT or SIGTERM and calls StopApplication to start the shutdown process.
- Unblocks extensions such as RunAsync and WaitForShutdownAsync.

IHostEnvironment

Inject the IHostEnvironment service into a class to get information about the following settings:

- ApplicationName
- EnvironmentName
- ContentRootPath

Web apps implement the `IWebHostEnvironment` interface, which inherits `IHostEnvironment` and adds the WebRootPath.

Host configuration

Host configuration is used for the properties of the IHostEnvironment implementation.

Host configuration is available from HostBuilderContext.Configuration inside ConfigureAppConfiguration. After `ConfigureAppConfiguration`, `HostBuilderContext.Configuration` is replaced with the app config.

To add host configuration, call ConfigureHostConfiguration on `IHostBuilder`. `ConfigureHostConfiguration` can be called multiple times with additive results. The host uses whichever option sets a value last on a given key.

The environment variable provider with prefix `DOTNET_` and command-line arguments are included by `CreateDefaultBuilder`. For web apps, the environment variable provider with prefix `ASPNETCORE_` is added. The prefix is removed when the environment variables are read. For example, the environment variable value for `ASPNETCORE_ENVIRONMENT` becomes the host configuration value for the `environment` key.

The following example creates host configuration:

```
// using Microsoft.Extensions.Configuration;

Host.CreateDefaultBuilder(args)
    .ConfigureHostConfiguration(configHost =>
    {
        configHost.SetBasePath(Directory.GetCurrentDirectory());
        configHost.AddJsonFile("hostsettings.json", optional: true);
        configHost.AddEnvironmentVariables(prefix: "PREFIX_");
        configHost.AddCommandLine(args);
    });
```

App configuration

App configuration is created by calling ConfigureAppConfiguration on `IHostBuilder`. `ConfigureAppConfiguration` can be called multiple times with additive results. The app uses whichever option sets a value last on a given key.

The configuration created by `ConfigureAppConfiguration` is available at HostBuilderContext.Configuration for subsequent operations and as a service from DI. The host configuration is also added to the app configuration.

For more information, see Configuration in ASP.NET Core.

Settings for all app types

This section lists host settings that apply to both HTTP and non-HTTP workloads. By default, environment variables used to configure these settings can have a `DOTNET_` or `ASPNETCORE_` prefix.

ApplicationName

The IHostEnvironment.ApplicationName property is set from host configuration during host construction.

Key: `applicationName`
Type: `string`

Default: The name of the assembly that contains the app's entry point.
Environment variable: `<PREFIX_>APPLICATIONNAME`

To set this value, use the environment variable.

ContentRoot

The IHostEnvironment.ContentRootPath property determines where the host begins searching for content files. If the path doesn't exist, the host fails to start.

Key: `contentRoot`
Type: `string`
Default: The folder where the app assembly resides.
Environment variable: `<PREFIX_>CONTENTROOT`

To set this value, use the environment variable or call `UseContentRoot` on `IHostBuilder`:

```
Host.CreateDefaultBuilder(args)
    .UseContentRoot("c:\\content-root")
    //...
```

For more information, see:

- Fundamentals: Content root
- WebRoot

EnvironmentName

The IHostEnvironment.EnvironmentName property can be set to any value. Framework-defined values include `Development`, `Staging`, and `Production`. Values aren't case-sensitive.

Key: `environment`
Type: `string`
Default: `Production`
Environment variable: `<PREFIX_>ENVIRONMENT`

To set this value, use the environment variable or call `UseEnvironment` on `IHostBuilder`:

```
Host.CreateDefaultBuilder(args)
    .UseEnvironment("Development")
    //...
```

ShutdownTimeout

HostOptions.ShutdownTimeout sets the timeout for StopAsync. The default value is five seconds. During the timeout period, the host:

- Triggers IHostApplicationLifetime.ApplicationStopping.
- Attempts to stop hosted services, logging errors for services that fail to stop.

If the timeout period expires before all of the hosted services stop, any remaining active services are stopped when the app shuts down. The services stop even if they haven't finished processing. If services require additional time to stop, increase the timeout.

Key: `shutdownTimeoutSeconds`
Type: `int`
Default: 5 seconds
Environment variable: `<PREFIX_>SHUTDOWNTIMEOUTSECONDS`

To set this value, use the environment variable or configure `HostOptions`. The following example sets the timeout to 20 seconds:

```
Host.CreateDefaultBuilder(args)
    .ConfigureServices((hostContext, services) =>
    {
        services.Configure<HostOptions>(option =>
        {
            option.ShutdownTimeout = System.TimeSpan.FromSeconds(20);
        });
    });
```

Settings for web apps

Some host settings apply only to HTTP workloads. By default, environment variables used to configure these settings can have a `DOTNET_` or `ASPNETCORE_` prefix.

Extension methods on `IWebHostBuilder` are available for these settings. Code samples that show how to call the extension methods assume `webBuilder` is an instance of `IWebHostBuilder`, as in the following example:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.CaptureStartupErrors(true);
            webBuilder.UseStartup<Startup>();
        });
```

CaptureStartupErrors

When `false`, errors during startup result in the host exiting. When `true`, the host captures exceptions during startup and attempts to start the server.

Key: `captureStartupErrors`
Type: `bool` (`true` or `1`)
Default: Defaults to `false` unless the app runs with Kestrel behind IIS, where the default is `true`.
Environment variable: `<PREFIX_>CAPTURESTARTUPERRORS`

To set this value, use configuration or call `CaptureStartupErrors`:

```
webBuilder.CaptureStartupErrors(true);
```

DetailedErrors

When enabled, or when the environment is `Development`, the app captures detailed errors.

Key: `detailedErrors`
Type: `bool` (`true` or `1`)
Default: `false`
Environment variable: `<PREFIX_>_DETAILEDERRORS`

To set this value, use configuration or call `UseSetting`:

```
webBuilder.UseSetting(WebHostDefaults.DetailedErrorsKey, "true");
```

HostingStartupAssemblies

A semicolon-delimited string of hosting startup assemblies to load on startup. Although the configuration value defaults to an empty string, the hosting startup assemblies always include the app's assembly. When hosting startup assemblies are provided, they're added to the app's assembly for loading when the app builds its common services during startup.

Key: `hostingStartupAssemblies`
Type: `string`
Default: Empty string
Environment variable: `<PREFIX_>_HOSTINGSTARTUPASSEMBLIES`

To set this value, use configuration or call `UseSetting`:

```
webBuilder.UseSetting(WebHostDefaults.HostingStartupAssembliesKey, "assembly1;assembly2");
```

HostingStartupExcludeAssemblies

A semicolon-delimited string of hosting startup assemblies to exclude on startup.

Key: `hostingStartupExcludeAssemblies`
Type: `string`
Default: Empty string
Environment variable: `<PREFIX_>_HOSTINGSTARTUPEXCLUDEASSEMBLIES`

To set this value, use configuration or call `UseSetting`:

```
webBuilder.UseSetting(WebHostDefaults.HostingStartupExcludeAssembliesKey, "assembly1;assembly2");
```

HTTPS_Port

The HTTPS redirect port. Used in enforcing HTTPS.

Key: `https_port`
Type: `string`
Default: A default value isn't set.
Environment variable: `<PREFIX_>HTTPS_PORT`

To set this value, use configuration or call `UseSetting`:

```
webBuilder.UseSetting("https_port", "8080");
```

PreferHostingUrls

Indicates whether the host should listen on the URLs configured with the `IWebHostBuilder` instead of those URLs configured with the `IServer` implementation.

Key: `preferHostingUrls`
Type: `bool` (`true` or `1`)
Default: `true`
Environment variable: `<PREFIX_>_PREFERHOSTINGURLS`

To set this value, use the environment variable or call `PreferHostingUrls`:

```
webBuilder.PreferHostingUrls(false);
```

PreventHostingStartup

Prevents the automatic loading of hosting startup assemblies, including hosting startup assemblies configured by the app's assembly. For more information, see Use hosting startup assemblies in ASP.NET Core.

Key: `preventHostingStartup`
Type: `bool` (`true` or `1`)
Default: `false`
Environment variable: `<PREFIX_>_PREVENTHOSTINGSTARTUP`

To set this value, use the environment variable or call `UseSetting` :

```
webBuilder.UseSetting(WebHostDefaults.PreventHostingStartupKey, "true");
```

StartupAssembly

The assembly to search for the `Startup` class.

Key: `startupAssembly`
Type: `string`
Default: The app's assembly
Environment variable: `<PREFIX_>STARTUPASSEMBLY`

To set this value, use the environment variable or call `UseStartup` . `UseStartup` can take an assembly name (`string`) or a type (`TStartup`). If multiple `UseStartup` methods are called, the last one takes precedence.

```
webBuilder.UseStartup("StartupAssemblyName");
```

```
webBuilder.UseStartup<Startup>();
```

URLs

A semicolon-delimited list of IP addresses or host addresses with ports and protocols that the server should listen on for requests. For example, `http://localhost:123` . Use "*" to indicate that the server should listen for requests on any IP address or hostname using the specified port and protocol (for example, `http://*:5000`). The protocol (`http://` or `https://`) must be included with each URL. Supported formats vary among servers.

Key: `urls`
Type: `string`
Default: `http://localhost:5000` and `https://localhost:5001`
Environment variable: `<PREFIX_>URLS`

To set this value, use the environment variable or call `UseUrls` :

```
webBuilder.UseUrls("http://*:5000;http://localhost:5001;https://hostname:5002");
```

Kestrel has its own endpoint configuration API. For more information, see Kestrel web server implementation in ASP.NET Core.

WebRoot

The IWebHostEnvironment.WebRootPath property determines the relative path to the app's static assets. If the path doesn't exist, a no-op file provider is used.

Key: `webroot`
Type: `string`

Default: The default is `wwwroot`. The path to *{content root}/wwwroot* must exist.
Environment variable: `<PREFIX_>WEBROOT`

To set this value, use the environment variable or call `UseWebRoot` on `IWebHostBuilder`:

```
webBuilder.UseWebRoot("public");
```

For more information, see:

- Fundamentals: Web root
- ContentRoot

Manage the host lifetime

Call methods on the built IHost implementation to start and stop the app. These methods affect all IHostedService implementations that are registered in the service container.

Run

Run runs the app and blocks the calling thread until the host is shut down.

RunAsync

RunAsync runs the app and returns a Task that completes when the cancellation token or shutdown is triggered.

RunConsoleAsync

RunConsoleAsync enables console support, builds and starts the host, and waits for `Ctrl+C`/SIGINT or SIGTERM to shut down.

Start

Start starts the host synchronously.

StartAsync

StartAsync starts the host and returns a Task that completes when the cancellation token or shutdown is triggered.

WaitForStartAsync is called at the start of `StartAsync`, which waits until it's complete before continuing. This can be used to delay startup until signaled by an external event.

StopAsync

StopAsync attempts to stop the host within the provided timeout.

WaitForShutdown

WaitForShutdown blocks the calling thread until shutdown is triggered by the IHostLifetime, such as via `Ctrl+C`/SIGINT or SIGTERM.

WaitForShutdownAsync

WaitForShutdownAsync returns a Task that completes when shutdown is triggered via the given token and calls StopAsync.

External control

Direct control of the host lifetime can be achieved using methods that can be called externally:

```
public class Program
{
    private IHost _host;

    public Program()
    {
        _host = new HostBuilder()
            .Build();
    }

    public async Task StartAsync()
    {
        _host.StartAsync();
    }

    public async Task StopAsync()
    {
        using (_host)
        {
            await _host.StopAsync(TimeSpan.FromSeconds(5));
        }
    }
}
```

ASP.NET Core apps configure and launch a host. The host is responsible for app startup and lifetime management.

This article covers the ASP.NET Core Generic Host (HostBuilder), which is used for apps that don't process HTTP requests.

The purpose of Generic Host is to decouple the HTTP pipeline from the Web Host API to enable a wider array of host scenarios. Messaging, background tasks, and other non-HTTP workloads based on Generic Host benefit from cross-cutting capabilities, such as configuration, dependency injection (DI), and logging.

Generic Host is new in ASP.NET Core 2.1 and isn't suitable for web hosting scenarios. For web hosting scenarios, use the Web Host. Generic Host will replace Web Host in a future release and act as the primary host API in both HTTP and non-HTTP scenarios.

View or download sample code (how to download)

When running the sample app in Visual Studio Code, use an *external or integrated terminal*. Don't run the sample in an `internalConsole`.

To set the console in Visual Studio Code:

1. Open the *.vscode/launch.json* file.
2. In the **.NET Core Launch (console)** configuration, locate the **console** entry. Set the value to either `externalTerminal` or `integratedTerminal`.

Introduction

The Generic Host library is available in the Microsoft.Extensions.Hosting namespace and provided by the Microsoft.Extensions.Hosting package. The `Microsoft.Extensions.Hosting` package is included in the Microsoft.AspNetCore.App metapackage (ASP.NET Core 2.1 or later).

IHostedService is the entry point to code execution. Each IHostedService implementation is executed in the order of service registration in ConfigureServices. StartAsync is called on each IHostedService when the host starts, and StopAsync is called in reverse registration order when the host shuts down gracefully.

Set up a host

IHostBuilder is the main component that libraries and apps use to initialize, build, and run the host:

```
public static async Task Main(string[] args)
{
    var host = new HostBuilder()
        .Build();

    await host.RunAsync();
}
```

Options

HostOptions configure options for the IHost.

Shutdown timeout

ShutdownTimeout sets the timeout for StopAsync. The default value is five seconds.

The following option configuration in `Program.Main` increases the default five-second shutdown timeout to 20 seconds:

```
var host = new HostBuilder()
    .ConfigureServices((hostContext, services) =>
    {
        services.Configure<HostOptions>(option =>
        {
            option.ShutdownTimeout = System.TimeSpan.FromSeconds(20);
        });
    })
    .Build();
```

Default services

The following services are registered during host initialization:

- Environment (IHostingEnvironment)
- HostBuilderContext
- Configuration (IConfiguration)
- IApplicationLifetime (`Microsoft.Extensions.Hosting.Internal.ApplicationLifetime`)
- IHostLifetime (`Microsoft.Extensions.Hosting.Internal.ConsoleLifetime`)
- IHost
- Options (AddOptions)
- Logging (AddLogging)

Host configuration

Host configuration is created by:

- Calling extension methods on IHostBuilder to set the content root and environment.
- Reading configuration from configuration providers in ConfigureHostConfiguration.

Extension methods

Application key (name)

The IHostingEnvironment.ApplicationName property is set from host configuration during host construction. To set the value explicitly, use the HostDefaults.ApplicationKey:

Key: `applicationName`
Type: `string`
Default: The name of the assembly containing the app's entry point.
Set using: `HostBuilderContext.HostingEnvironment.ApplicationName`
Environment variable: `<PREFIX_>APPLICATIONNAME` (`<PREFIX_>` is optional and user-defined)

Content root

This setting determines where the host begins searching for content files.

Key: `contentRoot`
Type: `string`
Default: Defaults to the folder where the app assembly resides.
Set using: `UseContentRoot`
Environment variable: `<PREFIX_>CONTENTROOT` (`<PREFIX_>` is optional and user-defined)

If the path doesn't exist, the host fails to start.

```
var host = new HostBuilder()
    .UseContentRoot("c:\\<content-root>")
```

For more information, see Fundamentals: Content root.

Environment

Sets the app's environment.

Key: `environment`
Type: `string`
Default: `Production`
Set using: `UseEnvironment`
Environment variable: `<PREFIX_>ENVIRONMENT` (`<PREFIX_>` is optional and user-defined)

The environment can be set to any value. Framework-defined values include `Development`, `Staging`, and `Production`. Values aren't case-sensitive.

```
var host = new HostBuilder()
    .UseEnvironment(EnvironmentName.Development)
```

ConfigureHostConfiguration

ConfigureHostConfiguration uses an IConfigurationBuilder to create an IConfiguration for the host. The host configuration is used to initialize the IHostingEnvironment for use in the app's build process.

ConfigureHostConfiguration can be called multiple times with additive results. The host uses whichever option sets a value last on a given key.

No providers are included by default. You must explicitly specify whatever configuration providers the app requires in ConfigureHostConfiguration, including:

- File configuration (for example, from a *hostsettings.json* file).
- Environment variable configuration.
- Command-line argument configuration.
- Any other required configuration providers.

File configuration of the host is enabled by specifying the app's base path with `SetBasePath` followed by a call to one of the file configuration providers. The sample app uses a JSON file, *hostsettings.json*, and calls AddJsonFile to consume the file's host configuration settings.

To add environment variable configuration of the host, call AddEnvironmentVariables on the host builder. `AddEnvironmentVariables` accepts an optional user-defined prefix. The sample app uses a prefix of `PREFIX_`. The prefix is removed when the environment variables are read. When the sample app's host is configured, the environment variable value for `PREFIX_ENVIRONMENT` becomes the host configuration value for the `environment` key.

During development when using Visual Studio or running an app with `dotnet run`, environment variables may be set in the *Properties/launchSettings.json* file. In Visual Studio Code, environment variables may be set in the *.vscode/launch.json* file during development. For more information, see Use multiple environments in ASP.NET Core.

Command-line configuration is added by calling AddCommandLine. Command-line configuration is added last to permit command-line arguments to override configuration provided by the earlier configuration providers.

hostsettings.json:

```
{
  "environment": "Development"
}
```

Additional configuration can be provided with the applicationName and contentRoot keys.

Example `HostBuilder` configuration using ConfigureHostConfiguration:

```
var host = new HostBuilder()
    .ConfigureHostConfiguration(configHost =>
    {
        configHost.SetBasePath(Directory.GetCurrentDirectory());
        configHost.AddJsonFile("hostsettings.json", optional: true);
        configHost.AddEnvironmentVariables(prefix: "PREFIX_");
        configHost.AddCommandLine(args);
    })
```

ConfigureAppConfiguration

App configuration is created by calling ConfigureAppConfiguration on the IHostBuilder implementation. ConfigureAppConfiguration uses an IConfigurationBuilder to create an IConfiguration for the app. ConfigureAppConfiguration can be called multiple times with additive results. The app uses whichever option sets a value last on a given key. The configuration created by ConfigureAppConfiguration is available at HostBuilderContext.Configuration for subsequent operations and in Services.

App configuration automatically receives host configuration provided by ConfigureHostConfiguration.

Example app configuration using ConfigureAppConfiguration:

```
var host = new HostBuilder()
    .ConfigureAppConfiguration((hostContext, configApp) =>
    {
        configApp.SetBasePath(Directory.GetCurrentDirectory());
        configApp.AddJsonFile("appsettings.json", optional: true);
        configApp.AddJsonFile(
            $"appsettings.{hostContext.HostingEnvironment.EnvironmentName}.json",
            optional: true);
        configApp.AddEnvironmentVariables(prefix: "PREFIX_");
        configApp.AddCommandLine(args);
    })
```

appsettings.json:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Warning"
    }
  },
  "AllowedHosts": "*"
}
```

appsettings.Development.json:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Debug",
      "System": "Information",
      "Microsoft": "Information"
    }
  }
}
```

appsettings.Production.json:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Error",
      "System": "Information",
      "Microsoft": "Information"
    }
  }
}
```

To move settings files to the output directory, specify the settings files as MSBuild project items in the project file. The sample app moves its JSON app settings files and *hostsettings.json* with the following `<Content>` item:

```
<ItemGroup>
  <Content Include="**\*.json" Exclude="bin\**\*;obj\**\*"
      CopyToOutputDirectory="PreserveNewest" />
</ItemGroup>
```

> **NOTE**
>
> Configuration extension methods, such as AddJsonFile and AddEnvironmentVariables require additional NuGet packages, such as Microsoft.Extensions.Configuration.Json and Microsoft.Extensions.Configuration.EnvironmentVariables. Unless the app uses the Microsoft.AspNetCore.App metapackage, these packages must be added to the project in addition to the core Microsoft.Extensions.Configuration package. For more information, see Configuration in ASP.NET Core.

ConfigureServices

ConfigureServices adds services to the app's dependency injection container. ConfigureServices can be called multiple times with additive results.

A hosted service is a class with background task logic that implements the IHostedService interface. For more information, see Background tasks with hosted services in ASP.NET Core.

The sample app uses the `AddHostedService` extension method to add a service for lifetime events, `LifetimeEventsHostedService`, and a timed background task, `TimedHostedService`, to the app:

```
var host = new HostBuilder()
    .ConfigureServices((hostContext, services) =>
    {
        if (hostContext.HostingEnvironment.IsDevelopment())
        {
            // Development service configuration
        }
        else
        {
            // Non-development service configuration
        }

        services.AddHostedService<LifetimeEventsHostedService>();
        services.AddHostedService<TimedHostedService>();
    })
```

ConfigureLogging

ConfigureLogging adds a delegate for configuring the provided ILoggingBuilder. ConfigureLogging may be called multiple times with additive results.

```
var host = new HostBuilder()
    .ConfigureLogging((hostContext, configLogging) =>
    {
        configLogging.AddConsole();
        configLogging.AddDebug();
    })
```

UseConsoleLifetime

UseConsoleLifetime listens for `Ctrl+C`/SIGINT or SIGTERM and calls StopApplication to start the shutdown process. UseConsoleLifetime unblocks extensions such as RunAsync and WaitForShutdownAsync. `Microsoft.Extensions.Hosting.Internal.ConsoleLifetime` is pre-registered as the default lifetime implementation. The last lifetime registered is used.

```
var host = new HostBuilder()
    .UseConsoleLifetime()
```

Container configuration

To support plugging in other containers, the host can accept an IServiceProviderFactory<TContainerBuilder>. Providing a factory isn't part of the DI container registration but is instead a host intrinsic used to create the concrete DI container. UseServiceProviderFactory(IServiceProviderFactory<TContainerBuilder>) overrides the default factory used to create the app's service provider.

Custom container configuration is managed by the ConfigureContainer method. ConfigureContainer provides a strongly-typed experience for configuring the container on top of the underlying host API. ConfigureContainer can be called multiple times with additive results.

Create a service container for the app:

```
namespace GenericHostSample
{
    internal class ServiceContainer
    {
    }
}
```

Provide a service container factory:

```
using System;
using Microsoft.Extensions.DependencyInjection;

namespace GenericHostSample
{
    internal class ServiceContainerFactory :
        IServiceProviderFactory<ServiceContainer>
    {
        public ServiceContainer CreateBuilder(
            IServiceCollection services)
        {
            return new ServiceContainer();
        }

        public IServiceProvider CreateServiceProvider(
            ServiceContainer containerBuilder)
        {
            throw new NotImplementedException();
        }
    }
}
```

Use the factory and configure the custom service container for the app:

```
var host = new HostBuilder()
    .UseServiceProviderFactory<ServiceContainer>(new ServiceContainerFactory())
    .ConfigureContainer<ServiceContainer>((hostContext, container) =>
    {
    })
```

Extensibility

Host extensibility is performed with extension methods on IHostBuilder. The following example shows how an extension method extends an IHostBuilder implementation with the TimedHostedService example demonstrated in Background tasks with hosted services in ASP.NET Core.

```
var host = new HostBuilder()
    .UseHostedService<TimedHostedService>()
    .Build();

await host.StartAsync();
```

An app establishes the `UseHostedService` extension method to register the hosted service passed in `T`:

```
using System;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

public static class Extensions
{
    public static IHostBuilder UseHostedService<T>(this IHostBuilder hostBuilder)
        where T : class, IHostedService, IDisposable
    {
        return hostBuilder.ConfigureServices(services =>
            services.AddHostedService<T>());
    }
}
```

Manage the host

The IHost implementation is responsible for starting and stopping the IHostedService implementations that are registered in the service container.

Run

Run runs the app and blocks the calling thread until the host is shut down:

```
public class Program
{
    public void Main(string[] args)
    {
        var host = new HostBuilder()
            .Build();

        host.Run();
    }
}
```

RunAsync

RunAsync runs the app and returns a Task that completes when the cancellation token or shutdown is triggered:

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var host = new HostBuilder()
            .Build();

        await host.RunAsync();
    }
}
```

RunConsoleAsync

RunConsoleAsync enables console support, builds and starts the host, and waits for `Ctrl+C`/SIGINT or SIGTERM to shut down.

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var hostBuilder = new HostBuilder();

        await hostBuilder.RunConsoleAsync();
    }
}
```

Start and StopAsync

Start starts the host synchronously.

StopAsync attempts to stop the host within the provided timeout.

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var host = new HostBuilder()
            .Build();

        using (host)
        {
            host.Start();

            await host.StopAsync(TimeSpan.FromSeconds(5));
        }
    }
}
```

StartAsync and StopAsync

StartAsync starts the app.

StopAsync stops the app.

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var host = new HostBuilder()
            .Build();

        using (host)
        {
            await host.StartAsync();

            await host.StopAsync();
        }
    }
}
```

WaitForShutdown

WaitForShutdown is triggered via the IHostLifetime, such as `Microsoft.Extensions.Hosting.Internal.ConsoleLifetime` (listens for `Ctrl+C`/SIGINT or SIGTERM).

WaitForShutdown calls StopAsync.

```
public class Program
{
    public void Main(string[] args)
    {
        var host = new HostBuilder()
            .Build();

        using (host)
        {
            host.Start();

            host.WaitForShutdown();
        }
    }
}
```

WaitForShutdownAsync

WaitForShutdownAsync returns a Task that completes when shutdown is triggered via the given token and calls StopAsync.

```
public class Program
{
    public static async Task Main(string[] args)
    {
        var host = new HostBuilder()
            .Build();

        using (host)
        {
            await host.StartAsync();

            await host.WaitForShutdownAsync();
        }

    }
}
```

External control

External control of the host can be achieved using methods that can be called externally:

```
public class Program
{
    private IHost _host;

    public Program()
    {
        _host = new HostBuilder()
            .Build();
    }

    public async Task StartAsync()
    {
        _host.StartAsync();
    }

    public async Task StopAsync()
    {
        using (_host)
        {
            await _host.StopAsync(TimeSpan.FromSeconds(5));
        }
    }
}
```

WaitForStartAsync is called at the start of StartAsync, which waits until it's complete before continuing. This can be used to delay startup until signaled by an external event.

IHostingEnvironment interface

IHostingEnvironment provides information about the app's hosting environment. Use constructor injection to obtain the IHostingEnvironment in order to use its properties and extension methods:

```
public class MyClass
{
    private readonly IHostingEnvironment _env;

    public MyClass(IHostingEnvironment env)
    {
        _env = env;
    }

    public void DoSomething()
    {
        var environmentName = _env.EnvironmentName;
    }
}
```

For more information, see Use multiple environments in ASP.NET Core.

IApplicationLifetime interface

IApplicationLifetime allows for post-startup and shutdown activities, including graceful shutdown requests. Three properties on the interface are cancellation tokens used to register Action methods that define startup and shutdown events.

CANCELLATION TOKEN	TRIGGERED WHEN...
ApplicationStarted	The host has fully started.

CANCELLATION TOKEN	TRIGGERED WHEN...
ApplicationStopped	The host is completing a graceful shutdown. All requests should be processed. Shutdown blocks until this event completes.
ApplicationStopping	The host is performing a graceful shutdown. Requests may still be processing. Shutdown blocks until this event completes.

Constructor-inject the IApplicationLifetime service into any class. The sample app uses constructor injection into a `LifetimeEventsHostedService` class (an IHostedService implementation) to register the events.

LifetimeEventsHostedService.cs:

```
internal class LifetimeEventsHostedService : IHostedService
{
    private readonly ILogger _logger;
    private readonly IApplicationLifetime _appLifetime;

    public LifetimeEventsHostedService(
        ILogger<LifetimeEventsHostedService> logger,
        IApplicationLifetime appLifetime)
    {
        _logger = logger;
        _appLifetime = appLifetime;
    }

    public Task StartAsync(CancellationToken cancellationToken)
    {
        _appLifetime.ApplicationStarted.Register(OnStarted);
        _appLifetime.ApplicationStopping.Register(OnStopping);
        _appLifetime.ApplicationStopped.Register(OnStopped);

        return Task.CompletedTask;
    }

    public Task StopAsync(CancellationToken cancellationToken)
    {
        return Task.CompletedTask;
    }

    private void OnStarted()
    {
        _logger.LogInformation("OnStarted has been called.");

        // Perform post-startup activities here
    }

    private void OnStopping()
    {
        _logger.LogInformation("OnStopping has been called.");

        // Perform on-stopping activities here
    }

    private void OnStopped()
    {
        _logger.LogInformation("OnStopped has been called.");

        // Perform post-stopped activities here
    }
}
```

StopApplication requests termination of the app. The following class uses StopApplication to gracefully shut down an app when the class's `Shutdown` method is called:

```
public class MyClass
{
    private readonly IApplicationLifetime _appLifetime;

    public MyClass(IApplicationLifetime appLifetime)
    {
        _appLifetime = appLifetime;
    }

    public void Shutdown()
    {
        _appLifetime.StopApplication();
    }
}
```

The ASP.NET Core templates create a .NET Core Generic Host (HostBuilder).

Host definition

A *host* is an object that encapsulates an app's resources, such as:

- Dependency injection (DI)
- Logging
- Configuration
- `IHostedService` implementations

When a host starts, it calls IHostedService.StartAsync on each implementation of IHostedService registered in the service container's collection of hosted services. In a web app, one of the `IHostedService` implementations is a web service that starts an HTTP server implementation.

The main reason for including all of the app's interdependent resources in one object is lifetime management: control over app startup and graceful shutdown.

Set up a host

The host is typically configured, built, and run by code in the `Program` class. The `Main` method:

- Calls a `CreateHostBuilder` method to create and configure a builder object.
- Calls `Build` and `Run` methods on the builder object.

The ASP.NET Core web templates generate the following code to create a host:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code creates a non-HTTP workload with a `IHostedService` implementation added to the DI container.

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureServices((hostContext, services) =>
            {
               services.AddHostedService<Worker>();
            });
}
```

For an HTTP workload, the `Main` method is the same but `CreateHostBuilder` calls `ConfigureWebHostDefaults`:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

If the app uses Entity Framework Core, don't change the name or signature of the `CreateHostBuilder` method. The Entity Framework Core tools expect to find a `CreateHostBuilder` method that configures the host without running the app. For more information, see Design-time DbContext Creation.

Default builder settings

The CreateDefaultBuilder method:

- Sets the content root to the path returned by GetCurrentDirectory.
- Loads host configuration from:
  - Environment variables prefixed with `DOTNET_`.
  - Command-line arguments.
- Loads app configuration from:
  - *appsettings.json*.
  - *appsettings.{Environment}.json*.

    - Secret Manager when the app runs in the `Development` environment.
    - Environment variables.
    - Command-line arguments.
- Adds the following logging providers:
    - Console
    - Debug
    - EventSource
    - EventLog (only when running on Windows)
- Enables scope validation and dependency validation when the environment is Development.

The `ConfigureWebHostDefaults` method:

- Loads host configuration from environment variables prefixed with `ASPNETCORE_`.
- Sets Kestrel server as the web server and configures it using the app's hosting configuration providers. For the Kestrel server's default options, see Kestrel web server implementation in ASP.NET Core.
- Adds Host Filtering middleware.
- Adds Forwarded Headers middleware if `ASPNETCORE_FORWARDEDHEADERS_ENABLED` equals `true`.
- Enables IIS integration. For the IIS default options, see Host ASP.NET Core on Windows with IIS.

The Settings for all app types and Settings for web apps sections later in this article show how to override default builder settings.

Framework-provided services

The following services are registered automatically:

- IHostApplicationLifetime
- IHostLifetime
- IHostEnvironment / IWebHostEnvironment

For more information on framework-provided services, see Dependency injection in ASP.NET Core.

IHostApplicationLifetime

Inject the IHostApplicationLifetime (formerly `IApplicationLifetime`) service into any class to handle post-startup and graceful shutdown tasks. Three properties on the interface are cancellation tokens used to register app start and app stop event handler methods. The interface also includes a `StopApplication` method.

The following example is an `IHostedService` implementation that registers `IHostApplicationLifetime` events:

```
internal class LifetimeEventsHostedService : IHostedService
{
    private readonly ILogger _logger;
    private readonly IHostApplicationLifetime _appLifetime;

    public LifetimeEventsHostedService(
        ILogger<LifetimeEventsHostedService> logger,
        IHostApplicationLifetime appLifetime)
    {
        _logger = logger;
        _appLifetime = appLifetime;
    }

    public Task StartAsync(CancellationToken cancellationToken)
    {
        _appLifetime.ApplicationStarted.Register(OnStarted);
        _appLifetime.ApplicationStopping.Register(OnStopping);
        _appLifetime.ApplicationStopped.Register(OnStopped);

        return Task.CompletedTask;
    }

    public Task StopAsync(CancellationToken cancellationToken)
    {
        return Task.CompletedTask;
    }

    private void OnStarted()
    {
        _logger.LogInformation("OnStarted has been called.");

        // Perform post-startup activities here
    }

    private void OnStopping()
    {
        _logger.LogInformation("OnStopping has been called.");

        // Perform on-stopping activities here
    }

    private void OnStopped()
    {
        _logger.LogInformation("OnStopped has been called.");

        // Perform post-stopped activities here
    }
}
```

IHostLifetime

The IHostLifetime implementation controls when the host starts and when it stops. The last implementation registered is used.

`Microsoft.Extensions.Hosting.Internal.ConsoleLifetime` is the default `IHostLifetime` implementation. `ConsoleLifetime`:

- Listens for `Ctrl+C`/SIGINT or SIGTERM and calls StopApplication to start the shutdown process.
- Unblocks extensions such as RunAsync and WaitForShutdownAsync.

IHostEnvironment

Inject the IHostEnvironment service into a class to get information about the following settings:

- ApplicationName
- EnvironmentName
- ContentRootPath

Web apps implement the `IWebHostEnvironment` interface, which inherits `IHostEnvironment` and adds the WebRootPath.

Host configuration

Host configuration is used for the properties of the IHostEnvironment implementation.

Host configuration is available from HostBuilderContext.Configuration inside ConfigureAppConfiguration. After `ConfigureAppConfiguration`, `HostBuilderContext.Configuration` is replaced with the app config.

To add host configuration, call ConfigureHostConfiguration on `IHostBuilder`. `ConfigureHostConfiguration` can be called multiple times with additive results. The host uses whichever option sets a value last on a given key.

The environment variable provider with prefix `DOTNET_` and command-line arguments are included by `CreateDefaultBuilder`. For web apps, the environment variable provider with prefix `ASPNETCORE_` is added. The prefix is removed when the environment variables are read. For example, the environment variable value for `ASPNETCORE_ENVIRONMENT` becomes the host configuration value for the `environment` key.

The following example creates host configuration:

```
// using Microsoft.Extensions.Configuration;

Host.CreateDefaultBuilder(args)
    .ConfigureHostConfiguration(configHost =>
    {
        configHost.SetBasePath(Directory.GetCurrentDirectory());
        configHost.AddJsonFile("hostsettings.json", optional: true);
        configHost.AddEnvironmentVariables(prefix: "PREFIX_");
        configHost.AddCommandLine(args);
    });
```

App configuration

App configuration is created by calling ConfigureAppConfiguration on `IHostBuilder`. `ConfigureAppConfiguration` can be called multiple times with additive results. The app uses whichever option sets a value last on a given key.

The configuration created by `ConfigureAppConfiguration` is available at HostBuilderContext.Configuration for subsequent operations and as a service from DI. The host configuration is also added to the app configuration.

For more information, see Configuration in ASP.NET Core.

Settings for all app types

This section lists host settings that apply to both HTTP and non-HTTP workloads. By default, environment variables used to configure these settings can have a `DOTNET_` or `ASPNETCORE_` prefix.

ApplicationName

The IHostEnvironment.ApplicationName property is set from host configuration during host construction.

Key: `applicationName`
Type: `string`

Default: The name of the assembly that contains the app's entry point.
Environment variable: `<PREFIX_>APPLICATIONNAME`

To set this value, use the environment variable.

ContentRoot

The IHostEnvironment.ContentRootPath property determines where the host begins searching for content files. If the path doesn't exist, the host fails to start.

Key: `contentRoot`
Type: `string`
Default: The folder where the app assembly resides.
Environment variable: `<PREFIX_>CONTENTROOT`

To set this value, use the environment variable or call `UseContentRoot` on `IHostBuilder`:

```
Host.CreateDefaultBuilder(args)
    .UseContentRoot("c:\\content-root")
    //...
```

For more information, see:

- Fundamentals: Content root
- WebRoot

EnvironmentName

The IHostEnvironment.EnvironmentName property can be set to any value. Framework-defined values include `Development`, `Staging`, and `Production`. Values aren't case-sensitive.

Key: `environment`
Type: `string`
Default: `Production`
Environment variable: `<PREFIX_>ENVIRONMENT`

To set this value, use the environment variable or call `UseEnvironment` on `IHostBuilder`:

```
Host.CreateDefaultBuilder(args)
    .UseEnvironment("Development")
    //...
```

ShutdownTimeout

HostOptions.ShutdownTimeout sets the timeout for StopAsync. The default value is five seconds. During the timeout period, the host:

- Triggers IHostApplicationLifetime.ApplicationStopping.
- Attempts to stop hosted services, logging errors for services that fail to stop.

If the timeout period expires before all of the hosted services stop, any remaining active services are stopped when the app shuts down. The services stop even if they haven't finished processing. If services require additional time to stop, increase the timeout.

Key: `shutdownTimeoutSeconds`
Type: `int`
Default: 5 seconds
Environment variable: `<PREFIX_>SHUTDOWNTIMEOUTSECONDS`

To set this value, use the environment variable or configure `HostOptions`. The following example sets the timeout to 20 seconds:

```
Host.CreateDefaultBuilder(args)
    .ConfigureServices((hostContext, services) =>
    {
        services.Configure<HostOptions>(option =>
        {
            option.ShutdownTimeout = System.TimeSpan.FromSeconds(20);
        });
    });
```

Disable app configuration reload on change

By default, *appsettings.json* and *appsettings.{Environment}.json* are reloaded when the file changes. To disable this reload behavior in ASP.NET Core 5.0 Preview 3 or later, set the `hostBuilder:reloadConfigOnChange` key to `false`.

Key: `hostBuilder:reloadConfigOnChange`
Type: `bool` (`true` or `1`)
Default: `true`
Command-line argument: `hostBuilder:reloadConfigOnChange`
Environment variable: `<PREFIX_>hostBuilder:reloadConfigOnChange`

> **WARNING**
> The colon (`:`) separator doesn't work with environment variable hierarchical keys on all platforms. For more information, see Environment variables.

Settings for web apps

Some host settings apply only to HTTP workloads. By default, environment variables used to configure these settings can have a `DOTNET_` or `ASPNETCORE_` prefix.

Extension methods on `IWebHostBuilder` are available for these settings. Code samples that show how to call the extension methods assume `webBuilder` is an instance of `IWebHostBuilder`, as in the following example:

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.CaptureStartupErrors(true);
            webBuilder.UseStartup<Startup>();
        });
```

CaptureStartupErrors

When `false`, errors during startup result in the host exiting. When `true`, the host captures exceptions during startup and attempts to start the server.

Key: `captureStartupErrors`
Type: `bool` (`true` or `1`)
Default: Defaults to `false` unless the app runs with Kestrel behind IIS, where the default is `true`.
Environment variable: `<PREFIX_>CAPTURESTARTUPERRORS`

To set this value, use configuration or call `CaptureStartupErrors`:

```
webBuilder.CaptureStartupErrors(true);
```

DetailedErrors

When enabled, or when the environment is `Development`, the app captures detailed errors.

Key: `detailedErrors`
Type: `bool` (`true` or `1`)
Default: `false`
Environment variable: `<PREFIX_>_DETAILEDERRORS`

To set this value, use configuration or call `UseSetting`:

```
webBuilder.UseSetting(WebHostDefaults.DetailedErrorsKey, "true");
```

HostingStartupAssemblies

A semicolon-delimited string of hosting startup assemblies to load on startup. Although the configuration value defaults to an empty string, the hosting startup assemblies always include the app's assembly. When hosting startup assemblies are provided, they're added to the app's assembly for loading when the app builds its common services during startup.

Key: `hostingStartupAssemblies`
Type: `string`
Default: Empty string
Environment variable: `<PREFIX_>_HOSTINGSTARTUPASSEMBLIES`

To set this value, use configuration or call `UseSetting`:

```
webBuilder.UseSetting(WebHostDefaults.HostingStartupAssembliesKey, "assembly1;assembly2");
```

HostingStartupExcludeAssemblies

A semicolon-delimited string of hosting startup assemblies to exclude on startup.

Key: `hostingStartupExcludeAssemblies`
Type: `string`
Default: Empty string
Environment variable: `<PREFIX_>_HOSTINGSTARTUPEXCLUDEASSEMBLIES`

To set this value, use configuration or call `UseSetting`:

```
webBuilder.UseSetting(WebHostDefaults.HostingStartupExcludeAssembliesKey, "assembly1;assembly2");
```

HTTPS_Port

The HTTPS redirect port. Used in enforcing HTTPS.

Key: `https_port`
Type: `string`
Default: A default value isn't set.
Environment variable: `<PREFIX_>HTTPS_PORT`

To set this value, use configuration or call `UseSetting`:

```
webBuilder.UseSetting("https_port", "8080");
```

PreferHostingUrls

Indicates whether the host should listen on the URLs configured with the `IWebHostBuilder` instead of those URLs configured with the `IServer` implementation.

Key: `preferHostingUrls`
Type: `bool` (`true` or `1`)
Default: `true`
Environment variable: `<PREFIX_>_PREFERHOSTINGURLS`

To set this value, use the environment variable or call `PreferHostingUrls` :

```
webBuilder.PreferHostingUrls(false);
```

PreventHostingStartup

Prevents the automatic loading of hosting startup assemblies, including hosting startup assemblies configured by the app's assembly. For more information, see Use hosting startup assemblies in ASP.NET Core.

Key: `preventHostingStartup`
Type: `bool` (`true` or `1`)
Default: `false`
Environment variable: `<PREFIX_>_PREVENTHOSTINGSTARTUP`

To set this value, use the environment variable or call `UseSetting` :

```
webBuilder.UseSetting(WebHostDefaults.PreventHostingStartupKey, "true");
```

StartupAssembly

The assembly to search for the `Startup` class.

Key: `startupAssembly`
Type: `string`
Default: The app's assembly
Environment variable: `<PREFIX_>STARTUPASSEMBLY`

To set this value, use the environment variable or call `UseStartup` . `UseStartup` can take an assembly name (`string`) or a type (`TStartup`). If multiple `UseStartup` methods are called, the last one takes precedence.

```
webBuilder.UseStartup("StartupAssemblyName");
```

```
webBuilder.UseStartup<Startup>();
```

URLs

A semicolon-delimited list of IP addresses or host addresses with ports and protocols that the server should listen on for requests. For example, `http://localhost:123` . Use "*" to indicate that the server should listen for requests on any IP address or hostname using the specified port and protocol (for example, `http://*:5000`). The protocol (`http://` or `https://`) must be included with each URL. Supported formats vary among servers.

Key: `urls`
Type: `string`
Default: `http://localhost:5000` and `https://localhost:5001`
Environment variable: `<PREFIX_>URLS`

To set this value, use the environment variable or call `UseUrls`:

```
webBuilder.UseUrls("http://*:5000;http://localhost:5001;https://hostname:5002");
```

Kestrel has its own endpoint configuration API. For more information, see Kestrel web server implementation in ASP.NET Core.

WebRoot

The IWebHostEnvironment.WebRootPath property determines the relative path to the app's static assets. If the path doesn't exist, a no-op file provider is used.

Key: `webroot`
Type: `string`
Default: The default is `wwwroot`. The path to *{content root}/wwwroot* must exist.
Environment variable: `<PREFIX_>WEBROOT`

To set this value, use the environment variable or call `UseWebRoot` on `IWebHostBuilder`:

```
webBuilder.UseWebRoot("public");
```

For more information, see:

- Fundamentals: Web root
- ContentRoot

Manage the host lifetime

Call methods on the built IHost implementation to start and stop the app. These methods affect all IHostedService implementations that are registered in the service container.

Run

Run runs the app and blocks the calling thread until the host is shut down.

RunAsync

RunAsync runs the app and returns a Task that completes when the cancellation token or shutdown is triggered.

RunConsoleAsync

RunConsoleAsync enables console support, builds and starts the host, and waits for `Ctrl+C`/SIGINT or SIGTERM to shut down.

Start

Start starts the host synchronously.

StartAsync

StartAsync starts the host and returns a Task that completes when the cancellation token or shutdown is triggered.

WaitForStartAsync is called at the start of `StartAsync`, which waits until it's complete before continuing. This

can be used to delay startup until signaled by an external event.

StopAsync

StopAsync attempts to stop the host within the provided timeout.

WaitForShutdown

WaitForShutdown blocks the calling thread until shutdown is triggered by the IHostLifetime, such as via `Ctrl+C`/SIGINT or SIGTERM.

WaitForShutdownAsync

WaitForShutdownAsync returns a Task that completes when shutdown is triggered via the given token and calls StopAsync.

External control

Direct control of the host lifetime can be achieved using methods that can be called externally:

```
public class Program
{
    private IHost _host;

    public Program()
    {
        _host = new HostBuilder()
            .Build();
    }

    public async Task StartAsync()
    {
        _host.StartAsync();
    }

    public async Task StopAsync()
    {
        using (_host)
        {
            await _host.StopAsync(TimeSpan.FromSeconds(5));
        }
    }
}
```

ASP.NET Core Web Host

9/22/2020 • 17 minutes to read • Edit Online

ASP.NET Core apps configure and launch a *host*. The host is responsible for app startup and lifetime management. At a minimum, the host configures a server and a request processing pipeline. The host can also set up logging, dependency injection, and configuration.

This article covers the Web Host, which remains available only for backward compatibility. The Generic Host is recommended for all app types.

This article covers the Web Host, which is for hosting web apps. For other kinds of apps, use the Generic Host.

Set up a host

Create a host using an instance of IWebHostBuilder. This is typically performed in the app's entry point, the `Main` method.

In the project templates, `Main` is located in *Program.cs*. A typical app calls CreateDefaultBuilder to start setting up a host:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

The code that calls `CreateDefaultBuilder` is in a method named `CreateWebHostBuilder`, which separates it from the code in `Main` that calls `Run` on the builder object. This separation is required if you use Entity Framework Core tools. The tools expect to find a `CreateWebHostBuilder` method that they can call at design time to configure the host without running the app. An alternative is to implement `IDesignTimeDbContextFactory`. For more information, see Design-time DbContext Creation.

`CreateDefaultBuilder` performs the following tasks:

- Configures Kestrel server as the web server using the app's hosting configuration providers. For the Kestrel server's default options, see Kestrel web server implementation in ASP.NET Core.
- Sets the content root to the path returned by Directory.GetCurrentDirectory.
- Loads host configuration from:
  - Environment variables prefixed with `ASPNETCORE_` (for example, `ASPNETCORE_ENVIRONMENT`).
  - Command-line arguments.
- Loads app configuration in the following order from:
  - *appsettings.json*.
  - *appsettings.{Environment}.json*.
  - Secret Manager when the app runs in the `Development` environment using the entry assembly.
  - Environment variables.

    - Command-line arguments.
- Configures logging for console and debug output. Logging includes log filtering rules specified in a Logging configuration section of an *appsettings.json* or *appsettings.{Environment}.json* file.
- When running behind IIS with the ASP.NET Core Module, `CreateDefaultBuilder` enables IIS Integration, which configures the app's base address and port. IIS Integration also configures the app to capture startup errors. For the IIS default options, see Host ASP.NET Core on Windows with IIS.
- Sets ServiceProviderOptions.ValidateScopes to `true` if the app's environment is Development. For more information, see Scope validation.

The configuration defined by `CreateDefaultBuilder` can be overridden and augmented by ConfigureAppConfiguration, ConfigureLogging, and other methods and extension methods of IWebHostBuilder. A few examples follow:

- ConfigureAppConfiguration is used to specify additional `IConfiguration` for the app. The following `ConfigureAppConfiguration` call adds a delegate to include app configuration in the *appsettings.xml* file. `ConfigureAppConfiguration` may be called multiple times. Note that this configuration doesn't apply to the host (for example, server URLs or environment). See the Host configuration values section.

```
WebHost.CreateDefaultBuilder(args)
    .ConfigureAppConfiguration((hostingContext, config) =>
    {
        config.AddXmlFile("appsettings.xml", optional: true, reloadOnChange: true);
    })
    ...
```

- The following `ConfigureLogging` call adds a delegate to configure the minimum logging level (SetMinimumLevel) to LogLevel.Warning. This setting overrides the settings in *appsettings.Development.json* (`LogLevel.Debug`) and *appsettings.Production.json* (`LogLevel.Error`) configured by `CreateDefaultBuilder` . `ConfigureLogging` may be called multiple times.

```
WebHost.CreateDefaultBuilder(args)
    .ConfigureLogging(logging =>
    {
        logging.SetMinimumLevel(LogLevel.Warning);
    })
    ...
```

- The following call to `ConfigureKestrel` overrides the default Limits.MaxRequestBodySize of 30,000,000 bytes established when Kestrel was configured by `CreateDefaultBuilder` :

```
WebHost.CreateDefaultBuilder(args)
    .ConfigureKestrel((context, options) =>
    {
        options.Limits.MaxRequestBodySize = 20000000;
    });
```

- The following call to UseKestrel overrides the default Limits.MaxRequestBodySize of 30,000,000 bytes established when Kestrel was configured by `CreateDefaultBuilder` :

```
WebHost.CreateDefaultBuilder(args)
    .UseKestrel(options =>
    {
        options.Limits.MaxRequestBodySize = 20000000;
    });
```

The content root determines where the host searches for content files, such as MVC view files. When the app is started from the project's root folder, the project's root folder is used as the content root. This is the default used in Visual Studio and the dotnet new templates.

For more information on app configuration, see Configuration in ASP.NET Core.

> **NOTE**
> As an alternative to using the static `CreateDefaultBuilder` method, creating a host from WebHostBuilder is a supported approach with ASP.NET Core 2.x.

When setting up a host, Configure and ConfigureServices methods can be provided. If a `Startup` class is specified, it must define a `Configure` method. For more information, see App startup in ASP.NET Core. Multiple calls to `ConfigureServices` append to one another. Multiple calls to `Configure` or `UseStartup` on the `WebHostBuilder` replace previous settings.

Host configuration values

WebHostBuilder relies on the following approaches to set the host configuration values:

- Host builder configuration, which includes environment variables with the format `ASPNETCORE_{configurationKey}`. For example, `ASPNETCORE_ENVIRONMENT`.
- Extensions such as UseContentRoot and UseConfiguration (see the Override configuration section).
- UseSetting and the associated key. When setting a value with `UseSetting`, the value is set as a string regardless of the type.

The host uses whichever option sets a value last. For more information, see Override configuration in the next section.

Application Key (Name)

The `IWebHostEnvironment.ApplicationName` property is automatically set when UseStartup or Configure is called during host construction. The value is set to the name of the assembly containing the app's entry point. To set the value explicitly, use the WebHostDefaults.ApplicationKey:

The IHostingEnvironment.ApplicationName property is automatically set when UseStartup or Configure is called during host construction. The value is set to the name of the assembly containing the app's entry point. To set the value explicitly, use the WebHostDefaults.ApplicationKey:

Key: applicationName
Type: *string*
Default: The name of the assembly containing the app's entry point.
Set using: `UseSetting`
Environment variable: `ASPNETCORE_APPLICATIONNAME`

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.ApplicationKey, "CustomApplicationName")
```

Capture Startup Errors

This setting controls the capture of startup errors.

Key: captureStartupErrors
Type: *bool* (`true` or `1`)
Default: Defaults to `false` unless the app runs with Kestrel behind IIS, where the default is `true`.
Set using: `CaptureStartupErrors`

Environment variable: `ASPNETCORE_CAPTURESTARTUPERRORS`

When `false`, errors during startup result in the host exiting. When `true`, the host captures exceptions during startup and attempts to start the server.

```
WebHost.CreateDefaultBuilder(args)
    .CaptureStartupErrors(true)
```

Content root

This setting determines where ASP.NET Core begins searching for content files.

Key: contentRoot
Type: *string*
Default: Defaults to the folder where the app assembly resides.
Set using: `UseContentRoot`
Environment variable: `ASPNETCORE_CONTENTROOT`

The content root is also used as the base path for the web root. If the content root path doesn't exist, the host fails to start.

```
WebHost.CreateDefaultBuilder(args)
    .UseContentRoot("c:\\<content-root>")
```

For more information, see:

- Fundamentals: Content root
- Web root

Detailed Errors

Determines if detailed errors should be captured.

Key: detailedErrors
Type: *bool* (`true` or `1`)
Default: false
Set using: `UseSetting`
Environment variable: `ASPNETCORE_DETAILEDERRORS`

When enabled (or when the Environment is set to `Development`), the app captures detailed exceptions.

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.DetailedErrorsKey, "true")
```

Environment

Sets the app's environment.

Key: environment
Type: *string*
Default: Production
Set using: `UseEnvironment`
Environment variable: `ASPNETCORE_ENVIRONMENT`

The environment can be set to any value. Framework-defined values include `Development`, `Staging`, and `Production`. Values aren't case sensitive. By default, the *Environment* is read from the `ASPNETCORE_ENVIRONMENT` environment variable. When using Visual Studio, environment variables may be set in the *launchSettings.json* file.

For more information, see Use multiple environments in ASP.NET Core.

```
WebHost.CreateDefaultBuilder(args)
    .UseEnvironment(EnvironmentName.Development)
```

Hosting Startup Assemblies

Sets the app's hosting startup assemblies.

Key: hostingStartupAssemblies
Type: *string*
Default: Empty string
Set using: `UseSetting`
Environment variable: `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES`

A semicolon-delimited string of hosting startup assemblies to load on startup.

Although the configuration value defaults to an empty string, the hosting startup assemblies always include the app's assembly. When hosting startup assemblies are provided, they're added to the app's assembly for loading when the app builds its common services during startup.

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.HostingStartupAssembliesKey, "assembly1;assembly2")
```

HTTPS Port

Set the HTTPS redirect port. Used in enforcing HTTPS.

Key: https_port **Type**: *string* **Default**: A default value isn't set. **Set using**: `UseSetting` **Environment variable**: `ASPNETCORE_HTTPS_PORT`

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting("https_port", "8080")
```

Hosting Startup Exclude Assemblies

A semicolon-delimited string of hosting startup assemblies to exclude on startup.

Key: hostingStartupExcludeAssemblies
Type: *string*
Default: Empty string
Set using: `UseSetting`
Environment variable: `ASPNETCORE_HOSTINGSTARTUPEXCLUDEASSEMBLIES`

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.HostingStartupExcludeAssembliesKey, "assembly1;assembly2")
```

Prefer Hosting URLs

Indicates whether the host should listen on the URLs configured with the `WebHostBuilder` instead of those configured with the `IServer` implementation.

Key: preferHostingUrls
Type: *bool* (`true` or `1`)
Default: true
Set using: `PreferHostingUrls`

Environment variable: `ASPNETCORE_PREFERHOSTINGURLS`

```
WebHost.CreateDefaultBuilder(args)
    .PreferHostingUrls(false)
```

Prevent Hosting Startup

Prevents the automatic loading of hosting startup assemblies, including hosting startup assemblies configured by the app's assembly. For more information, see Use hosting startup assemblies in ASP.NET Core.

Key: preventHostingStartup
Type: *bool* (`true` or `1`)
Default: false
Set using: `UseSetting`
Environment variable: `ASPNETCORE_PREVENTHOSTINGSTARTUP`

```
WebHost.CreateDefaultBuilder(args)
    .UseSetting(WebHostDefaults.PreventHostingStartupKey, "true")
```

Server URLs

Indicates the IP addresses or host addresses with ports and protocols that the server should listen on for requests.

Key: urls
Type: *string*
Default: http://localhost:5000
Set using: `UseUrls`
Environment variable: `ASPNETCORE_URLS`

Set to a semicolon-separated (;) list of URL prefixes to which the server should respond. For example, `http://localhost:123`. Use "*" to indicate that the server should listen for requests on any IP address or hostname using the specified port and protocol (for example, `http://*:5000`). The protocol (`http://` or `https://`) must be included with each URL. Supported formats vary among servers.

```
WebHost.CreateDefaultBuilder(args)
    .UseUrls("http://*:5000;http://localhost:5001;https://hostname:5002")
```

Kestrel has its own endpoint configuration API. For more information, see Kestrel web server implementation in ASP.NET Core.

Shutdown Timeout

Specifies the amount of time to wait for Web Host to shut down.

Key: shutdownTimeoutSeconds
Type: *int*
Default: 5
Set using: `UseShutdownTimeout`
Environment variable: `ASPNETCORE_SHUTDOWNTIMEOUTSECONDS`

Although the key accepts an *int* with `UseSetting` (for example, `.UseSetting(WebHostDefaults.ShutdownTimeoutKey, "10")`), the UseShutdownTimeout extension method takes a TimeSpan.

During the timeout period, hosting:

- Triggers IApplicationLifetime.ApplicationStopping.
- Attempts to stop hosted services, logging any errors for services that fail to stop.

If the timeout period expires before all of the hosted services stop, any remaining active services are stopped when the app shuts down. The services stop even if they haven't finished processing. If services require additional time to stop, increase the timeout.

```
WebHost.CreateDefaultBuilder(args)
    .UseShutdownTimeout(TimeSpan.FromSeconds(10))
```

Startup Assembly

Determines the assembly to search for the `Startup` class.

Key: startupAssembly
Type: *string*
Default: The app's assembly
Set using: `UseStartup`
Environment variable: `ASPNETCORE_STARTUPASSEMBLY`

The assembly by name (`string`) or type (`TStartup`) can be referenced. If multiple `UseStartup` methods are called, the last one takes precedence.

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup("StartupAssemblyName")
```

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup<TStartup>()
```

Web root

Sets the relative path to the app's static assets.

Key: webroot
Type: *string*
Default: The default is `wwwroot`. The path to *{content root}/wwwroot* must exist. If the path doesn't exist, a no-op file provider is used.
Set using: `UseWebRoot`
Environment variable: `ASPNETCORE_WEBROOT`

```
WebHost.CreateDefaultBuilder(args)
    .UseWebRoot("public")
```

For more information, see:

- Fundamentals: Web root
- Content root

Override configuration

Use Configuration to configure Web Host. In the following example, host configuration is optionally specified in a *hostsettings.json* file. Any configuration loaded from the *hostsettings.json* file may be overridden by command-line arguments. The built configuration (in `config`) is used to configure the host with UseConfiguration. `IWebHostBuilder` configuration is added to the app's configuration, but the converse isn't true—

`ConfigureAppConfiguration` doesn't affect the `IWebHostBuilder` configuration.

Overriding the configuration provided by `UseUrls` with *hostsettings.json* config first, command-line argument config second:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args)
    {
        var config = new ConfigurationBuilder()
            .SetBasePath(Directory.GetCurrentDirectory())
            .AddJsonFile("hostsettings.json", optional: true)
            .AddCommandLine(args)
            .Build();

        return WebHost.CreateDefaultBuilder(args)
            .UseUrls("http://*:5000")
            .UseConfiguration(config)
            .Configure(app =>
            {
                app.Run(context =>
                    context.Response.WriteAsync("Hello, World!"));
            });
    }
}
```

hostsettings.json:

```
{
    urls: "http://*:5005"
}
```

> **NOTE**
>
> UseConfiguration only copies keys from the provided `IConfiguration` to the host builder configuration. Therefore, setting `reloadOnChange: true` for JSON, INI, and XML settings files has no effect.

To specify the host run on a particular URL, the desired value can be passed in from a command prompt when executing dotnet run. The command-line argument overrides the `urls` value from the *hostsettings.json* file, and the server listens on port 8080:

```
dotnet run --urls "http://*:8080"
```

Manage the host

Run

The `Run` method starts the web app and blocks the calling thread until the host is shut down:

```
host.Run();
```

Start

Run the host in a non-blocking manner by calling its `Start` method:

```
using (host)
{
    host.Start();
    Console.ReadLine();
}
```

If a list of URLs is passed to the `Start` method, it listens on the URLs specified:

```
var urls = new List<string>()
{
    "http://*:5000",
    "http://localhost:5001"
};

var host = new WebHostBuilder()
    .UseKestrel()
    .UseStartup<Startup>()
    .Start(urls.ToArray());

using (host)
{
    Console.ReadLine();
}
```

The app can initialize and start a new host using the pre-configured defaults of `CreateDefaultBuilder` using a static convenience method. These methods start the server without console output and with WaitForShutdown wait for a break (Ctrl-C/SIGINT or SIGTERM):

Start(RequestDelegate app)

Start with a `RequestDelegate`:

```
using (var host = WebHost.Start(app => app.Response.WriteAsync("Hello, World!")))
{
    Console.WriteLine("Use Ctrl-C to shutdown the host...");
    host.WaitForShutdown();
}
```

Make a request in the browser to `http://localhost:5000` to receive the response "Hello World!" `WaitForShutdown` blocks until a break (Ctrl-C/SIGINT or SIGTERM) is issued. The app displays the `Console.WriteLine` message and waits for a keypress to exit.

Start(string url, RequestDelegate app)

Start with a URL and `RequestDelegate`:

```
using (var host = WebHost.Start("http://localhost:8080", app => app.Response.WriteAsync("Hello, World!")))
{
    Console.WriteLine("Use Ctrl-C to shutdown the host...");
    host.WaitForShutdown();
}
```

Produces the same result as **Start(RequestDelegate app)**, except the app responds on `http://localhost:8080`.

Start(Action<IRouteBuilder> routeBuilder)

Use an instance of `IRouteBuilder` (Microsoft.AspNetCore.Routing) to use routing middleware:

```
using (var host = WebHost.Start(router => router
    .MapGet("hello/{name}", (req, res, data) =>
        res.WriteAsync($"Hello, {data.Values["name"]}!"))
    .MapGet("buenosdias/{name}", (req, res, data) =>
        res.WriteAsync($"Buenos dias, {data.Values["name"]}!"))
    .MapGet("throw/{message?}", (req, res, data) =>
        throw new Exception((string)data.Values["message"] ?? "Uh oh!"))
    .MapGet("{greeting}/{name}", (req, res, data) =>
        res.WriteAsync($"{data.Values["greeting"]}, {data.Values["name"]}!"))
    .MapGet("", (req, res, data) => res.WriteAsync("Hello, World!"))))
{
    Console.WriteLine("Use Ctrl-C to shutdown the host...");
    host.WaitForShutdown();
}
```

Use the following browser requests with the example:

REQUEST	RESPONSE
`http://localhost:5000/hello/Martin`	Hello, Martin!
`http://localhost:5000/buenosdias/Catrina`	Buenos dias, Catrina!
`http://localhost:5000/throw/ooops!`	Throws an exception with string "ooops!"
`http://localhost:5000/throw`	Throws an exception with string "Uh oh!"
`http://localhost:5000/Sante/Kevin`	Sante, Kevin!
`http://localhost:5000`	Hello World!

`WaitForShutdown` blocks until a break (Ctrl-C/SIGINT or SIGTERM) is issued. The app displays the `Console.WriteLine` message and waits for a keypress to exit.

Start(string url, Action<IRouteBuilder> routeBuilder)

Use a URL and an instance of `IRouteBuilder`:

```
using (var host = WebHost.Start("http://localhost:8080", router => router
    .MapGet("hello/{name}", (req, res, data) =>
        res.WriteAsync($"Hello, {data.Values["name"]}!"))
    .MapGet("buenosdias/{name}", (req, res, data) =>
        res.WriteAsync($"Buenos dias, {data.Values["name"]}!"))
    .MapGet("throw/{message?}", (req, res, data) =>
        throw new Exception((string)data.Values["message"] ?? "Uh oh!"))
    .MapGet("{greeting}/{name}", (req, res, data) =>
        res.WriteAsync($"{data.Values["greeting"]}, {data.Values["name"]}!"))
    .MapGet("", (req, res, data) => res.WriteAsync("Hello, World!"))))
{
    Console.WriteLine("Use Ctrl-C to shut down the host...");
    host.WaitForShutdown();
}
```

Produces the same result as **Start(Action<IRouteBuilder> routeBuilder)**, except the app responds at `http://localhost:8080`.

StartWith(Action<IApplicationBuilder> app)

Provide a delegate to configure an `IApplicationBuilder`:

```
using (var host = WebHost.StartWith(app =>
    app.Use(next =>
    {
        return async context =>
        {
            await context.Response.WriteAsync("Hello World!");
        };
    })))
{
    Console.WriteLine("Use Ctrl-C to shut down the host...");
    host.WaitForShutdown();
}
```

Make a request in the browser to `http://localhost:5000` to receive the response "Hello World!" `WaitForShutdown` blocks until a break (Ctrl-C/SIGINT or SIGTERM) is issued. The app displays the `Console.WriteLine` message and waits for a keypress to exit.

StartWith(string url, Action<IApplicationBuilder> app)

Provide a URL and a delegate to configure an `IApplicationBuilder`:

```
using (var host = WebHost.StartWith("http://localhost:8080", app =>
    app.Use(next =>
    {
        return async context =>
        {
            await context.Response.WriteAsync("Hello World!");
        };
    })))
{
    Console.WriteLine("Use Ctrl-C to shut down the host...");
    host.WaitForShutdown();
}
```

Produces the same result as **StartWith(Action<IApplicationBuilder> app)**, except the app responds on `http://localhost:8080`.

IWebHostEnvironment interface

The `IWebHostEnvironment` interface provides information about the app's web hosting environment. Use constructor injection to obtain the `IWebHostEnvironment` in order to use its properties and extension methods:

```
public class CustomFileReader
{
    private readonly IWebHostEnvironment _env;

    public CustomFileReader(IWebHostEnvironment env)
    {
        _env = env;
    }

    public string ReadFile(string filePath)
    {
        var fileProvider = _env.WebRootFileProvider;
        // Process the file here
    }
}
```

A convention-based approach can be used to configure the app at startup based on the environment. Alternatively, inject the `IWebHostEnvironment` into the `Startup` constructor for use in `ConfigureServices`:

```
public class Startup
{
    public Startup(IWebHostEnvironment env)
    {
        HostingEnvironment = env;
    }

    public IWebHostEnvironment HostingEnvironment { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        if (HostingEnvironment.IsDevelopment())
        {
            // Development configuration
        }
        else
        {
            // Staging/Production configuration
        }

        var contentRootPath = HostingEnvironment.ContentRootPath;
    }
}
```

NOTE

In addition to the `IsDevelopment` extension method, `IWebHostEnvironment` offers `IsStaging`, `IsProduction`, and `IsEnvironment(string environmentName)` methods. For more information, see Use multiple environments in ASP.NET Core.

The `IWebHostEnvironment` service can also be injected directly into the `Configure` method for setting up the processing pipeline:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        // In Development, use the Developer Exception Page
        app.UseDeveloperExceptionPage();
    }
    else
    {
        // In Staging/Production, route exceptions to /error
        app.UseExceptionHandler("/error");
    }

    var contentRootPath = env.ContentRootPath;
}
```

`IWebHostEnvironment` can be injected into the `Invoke` method when creating custom middleware:

```
public async Task Invoke(HttpContext context, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        // Configure middleware for Development
    }
    else
    {
        // Configure middleware for Staging/Production
    }

    var contentRootPath = env.ContentRootPath;
}
```

IHostingEnvironment interface

The IHostingEnvironment interface provides information about the app's web hosting environment. Use constructor injection to obtain the `IHostingEnvironment` in order to use its properties and extension methods:

```
public class CustomFileReader
{
    private readonly IHostingEnvironment _env;

    public CustomFileReader(IHostingEnvironment env)
    {
        _env = env;
    }

    public string ReadFile(string filePath)
    {
        var fileProvider = _env.WebRootFileProvider;
        // Process the file here
    }
}
```

A convention-based approach can be used to configure the app at startup based on the environment. Alternatively, inject the `IHostingEnvironment` into the `Startup` constructor for use in `ConfigureServices`:

```
public class Startup
{
    public Startup(IHostingEnvironment env)
    {
        HostingEnvironment = env;
    }

    public IHostingEnvironment HostingEnvironment { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        if (HostingEnvironment.IsDevelopment())
        {
            // Development configuration
        }
        else
        {
            // Staging/Production configuration
        }

        var contentRootPath = HostingEnvironment.ContentRootPath;
    }
}
```

NOTE

In addition to the `IsDevelopment` extension method, `IHostingEnvironment` offers `IsStaging`, `IsProduction`, and `IsEnvironment(string environmentName)` methods. For more information, see Use multiple environments in ASP.NET Core.

The `IHostingEnvironment` service can also be injected directly into the `Configure` method for setting up the processing pipeline:

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        // In Development, use the Developer Exception Page
        app.UseDeveloperExceptionPage();
    }
    else
    {
        // In Staging/Production, route exceptions to /error
        app.UseExceptionHandler("/error");
    }

    var contentRootPath = env.ContentRootPath;
}
```

`IHostingEnvironment` can be injected into the `Invoke` method when creating custom middleware:

```
public async Task Invoke(HttpContext context, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        // Configure middleware for Development
    }
    else
    {
        // Configure middleware for Staging/Production
    }

    var contentRootPath = env.ContentRootPath;
}
```

IHostApplicationLifetime interface

`IHostApplicationLifetime` allows for post-startup and shutdown activities. Three properties on the interface are cancellation tokens used to register `Action` methods that define startup and shutdown events.

CANCELLATION TOKEN	TRIGGERED WHEN...
`ApplicationStarted`	The host has fully started.
`ApplicationStopped`	The host is completing a graceful shutdown. All requests should be processed. Shutdown blocks until this event completes.
`ApplicationStopping`	The host is performing a graceful shutdown. Requests may still be processing. Shutdown blocks until this event completes.

```
public class Startup
{
    public void Configure(IApplicationBuilder app, IHostApplicationLifetime appLifetime)
    {
        appLifetime.ApplicationStarted.Register(OnStarted);
        appLifetime.ApplicationStopping.Register(OnStopping);
        appLifetime.ApplicationStopped.Register(OnStopped);

        Console.CancelKeyPress += (sender, eventArgs) =>
        {
            appLifetime.StopApplication();
            // Don't terminate the process immediately, wait for the Main thread to exit gracefully.
            eventArgs.Cancel = true;
        };
    }

    private void OnStarted()
    {
        // Perform post-startup activities here
    }

    private void OnStopping()
    {
        // Perform on-stopping activities here
    }

    private void OnStopped()
    {
        // Perform post-stopped activities here
    }
}
```

`StopApplication` requests termination of the app. The following class uses `StopApplication` to gracefully shut down an app when the class's `Shutdown` method is called:

```
public class MyClass
{
    private readonly IHostApplicationLifetime _appLifetime;

    public MyClass(IHostApplicationLifetime appLifetime)
    {
        _appLifetime = appLifetime;
    }

    public void Shutdown()
    {
        _appLifetime.StopApplication();
    }
}
```

IApplicationLifetime interface

IApplicationLifetime allows for post-startup and shutdown activities. Three properties on the interface are cancellation tokens used to register `Action` methods that define startup and shutdown events.

CANCELLATION TOKEN	TRIGGERED WHEN...
ApplicationStarted	The host has fully started.

CANCELLATION TOKEN	TRIGGERED WHEN...
ApplicationStopped	The host is completing a graceful shutdown. All requests should be processed. Shutdown blocks until this event completes.
ApplicationStopping	The host is performing a graceful shutdown. Requests may still be processing. Shutdown blocks until this event completes.

```
public class Startup
{
    public void Configure(IApplicationBuilder app, IApplicationLifetime appLifetime)
    {
        appLifetime.ApplicationStarted.Register(OnStarted);
        appLifetime.ApplicationStopping.Register(OnStopping);
        appLifetime.ApplicationStopped.Register(OnStopped);

        Console.CancelKeyPress += (sender, eventArgs) =>
        {
            appLifetime.StopApplication();
            // Don't terminate the process immediately, wait for the Main thread to exit gracefully.
            eventArgs.Cancel = true;
        };
    }

    private void OnStarted()
    {
        // Perform post-startup activities here
    }

    private void OnStopping()
    {
        // Perform on-stopping activities here
    }

    private void OnStopped()
    {
        // Perform post-stopped activities here
    }
}
```

StopApplication requests termination of the app. The following class uses `StopApplication` to gracefully shut down an app when the class's `Shutdown` method is called:

```
public class MyClass
{
    private readonly IApplicationLifetime _appLifetime;

    public MyClass(IApplicationLifetime appLifetime)
    {
        _appLifetime = appLifetime;
    }

    public void Shutdown()
    {
        _appLifetime.StopApplication();
    }
}
```

Scope validation

CreateDefaultBuilder sets ServiceProviderOptions.ValidateScopes to `true` if the app's environment is Development.

When `ValidateScopes` is set to `true`, the default service provider performs checks to verify that:

- Scoped services aren't directly or indirectly resolved from the root service provider.
- Scoped services aren't directly or indirectly injected into singletons.

The root service provider is created when BuildServiceProvider is called. The root service provider's lifetime corresponds to the app/server's lifetime when the provider starts with the app and is disposed when the app shuts down.

Scoped services are disposed by the container that created them. If a scoped service is created in the root container, the service's lifetime is effectively promoted to singleton because it's only disposed by the root container when app/server is shut down. Validating service scopes catches these situations when `BuildServiceProvider` is called.

To always validate scopes, including in the Production environment, configure the ServiceProviderOptions with UseDefaultServiceProvider on the host builder:

```
WebHost.CreateDefaultBuilder(args)
    .UseDefaultServiceProvider((context, options) => {
        options.ValidateScopes = true;
    })
```

Web server implementations in ASP.NET Core

9/22/2020 • 7 minutes to read • Edit Online

By Tom Dykstra, Steve Smith, Stephen Halter, and Chris Ross

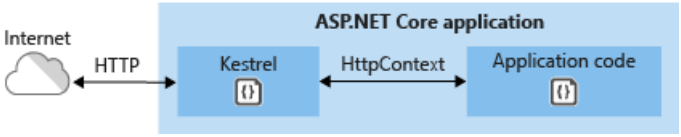
An ASP.NET Core app runs with an in-process HTTP server implementation. The server implementation listens for HTTP requests and surfaces them to the app as a set of request features composed into an HttpContext.

Kestrel

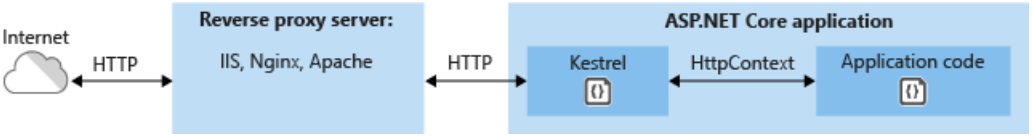
Kestrel is the default web server specified by the ASP.NET Core project templates.

Use Kestrel:

- By itself as an edge server processing requests directly from a network, including the Internet.



- With a *reverse proxy server*, such as Internet Information Services (IIS), Nginx, or Apache. A reverse proxy server receives HTTP requests from the Internet and forwards them to Kestrel.



Either hosting configuration—with or without a reverse proxy server—is supported.

For Kestrel configuration guidance and information on when to use Kestrel in a reverse proxy configuration, see Kestrel web server implementation in ASP.NET Core.

- Windows
- macOS
- Linux

ASP.NET Core ships with the following:

- Kestrel server is the default, cross-platform HTTP server implementation.
- IIS HTTP Server is an in-process server for IIS.
- HTTP.sys server is a Windows-only HTTP server based on the HTTP.sys kernel driver and HTTP Server API.

When using IIS or IIS Express, the app either runs:

- In the same process as the IIS worker process (the in-process hosting model) with the IIS HTTP Server. *In-process* is the recommended configuration.
- In a process separate from the IIS worker process (the out-of-process hosting model) with the Kestrel server.

The ASP.NET Core Module is a native IIS module that handles native IIS requests between IIS and the in-process IIS HTTP Server or Kestrel. For more information, see ASP.NET Core Module.

Hosting models

Using in-process hosting, an ASP.NET Core app runs in the same process as its IIS worker process. In-process hosting provides improved performance over out-of-process hosting because requests aren't proxied over the loopback adapter, a network interface that returns outgoing network traffic back to the same machine. IIS handles process management with the Windows Process Activation Service (WAS).

Using out-of-process hosting, ASP.NET Core apps run in a process separate from the IIS worker process, and the module handles process management. The module starts the process for the ASP.NET Core app when the first request arrives and restarts the app if it shuts down or crashes. This is essentially the same behavior as seen with apps that run in-process that are managed by the Windows Process Activation Service (WAS).

For more information and configuration guidance, see the following topics:

- Host ASP.NET Core on Windows with IIS
- ASP.NET Core Module

- Windows
- macOS
- Linux

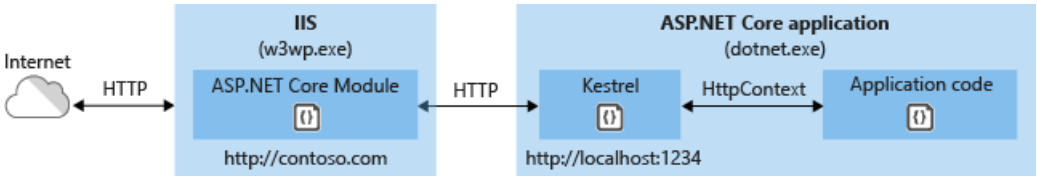
ASP.NET Core ships with the following:

- Kestrel server is the default, cross-platform HTTP server.
- HTTP.sys server is a Windows-only HTTP server based on the HTTP.sys kernel driver and HTTP Server API.

When using IIS or IIS Express, the app runs in a process separate from the IIS worker process (*out-of-process*) with the Kestrel server.

Because ASP.NET Core apps run in a process separate from the IIS worker process, the module handles process management. The module starts the process for the ASP.NET Core app when the first request arrives and restarts the app if it shuts down or crashes. This is essentially the same behavior as seen with apps that run in-process that are managed by the Windows Process Activation Service (WAS).

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app hosted out-of-process:



Requests arrive from the web to the kernel-mode HTTP.sys driver. The driver routes the requests to IIS on the website's configured port, usually 80 (HTTP) or 443 (HTTPS). The module forwards the requests to Kestrel on a random port for the app, which isn't port 80 or 443.

The module specifies the port via an environment variable at startup, and the IIS Integration Middleware configures the server to listen on `http://localhost:{port}`. Additional checks are performed, and requests that don't originate from the module are rejected. The module doesn't support HTTPS forwarding, so requests are forwarded over HTTP even if received by IIS over HTTPS.

After Kestrel picks up the request from the module, the request is pushed into the ASP.NET Core middleware pipeline. The middleware pipeline handles the request and passes it on as an `HttpContext` instance to the app's logic. Middleware added by IIS Integration updates the scheme, remote IP, and pathbase to account for forwarding the request to Kestrel. The app's response is passed back to IIS, which pushes it back out to the HTTP client that initiated the request.

For IIS and ASP.NET Core Module configuration guidance, see the following topics:

- Host ASP.NET Core on Windows with IIS
- ASP.NET Core Module

Nginx with Kestrel

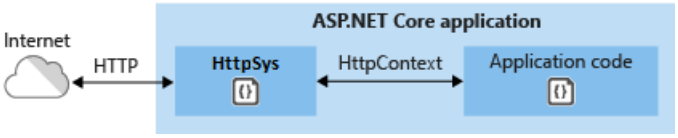
For information on how to use Nginx on Linux as a reverse proxy server for Kestrel, see Host ASP.NET Core on Linux with Nginx.

Apache with Kestrel

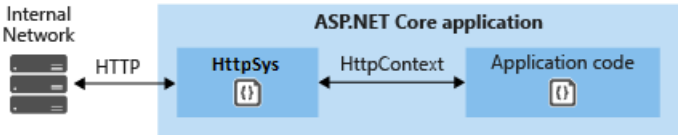
For information on how to use Apache on Linux as a reverse proxy server for Kestrel, see Host ASP.NET Core on Linux with Apache.

HTTP.sys

If ASP.NET Core apps are run on Windows, HTTP.sys is an alternative to Kestrel. Kestrel is generally recommended for best performance. HTTP.sys can be used in scenarios where the app is exposed to the Internet and required capabilities are supported by HTTP.sys but not Kestrel. For more information, see HTTP.sys web server implementation in ASP.NET Core.



HTTP.sys can also be used for apps that are only exposed to an internal network.



For HTTP.sys configuration guidance, see HTTP.sys web server implementation in ASP.NET Core.

ASP.NET Core server infrastructure

The IApplicationBuilder available in the `Startup.Configure` method exposes the ServerFeatures property of type IFeatureCollection. Kestrel and HTTP.sys only expose a single feature each, IServerAddressesFeature, but different server implementations may expose additional functionality.

`IServerAddressesFeature` can be used to find out which port the server implementation has bound at runtime.

Custom servers

If the built-in servers don't meet the app's requirements, a custom server implementation can be created. The Open Web Interface for .NET (OWIN) guide demonstrates how to write a Nowin-based IServer implementation. Only the feature interfaces that the app uses require implementation, though at a minimum IHttpRequestFeature and IHttpResponseFeature must be supported.

Server startup

The server is launched when the Integrated Development Environment (IDE) or editor starts the app:

- Visual Studio: Launch profiles can be used to start the app and server with either IIS Express/ASP.NET Core Module or the console.
- Visual Studio Code: The app and server are started by Omnisharp, which activates the CoreCLR debugger.
- Visual Studio for Mac: The app and server are started by the Mono Soft-Mode Debugger.

When launching the app from a command prompt in the project's folder, dotnet run launches the app and server

(Kestrel and HTTP.sys only). The configuration is specified by the `-c|--configuration` option, which is set to either `Debug` (default) or `Release`.

A *launchSettings.json* file provides configuration when launching an app with `dotnet run` or with a debugger built into tooling, such as Visual Studio. If launch profiles are present in a *launchSettings.json* file, use the `--launch-profile {PROFILE NAME}` option with the `dotnet run` command or select the profile in Visual Studio. For more information, see dotnet run and .NET Core distribution packaging.

HTTP/2 support

HTTP/2 is supported with ASP.NET Core in the following deployment scenarios:

- Kestrel
  - Operating system
    - Windows Server 2016/Windows 10 or later†
    - Linux with OpenSSL 1.0.2 or later (for example, Ubuntu 16.04 or later)
    - HTTP/2 will be supported on macOS in a future release.
  - Target framework: .NET Core 2.2 or later
- HTTP.sys
  - Windows Server 2016/Windows 10 or later
  - Target framework: Not applicable to HTTP.sys deployments.
- IIS (in-process)
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - Target framework: .NET Core 2.2 or later
- IIS (out-of-process)
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - Public-facing edge server connections use HTTP/2, but the reverse proxy connection to Kestrel uses HTTP/1.1.
  - Target framework: Not applicable to IIS out-of-process deployments.

†Kestrel has limited support for HTTP/2 on Windows Server 2012 R2 and Windows 8.1. Support is limited because the list of supported TLS cipher suites available on these operating systems is limited. A certificate generated using an Elliptic Curve Digital Signature Algorithm (ECDSA) may be required to secure TLS connections.

- HTTP.sys
  - Windows Server 2016/Windows 10 or later
  - Target framework: Not applicable to HTTP.sys deployments.
- IIS (out-of-process)
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - Public-facing edge server connections use HTTP/2, but the reverse proxy connection to Kestrel uses HTTP/1.1.
  - Target framework: Not applicable to IIS out-of-process deployments.

An HTTP/2 connection must use Application-Layer Protocol Negotiation (ALPN) and TLS 1.2 or later. For more information, see the topics that pertain to your server deployment scenarios.

Configuration in ASP.NET Core

9/22/2020 • 60 minutes to read • Edit Online

By Rick Anderson and Kirk Larkin

Configuration in ASP.NET Core is performed using one or more configuration providers. Configuration providers read configuration data from key-value pairs using a variety of configuration sources:

- Settings files, such as *appsettings.json*
- Environment variables
- Azure Key Vault
- Azure App Configuration
- Command-line arguments
- Custom providers, installed or created
- Directory files
- In-memory .NET objects

View or download sample code (how to download)

Default configuration

ASP.NET Core web apps created with dotnet new or Visual Studio generate the following code:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

CreateDefaultBuilder provides default configuration for the app in the following order:

1. ChainedConfigurationProvider : Adds an existing `IConfiguration` as a source. In the default configuration case, adds the host configuration and setting it as the first source for the *app* configuration.
2. appsettings.json using the JSON configuration provider.
3. *appsettings.*`Environment`*.json* using the JSON configuration provider. For example, *appsettings.**Production**.json* and *appsettings.**Development**.json*.
4. App secrets when the app runs in the `Development` environment.
5. Environment variables using the Environment Variables configuration provider.
6. Command-line arguments using the Command-line configuration provider.

Configuration providers that are added later override previous key settings. For example, if

`MyKey` is set in both *appsettings.json* and the environment, the environment value is used. Using the default configuration providers, the Command-line configuration provider overrides all other providers.

For more information on `CreateDefaultBuilder`, see Default builder settings.

The following code displays the enabled configuration providers in the order they were added:

```
public class Index2Model : PageModel
{
    private IConfigurationRoot ConfigRoot;

    public Index2Model(IConfiguration configRoot)
    {
        ConfigRoot = (IConfigurationRoot)configRoot;
    }

    public ContentResult OnGet()
    {
        string str = "";
        foreach (var provider in ConfigRoot.Providers.ToList())
        {
            str += provider.ToString() + "\n";
        }

        return Content(str);
    }
}
```

appsettings.json

Consider the following *appsettings.json* file:

```
{
  "Position": {
    "Title": "Editor",
    "Name": "Joe Smith"
  },
  "MyKey":  "My appsettings.json Value",
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

The following code from the sample download displays several of the preceding configurations settings:

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

The default JsonConfigurationProvider loads configuration in the following order:

1. *appsettings.json*
2. *appsettings.*`Environment`*.json* : For example, the *appsettings.**Production**.json* and *appsettings.**Development**.json* files. The environment version of the file is loaded based on the IHostingEnvironment.EnvironmentName. For more information, see Use multiple environments in ASP.NET Core.

appsettings.`Environment`*.json* values override keys in *appsettings.json*. For example, by default:

- In development, *appsettings.**Development**.json* configuration overwrites values found in *appsettings.json*.
- In production, *appsettings.**Production**.json* configuration overwrites values found in *appsettings.json*. For example, when deploying the app to Azure.

Bind hierarchical configuration data using the options pattern

The preferred way to read related configuration values is using the options pattern. For example, to read the following configuration values:

```
  "Position": {
    "Title": "Editor",
    "Name": "Joe Smith"
  }
```

Create the following `PositionOptions` class:

```
public class PositionOptions
{
    public const string Position = "Position";

    public string Title { get; set; }
    public string Name { get; set; }
}
```

An options class:

- Must be non-abstract with a public parameterless constructor.
- All public read-write properties of the type are bound.
- Fields are ***not*** bound. In the preceding code, `Position` is not bound. The `Position` property is used so the string `"Position"` doesn't need to be hard coded in the app when binding the class to a configuration provider.

The following code:

- Calls ConfigurationBinder.Bind to bind the `PositionOptions` class to the `Position` section.
- Displays the `Position` configuration data.

```
public class Test22Model : PageModel
{
    private readonly IConfiguration Configuration;

    public Test22Model(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var positionOptions = new PositionOptions();
        Configuration.GetSection(PositionOptions.Position).Bind(positionOptions);

        return Content($"Title: {positionOptions.Title} \n" +
                       $"Name: {positionOptions.Name}");
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has started are read.

`ConfigurationBinder.Get<T>` binds and returns the specified type. `ConfigurationBinder.Get<T>` may be more convenient than using `ConfigurationBinder.Bind`. The following code shows how to use `ConfigurationBinder.Get<T>` with the `PositionOptions` class:

```
public class Test21Model : PageModel
{
    private readonly IConfiguration Configuration;
    public PositionOptions positionOptions { get; private set; }

    public Test21Model(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        positionOptions = Configuration.GetSection(PositionOptions.Position)
                                                    .Get<PositionOptions>();

        return Content($"Title: {positionOptions.Title} \n" +
                       $"Name: {positionOptions.Name}");
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has

started are read.

An alternative approach when using the ***options pattern*** is to bind the `Position` section and add it to the dependency injection service container. In the following code, `PositionOptions` is added to the service container with Configure and bound to configuration:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<PositionOptions>(Configuration.GetSection(
                                        PositionOptions.Position));
    services.AddRazorPages();
}
```

Using the preceding code, the following code reads the position options:

```
public class Test2Model : PageModel
{
    private readonly PositionOptions _options;

    public Test2Model(IOptions<PositionOptions> options)
    {
        _options = options.Value;
    }

    public ContentResult OnGet()
    {
        return Content($"Title: {_options.Title} \n" +
                       $"Name: {_options.Name}");
    }
}
```

In the preceding code, changes to the JSON configuration file after the app has started are ***not*** read. To read changes after the app has started, use IOptionsSnapshot.

Using the default configuration, the *appsettings.json* and *appsettings.*`Environment`*.json* files are enabled with reloadOnChange: true. Changes made to the *appsettings.json* and *appsettings.*`Environment`*.json* file ***after*** the app starts are read by the JSON configuration provider.

See JSON configuration provider in this document for information on adding additional JSON configuration files.

Combining service collection

Consider the following `ConfigureServices` method, which registers services and configures options:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<PositionOptions>(
        Configuration.GetSection(PositionOptions.Position));
    services.Configure<ColorOptions>(
        Configuration.GetSection(ColorOptions.Color));

    services.AddScoped<IMyDependency, MyDependency>();
    services.AddScoped<IMyDependency2, MyDependency2>();

    services.AddRazorPages();
}
```

Related groups of registrations can be moved to an extension method to register services. For example, the configuration services are added to the following class:

```
using ConfigSample.Options;
using Microsoft.Extensions.Configuration;

namespace Microsoft.Extensions.DependencyInjection
{
    public static class MyConfigServiceCollectionExtensions
    {
        public static IServiceCollection AddConfig(
             this IServiceCollection services, IConfiguration config)
        {
            services.Configure<PositionOptions>(
                config.GetSection(PositionOptions.Position));
            services.Configure<ColorOptions>(
                config.GetSection(ColorOptions.Color));

            return services;
        }
    }
}
```

The remaining services are registered in a similar class. The following `ConfigureServices` method uses the new extension methods to register the services:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddConfig(Configuration)
            .AddMyDependencyGroup();

    services.AddRazorPages();
}
```

Note: Each `services.Add{GROUP_NAME}` extension method adds and potentially configures services. For example, AddControllersWithViews adds the services MVC controllers with views require, and AddRazorPages adds the services Razor Pages requires. We recommended that apps follow this naming convention. Place extension methods in the Microsoft.Extensions.DependencyInjection namespace to encapsulate groups of service registrations.

Security and secret manager

Configuration data guidelines:

- Never store passwords or other sensitive data in configuration provider code or in plain text configuration files. The Secret manager can be used to store secrets in development.
- Don't use production secrets in development or test environments.
- Specify secrets outside of the project so that they can't be accidentally committed to a source code repository.

By default, Secret manager reads configuration settings after *appsettings.json* and *appsettings.* `Environment` *.json*.

For more information on storing passwords or other sensitive data:

- Use multiple environments in ASP.NET Core
- Safe storage of app secrets in development in ASP.NET Core: Includes advice on using

environment variables to store sensitive data. The Secret Manager uses the File configuration provider to store user secrets in a JSON file on the local system.

Azure Key Vault safely stores app secrets for ASP.NET Core apps. For more information, see Azure Key Vault Configuration Provider in ASP.NET Core.

Environment variables

Using the default configuration, the EnvironmentVariablesConfigurationProvider loads configuration from environment variable key-value pairs after reading *appsettings.json*, *appsettings.*`Environment`*.json*, and Secret manager. Therefore, key values read from the environment override values read from *appsettings.json*, *appsettings.*`Environment`*.json*, and Secret manager.

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

The following `set` commands:

- Set the environment keys and values of the preceding example on Windows.
- Test the settings when using the sample download. The `dotnet run` command must be run in the project directory.

```
set MyKey="My key from Environment"
set Position__Title=Environment_Editor
set Position__Name=Environment_Rick
dotnet run
```

The preceding environment settings:

- Are only set in processes launched from the command window they were set in.
- Won't be read by browsers launched with Visual Studio.

The following setx commands can be used to set the environment keys and values on Windows. Unlike `set`, `setx` settings are persisted. `/M` sets the variable in the system environment. If the `/M` switch isn't used, a user environment variable is set.

```
setx MyKey "My key from setx Environment" /M
setx Position__Title Setx_Environment_Editor /M
setx Position__Name Environment_Rick /M
```

To test that the preceding commands override *appsettings.json* and *appsettings.*`Environment`*.json*:

- With Visual Studio: Exit and restart Visual Studio.
- With the CLI: Start a new command window and enter `dotnet run`.

Call AddEnvironmentVariables with a string to specify a prefix for environment variables:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddEnvironmentVariables(prefix: "MyCustomPrefix_");
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

In the preceding code:

- `config.AddEnvironmentVariables(prefix: "MyCustomPrefix_")` is added after the default configuration providers. For an example of ordering the configuration providers, see JSON configuration provider.
- Environment variables set with the `MyCustomPrefix_` prefix override the default configuration providers. This includes environment variables without the prefix.

The prefix is stripped off when the configuration key-value pairs are read.

The following commands test the custom prefix:

```
set MyCustomPrefix_MyKey="My key with MyCustomPrefix_ Environment"
set MyCustomPrefix_Position__Title=Editor_with_customPrefix
set MyCustomPrefix_Position__Name=Environment_Rick_cp
dotnet run
```

The default configuration loads environment variables and command line arguments prefixed with `DOTNET_` and `ASPNETCORE_`. The `DOTNET_` and `ASPNETCORE_` prefixes are used by ASP.NET Core for host and app configuration, but not for user configuration. For more information on host and app configuration, see .NET Generic Host.

On Azure App Service, select **New application setting** on the **Settings > Configuration** page. Azure App Service application settings are:

- Encrypted at rest and transmitted over an encrypted channel.
- Exposed as environment variables.

For more information, see Azure Apps: Override app configuration using the Azure Portal.

See Connection string prefixes for information on Azure database connection strings.

Environment variables set in launchSettings.json

Environment variables set in *launchSettings.json* override those set in the system environment.

Command-line

Using the default configuration, the CommandLineConfigurationProvider loads configuration from command-line argument key-value pairs after the following configuration sources:

- *appsettings.json* and *appsettings.*`Environment`*.json* files.
- App secrets (Secret Manager) in the Development environment.
- Environment variables.

By default, configuration values set on the command-line override configuration values set with all the other configuration providers.

Command-line arguments

The following command sets keys and values using `=`:

```
dotnet run MyKey="My key from command line" Position:Title=Cmd Position:Name=Cmd_Rick
```

The following command sets keys and values using `/`:

```
dotnet run /MyKey "Using /" /Position:Title=Cmd_ /Position:Name=Cmd_Rick
```

The following command sets keys and values using `--`:

```
dotnet run --MyKey "Using --" --Position:Title=Cmd-- --Position:Name=Cmd--Rick
```

The key value:

- Must follow `=`, or the key must have a prefix of `--` or `/` when the value follows a space.
- Isn't required if `=` is used. For example, `MySetting=`.

Within the same command, don't mix command-line argument key-value pairs that use `=` with key-value pairs that use a space.

Switch mappings

Switch mappings allow **key** name replacement logic. Provide a dictionary of switch replacements to the AddCommandLine method.

When the switch mappings dictionary is used, the dictionary is checked for a key that matches the key provided by a command-line argument. If the command-line key is found in the dictionary, the dictionary value is passed back to set the key-value pair into the app's configuration. A switch mapping is required for any command-line key prefixed with a single dash (`-`).

Switch mappings dictionary key rules:

- Switches must start with `-` or `--`.
- The switch mappings dictionary must not contain duplicate keys.

To use a switch mappings dictionary, pass it into the call to `AddCommandLine`:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args)
    {
        var switchMappings = new Dictionary<string, string>()
         {
             { "-k1", "key1" },
             { "-k2", "key2" },
             { "--alt3", "key3" },
             { "--alt4", "key4" },
             { "--alt5", "key5" },
             { "--alt6", "key6" },
         };

        return Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddCommandLine(args, switchMappings);
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
    }
}
```

The following code shows the key values for the replaced keys:

```
public class Test3Model : PageModel
{
    private readonly IConfiguration Config;

    public Test3Model(IConfiguration configuration)
    {
        Config = configuration;
    }

    public ContentResult OnGet()
    {
        return Content(
                $"Key1: '{Config["Key1"]}'\n" +
                $"Key2: '{Config["Key2"]}'\n" +
                $"Key3: '{Config["Key3"]}'\n" +
                $"Key4: '{Config["Key4"]}'\n" +
                $"Key5: '{Config["Key5"]}'\n" +
                $"Key6: '{Config["Key6"]}'");
    }
}
```

The following command works to test key replacement:

```
dotnet run -k1 value1 -k2 value2 --alt3=value2 /alt4=value3 --alt5 value5 /alt6 value6
```

For apps that use switch mappings, the call to `CreateDefaultBuilder` shouldn't pass arguments. The `CreateDefaultBuilder` method's `AddCommandLine` call doesn't include mapped switches, and there's no way to pass the switch-mapping dictionary to `CreateDefaultBuilder`. The solution isn't to pass the arguments to `CreateDefaultBuilder` but instead to allow the `ConfigurationBuilder`

method's `AddCommandLine` method to process both the arguments and the switch-mapping dictionary.

Hierarchical configuration data

The Configuration API reads hierarchical configuration data by flattening the hierarchical data with the use of a delimiter in the configuration keys.

The sample download contains the following *appsettings.json* file:

```
{
  "Position": {
    "Title": "Editor",
    "Name": "Joe Smith"
  },
  "MyKey":  "My appsettings.json Value",
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

The following code from the sample download displays several of the configurations settings:

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

The preferred way to read hierarchical configuration data is using the options pattern. For more information, see Bind hierarchical configuration data in this document.

GetSection and GetChildren methods are available to isolate sections and children of a section in the configuration data. These methods are described later in GetSection, GetChildren, and Exists.

Configuration keys and values

Configuration keys:

- Are case-insensitive. For example, `ConnectionString` and `connectionstring` are treated as equivalent keys.
- If a key and value is set in more than one configuration providers, the value from the last provider added is used. For more information, see Default configuration.
- Hierarchical keys
  - Within the Configuration API, a colon separator (`:`) works on all platforms.
  - In environment variables, a colon separator may not work on all platforms. A double underscore, `__`, is supported by all platforms and is automatically converted into a colon `:`.
  - In Azure Key Vault, hierarchical keys use `--` as a separator. The Azure Key Vault configuration provider automatically replaces `--` with a `:` when the secrets are loaded into the app's configuration.
- The ConfigurationBinder supports binding arrays to objects using array indices in configuration keys. Array binding is described in the Bind an array to a class section.

Configuration values:

- Are strings.
- Null values can't be stored in configuration or bound to objects.

Configuration providers

The following table shows the configuration providers available to ASP.NET Core apps.

PROVIDER	PROVIDES CONFIGURATION FROM
Azure Key Vault configuration provider	Azure Key Vault
Azure App configuration provider	Azure App Configuration
Command-line configuration provider	Command-line parameters
Custom configuration provider	Custom source
Environment Variables configuration provider	Environment variables
File configuration provider	INI, JSON, and XML files
Key-per-file configuration provider	Directory files
Memory configuration provider	In-memory collections
Secret Manager	File in the user profile directory

Configuration sources are read in the order that their configuration providers are specified. Order configuration providers in code to suit the priorities for the underlying configuration sources that the app requires.

A typical sequence of configuration providers is:

1. *appsettings.json*

2. *appsettings.*`Environment`*.json*
3. Secret Manager
4. Environment variables using the Environment Variables configuration provider.
5. Command-line arguments using the Command-line configuration provider.

A common practice is to add the Command-line configuration provider last in a series of providers to allow command-line arguments to override configuration set by the other providers.

The preceding sequence of providers is used in the default configuration.

Connection string prefixes

The Configuration API has special processing rules for four connection string environment variables. These connection strings are involved in configuring Azure connection strings for the app environment. Environment variables with the prefixes shown in the table are loaded into the app with the default configuration or when no prefix is supplied to `AddEnvironmentVariables`.

CONNECTION STRING PREFIX	PROVIDER
`CUSTOMCONNSTR_`	Custom provider
`MYSQLCONNSTR_`	MySQL
`SQLAZURECONNSTR_`	Azure SQL Database
`SQLCONNSTR_`	SQL Server

When an environment variable is discovered and loaded into configuration with any of the four prefixes shown in the table:

- The configuration key is created by removing the environment variable prefix and adding a configuration key section (`ConnectionStrings`).
- A new configuration key-value pair is created that represents the database connection provider (except for `CUSTOMCONNSTR_`, which has no stated provider).

ENVIRONMENT VARIABLE KEY	CONVERTED CONFIGURATION KEY	PROVIDER CONFIGURATION ENTRY
`CUSTOMCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Configuration entry not created.
`MYSQLCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName` : Value: `MySql.Data.MySqlClient`
`SQLAZURECONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName` : Value: `System.Data.SqlClient`
`SQLCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName` : Value: `System.Data.SqlClient`

ENVIRONMENT VARIABLE KEY	CONVERTED CONFIGURATION KEY	PROVIDER CONFIGURATION ENTRY
`SQLCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName` : Value: `System.Data.SqlClient`

File configuration provider

FileConfigurationProvider is the base class for loading configuration from the file system. The following configuration providers derive from `FileConfigurationProvider`:

- INI configuration provider
- JSON configuration provider
- XML configuration provider

INI configuration provider

The IniConfigurationProvider loads configuration from INI file key-value pairs at runtime.

The following code clears all the configuration providers and adds several configuration providers:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.Sources.Clear();

                var env = hostingContext.HostingEnvironment;

                config.AddIniFile("MyIniConfig.ini", optional: true, reloadOnChange: true)
                      .AddIniFile($"MyIniConfig.{env.EnvironmentName}.ini",
                                  optional: true, reloadOnChange: true);

                config.AddEnvironmentVariables();

                if (args != null)
                {
                    config.AddCommandLine(args);
                }
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

In the preceding code, settings in the *MyIniConfig.ini* and *MyIniConfig.* `Environment` *.ini* files are overridden by settings in the:

- Environment variables configuration provider

- Command-line configuration provider.

The sample download contains the following *MyIniConfig.ini* file:

```
MyKey="MyIniConfig.ini Value"

[Position]
Title="My INI Config title"
Name="My INI Config name"

[Logging:LogLevel]
Default=Information
Microsoft=Warning
```

The following code from the sample download displays several of the preceding configurations settings:

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

JSON configuration provider

The JsonConfigurationProvider loads configuration from JSON file key-value pairs.

Overloads can specify:

- Whether the file is optional.
- Whether the configuration is reloaded if the file changes.

Consider the following code:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddJsonFile("MyConfig.json",
                    optional: true,
                    reloadOnChange: true);
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The preceding code:

- Configures the JSON configuration provider to load the *MyConfig.json* file with the following options:
  - `optional: true` : The file is optional.
  - `reloadOnChange: true` : The file is reloaded when changes are saved.
- Reads the default configuration providers before the *MyConfig.json* file. Settings in the *MyConfig.json* file override setting in the default configuration providers, including the Environment variables configuration provider and the Command-line configuration provider.

You typically ***don't*** want a custom JSON file overriding values set in the Environment variables configuration provider and the Command-line configuration provider.

The following code clears all the configuration providers and adds several configuration providers:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.Sources.Clear();

                var env = hostingContext.HostingEnvironment;

                config.AddJsonFile("appsettings.json", optional: true, reloadOnChange: true)
                      .AddJsonFile($"appsettings.{env.EnvironmentName}.json",
                                   optional: true, reloadOnChange: true);

                config.AddJsonFile("MyConfig.json", optional: true, reloadOnChange: true)
                      .AddJsonFile($"MyConfig.{env.EnvironmentName}.json",
                                   optional: true, reloadOnChange: true);

                config.AddEnvironmentVariables();

                if (args != null)
                {
                    config.AddCommandLine(args);
                }
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

In the preceding code, settings in the *MyConfig.json* and *MyConfig.*`Environment`*.json* files:

- Override settings in the *appsettings.json* and *appsettings.*`Environment`*.json* files.
- Are overridden by settings in the Environment variables configuration provider and the Command-line configuration provider.

The sample download contains the following *MyConfig.json* file:

```
{
  "Position": {
    "Title": "My Config title",
    "Name": "My Config Smith"
  },
  "MyKey":  "MyConfig.json Value",
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

The following code from the sample download displays several of the preceding configurations settings:

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

XML configuration provider

The XmlConfigurationProvider loads configuration from XML file key-value pairs at runtime.

The following code clears all the configuration providers and adds several configuration providers:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.Sources.Clear();

                var env = hostingContext.HostingEnvironment;

                config.AddXmlFile("MyXMLFile.xml", optional: true, reloadOnChange: true)
                      .AddXmlFile($"MyXMLFile.{env.EnvironmentName}.xml",
                                  optional: true, reloadOnChange: true);

                config.AddEnvironmentVariables();

                if (args != null)
                {
                    config.AddCommandLine(args);
                }
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

In the preceding code, settings in the *MyXMLFile.xml* and *MyXMLFile.`Environment`.xml* files are overridden by settings in the:

- Environment variables configuration provider
- Command-line configuration provider.

The sample download contains the following *MyXMLFile.xml* file:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <MyKey>MyXMLFile Value</MyKey>
  <Position>
    <Title>Title from  MyXMLFile</Title>
    <Name>Name from MyXMLFile</Name>
  </Position>
  <Logging>
    <LogLevel>
      <Default>Information</Default>
      <Microsoft>Warning</Microsoft>
    </LogLevel>
  </Logging>
</configuration>
```

The following code from the sample download displays several of the preceding configurations settings:

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

Repeating elements that use the same element name work if the `name` attribute is used to distinguish the elements:

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <section name="section0">
    <key name="key0">value 00</key>
    <key name="key1">value 01</key>
  </section>
  <section name="section1">
    <key name="key0">value 10</key>
    <key name="key1">value 11</key>
  </section>
</configuration>
```

The following code reads the previous configuration file and displays the keys and values:

```
public class IndexModel : PageModel
{
    private readonly IConfiguration Configuration;

    public IndexModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var key00 = "section:section0:key:key0";
        var key01 = "section:section0:key:key1";
        var key10 = "section:section1:key:key0";
        var key11 = "section:section1:key:key1";

        var val00 = Configuration[key00];
        var val01 = Configuration[key01];
        var val10 = Configuration[key10];
        var val11 = Configuration[key11];

        return Content($"{key00} value: {val00} \n" +
                       $"{key01} value: {val01} \n" +
                       $"{key10} value: {val10} \n" +
                       $"{key10} value: {val11} \n"
                       );
    }
}
```

Attributes can be used to supply values:

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <key attribute="value" />
  <section>
    <key attribute="value" />
  </section>
</configuration>
```

The previous configuration file loads the following keys with `value`:

- key:attribute
- section:key:attribute

Key-per-file configuration provider

The KeyPerFileConfigurationProvider uses a directory's files as configuration key-value pairs.

The key is the file name. The value contains the file's contents. The Key-per-file configuration provider is used in Docker hosting scenarios.

To activate key-per-file configuration, call the AddKeyPerFile extension method on an instance of ConfigurationBuilder. The `directoryPath` to the files must be an absolute path.

Overloads permit specifying:

- An `Action<KeyPerFileConfigurationSource>` delegate that configures the source.
- Whether the directory is optional and the path to the directory.

The double-underscore (`__`) is used as a configuration key delimiter in file names. For example, the file name `Logging__LogLevel__System` produces the configuration key `Logging:LogLevel:System`.

Call `ConfigureAppConfiguration` when building the host to specify the app's configuration:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    var path = Path.Combine(
        Directory.GetCurrentDirectory(), "path/to/files");
    config.AddKeyPerFile(directoryPath: path, optional: true);
})
```

Memory configuration provider

The MemoryConfigurationProvider uses an in-memory collection as configuration key-value pairs.

The following code adds a memory collection to the configuration system:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args)
    {
        var Dict = new Dictionary<string, string>
        {
           {"MyKey", "Dictionary MyKey Value"},
           {"Position:Title", "Dictionary_Title"},
           {"Position:Name", "Dictionary_Name" },
           {"Logging:LogLevel:Default", "Warning"}
        };

        return Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddInMemoryCollection(Dict);
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
    }
}
```

The following code from the sample download displays the preceding configurations settings:

```
public class TestModel : PageModel
{
    // requires using Microsoft.Extensions.Configuration;
    private readonly IConfiguration Configuration;

    public TestModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var myKeyValue = Configuration["MyKey"];
        var title = Configuration["Position:Title"];
        var name = Configuration["Position:Name"];
        var defaultLogLevel = Configuration["Logging:LogLevel:Default"];

        return Content($"MyKey value: {myKeyValue} \n" +
                       $"Title: {title} \n" +
                       $"Name: {name} \n" +
                       $"Default Log Level: {defaultLogLevel}");
    }
}
```

In the preceding code, `config.AddInMemoryCollection(Dict)` is added after the default configuration providers. For an example of ordering the configuration providers, see JSON configuration provider.

See Bind an array for another example using `MemoryConfigurationProvider`.

GetValue

`ConfigurationBinder.GetValue<T>` extracts a single value from configuration with a specified key and converts it to the specified type:

```
public class TestNumModel : PageModel
{
    private readonly IConfiguration Configuration;

    public TestNumModel(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var number = Configuration.GetValue<int>("NumberKey", 99);
        return Content($"{number}");
    }
}
```

In the preceding code, if `NumberKey` isn't found in the configuration, the default value of `99` is used.

GetSection, GetChildren, and Exists

For the examples that follow, consider the following *MySubsection.json* file:

```
{
  "section0": {
    "key0": "value00",
    "key1": "value01"
  },
  "section1": {
    "key0": "value10",
    "key1": "value11"
  },
  "section2": {
    "subsection0": {
      "key0": "value200",
      "key1": "value201"
    },
    "subsection1": {
      "key0": "value210",
      "key1": "value211"
    }
  }
}
```

The following code adds *MySubsection.json* to the configuration providers:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddJsonFile("MySubsection.json",
                    optional: true,
                    reloadOnChange: true);
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

GetSection

IConfiguration.GetSection returns a configuration subsection with the specified subsection key.

The following code returns values for `section1`:

```
public class TestSectionModel : PageModel
{
    private readonly IConfiguration Config;

    public TestSectionModel(IConfiguration configuration)
    {
        Config = configuration.GetSection("section1");
    }

    public ContentResult OnGet()
    {
        return Content(
                $"section1:key0: '{Config["key0"]}'\n" +
                $"section1:key1: '{Config["key1"]}'");
    }
}
```

The following code returns values for `section2:subsection0`:

```
public class TestSection2Model : PageModel
{
    private readonly IConfiguration Config;

    public TestSection2Model(IConfiguration configuration)
    {
        Config = configuration.GetSection("section2:subsection0");
    }

    public ContentResult OnGet()
    {
        return Content(
                $"section2:subsection0:key0 '{Config["key0"]}'\n" +
                $"section2:subsection0:key1:'{Config["key1"]}'");
    }
}
```

`GetSection` never returns `null`. If a matching section isn't found, an empty `IConfigurationSection` is returned.

When `GetSection` returns a matching section, Value isn't populated. A Key and Path are returned when the section exists.

GetChildren and Exists

The following code calls IConfiguration.GetChildren and returns values for `section2:subsection0`:

```
public class TestSection4Model : PageModel
{
    private readonly IConfiguration Config;

    public TestSection4Model(IConfiguration configuration)
    {
        Config = configuration;
    }

    public ContentResult OnGet()
    {
        string s = null;
        var selection = Config.GetSection("section2");
        if (!selection.Exists())
        {
            throw new System.Exception("section2 does not exist.");
        }
        var children = selection.GetChildren();

        foreach (var subSection in children)
        {
            int i = 0;
            var key1 = subSection.Key + ":key" + i++.ToString();
            var key2 = subSection.Key + ":key" + i.ToString();
            s += key1 + " value: " + selection[key1] + "\n";
            s += key2 + " value: " + selection[key2] + "\n";
        }
        return Content(s);
    }
}
```

The preceding code calls ConfigurationExtensions.Exists to verify the section exists:

Bind an array

The ConfigurationBinder.Bind supports binding arrays to objects using array indices in configuration keys. Any array format that exposes a numeric key segment is capable of array binding to a POCO class array.

Consider *MyArray.json* from the sample download:

```
{
  "array": {
    "entries": {
      "0": "value00",
      "1": "value10",
      "2": "value20",
      "4": "value40",
      "5": "value50"
    }
  }
}
```

The following code adds *MyArray.json* to the configuration providers:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddJsonFile("MyArray.json",
                    optional: true,
                    reloadOnChange: true);
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The following code reads the configuration and displays the values:

```
public class ArrayModel : PageModel
{
    private readonly IConfiguration Config;
    public ArrayExample _array { get; private set; }

    public ArrayModel(IConfiguration config)
    {
        Config = config;
    }

    public ContentResult OnGet()
    {
        _array = Config.GetSection("array").Get<ArrayExample>();
        string s = null;

        for (int j = 0; j < _array.Entries.Length; j++)
        {
            s += $"Index: {j}  Value:  {_array.Entries[j]} \n";
        }

        return Content(s);
    }
}
```

The preceding code returns the following output:

```
Index: 0  Value: value00
Index: 1  Value: value10
Index: 2  Value: value20
Index: 3  Value: value40
Index: 4  Value: value50
```

In the preceding output, Index 3 has value `value40`, corresponding to `"4": "value40",` in *MyArray.json*. The bound array indices are continuous and not bound to the configuration key index. The configuration binder isn't capable of binding null values or creating null entries in bound objects

The following code loads the `array:entries` configuration with the AddInMemoryCollection

extension method:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args)
    {
        var arrayDict = new Dictionary<string, string>
        {
            {"array:entries:0", "value0"},
            {"array:entries:1", "value1"},
            {"array:entries:2", "value2"},
            //              3   Skipped
            {"array:entries:4", "value4"},
            {"array:entries:5", "value5"}
        };

        return Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddInMemoryCollection(arrayDict);
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
    }
}
```

The following code reads the configuration in the `arrayDict` `Dictionary` and displays the values:

```
public class ArrayModel : PageModel
{
    private readonly IConfiguration Config;
    public ArrayExample _array { get; private set; }

    public ArrayModel(IConfiguration config)
    {
        Config = config;
    }

    public ContentResult OnGet()
    {
        _array = Config.GetSection("array").Get<ArrayExample>();
        string s = null;

        for (int j = 0; j < _array.Entries.Length; j++)
        {
            s += $"Index: {j}  Value:  {_array.Entries[j]} \n";
        }

        return Content(s);
    }
}
```

The preceding code returns the following output:

```
Index: 0  Value: value0
Index: 1  Value: value1
Index: 2  Value: value2
Index: 3  Value: value4
Index: 4  Value: value5
```

Index #3 in the bound object holds the configuration data for the `array:4` configuration key and its value of `value4`. When configuration data containing an array is bound, the array indices in the configuration keys are used to iterate the configuration data when creating the object. A null value can't be retained in configuration data, and a null-valued entry isn't created in a bound object when an array in configuration keys skip one or more indices.

The missing configuration item for index #3 can be supplied before binding to the `ArrayExample` instance by any configuration provider that reads the index #3 key/value pair. Consider the following *Value3.json* file from the sample download:

```
{
  "array:entries:3": "value3"
}
```

The following code includes configuration for *Value3.json* and the `arrayDict` `Dictionary`:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args)
    {
        var arrayDict = new Dictionary<string, string>
        {
            {"array:entries:0", "value0"},
            {"array:entries:1", "value1"},
            {"array:entries:2", "value2"},
            //              3   Skipped
            {"array:entries:4", "value4"},
            {"array:entries:5", "value5"}
        };

        return Host.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddInMemoryCollection(arrayDict);
                config.AddJsonFile("Value3.json",
                                   optional: false, reloadOnChange: false);
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
    }
}
```

The following code reads the preceding configuration and displays the values:

```
public class ArrayModel : PageModel
{
    private readonly IConfiguration Config;
    public ArrayExample _array { get; private set; }

    public ArrayModel(IConfiguration config)
    {
        Config = config;
    }

    public ContentResult OnGet()
    {
        _array = Config.GetSection("array").Get<ArrayExample>();
        string s = null;

        for (int j = 0; j < _array.Entries.Length; j++)
        {
            s += $"Index: {j}  Value:  {_array.Entries[j]} \n";
        }

        return Content(s);
    }
}
```

The preceding code returns the following output:

```
Index: 0  Value: value0
Index: 1  Value: value1
Index: 2  Value: value2
Index: 3  Value: value3
Index: 4  Value: value4
Index: 5  Value: value5
```

Custom configuration providers aren't required to implement array binding.

Custom configuration provider

The sample app demonstrates how to create a basic configuration provider that reads configuration key-value pairs from a database using Entity Framework (EF).

The provider has the following characteristics:

- The EF in-memory database is used for demonstration purposes. To use a database that requires a connection string, implement a secondary `ConfigurationBuilder` to supply the connection string from another configuration provider.
- The provider reads a database table into configuration at startup. The provider doesn't query the database on a per-key basis.
- Reload-on-change isn't implemented, so updating the database after the app starts has no effect on the app's configuration.

Define an `EFConfigurationValue` entity for storing configuration values in the database.

Models/EFConfigurationValue.cs:

```
public class EFConfigurationValue
{
    public string Id { get; set; }
    public string Value { get; set; }
}
```

Add an `EFConfigurationContext` to store and access the configured values.

EFConfigurationProvider/EFConfigurationContext.cs:

```
// using Microsoft.EntityFrameworkCore;

public class EFConfigurationContext : DbContext
{
    public EFConfigurationContext(DbContextOptions options) : base(options)
    {
    }

    public DbSet<EFConfigurationValue> Values { get; set; }
}
```

Create a class that implements IConfigurationSource.

EFConfigurationProvider/EFConfigurationSource.cs:

```
// using Microsoft.EntityFrameworkCore;
// using Microsoft.Extensions.Configuration;

public class EFConfigurationSource : IConfigurationSource
{
    private readonly Action<DbContextOptionsBuilder> _optionsAction;

    public EFConfigurationSource(Action<DbContextOptionsBuilder> optionsAction)
    {
        _optionsAction = optionsAction;
    }

    public IConfigurationProvider Build(IConfigurationBuilder builder)
    {
        return new EFConfigurationProvider(_optionsAction);
    }
}
```

Create the custom configuration provider by inheriting from ConfigurationProvider. The configuration provider initializes the database when it's empty. Since configuration keys are case-insensitive, the dictionary used to initialize the database is created with the case-insensitive comparer (StringComparer.OrdinalIgnoreCase).

EFConfigurationProvider/EFConfigurationProvider.cs:

```
// using Microsoft.EntityFrameworkCore;
// using Microsoft.Extensions.Configuration;

public class EFConfigurationProvider : ConfigurationProvider
{
    public EFConfigurationProvider(Action<DbContextOptionsBuilder> optionsAction)
    {
        OptionsAction = optionsAction;
    }

    Action<DbContextOptionsBuilder> OptionsAction { get; }

    public override void Load()
    {
        var builder = new DbContextOptionsBuilder<EFConfigurationContext>();

        OptionsAction(builder);

        using (var dbContext = new EFConfigurationContext(builder.Options))
        {
            dbContext.Database.EnsureCreated();

            Data = !dbContext.Values.Any()
                ? CreateAndSaveDefaultValues(dbContext)
                : dbContext.Values.ToDictionary(c => c.Id, c => c.Value);
        }
    }

    private static IDictionary<string, string> CreateAndSaveDefaultValues(
        EFConfigurationContext dbContext)
    {
        // Quotes (c)2005 Universal Pictures: Serenity
        // https://www.uphe.com/movies/serenity
        var configValues =
            new Dictionary<string, string>(StringComparer.OrdinalIgnoreCase)
            {
                { "quote1", "I aim to misbehave." },
                { "quote2", "I swallowed a bug." },
                { "quote3", "You can't stop the signal, Mal." }
            };

        dbContext.Values.AddRange(configValues
            .Select(kvp => new EFConfigurationValue
                {
                    Id = kvp.Key,
                    Value = kvp.Value
                })
            .ToArray());

        dbContext.SaveChanges();

        return configValues;
    }
}
```

An `AddEFConfiguration` extension method permits adding the configuration source to a `ConfigurationBuilder`.

Extensions/EntityFrameworkExtensions.cs:

```
// using Microsoft.EntityFrameworkCore;
// using Microsoft.Extensions.Configuration;

public static class EntityFrameworkExtensions
{
    public static IConfigurationBuilder AddEFConfiguration(
        this IConfigurationBuilder builder,
        Action<DbContextOptionsBuilder> optionsAction)
    {
        return builder.Add(new EFConfigurationSource(optionsAction));
    }
}
```

The following code shows how to use the custom `EFConfigurationProvider` in *Program.cs*:

```
// using Microsoft.EntityFrameworkCore;

public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureAppConfiguration((hostingContext, config) =>
        {
            config.AddEFConfiguration(
                options => options.UseInMemoryDatabase("InMemoryDb"));
        })
```

Access configuration in Startup

The following code displays configuration data in `Startup` methods:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
        Console.WriteLine($"MyKey : {Configuration["MyKey"]}");
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        Console.WriteLine($"Position:Title : {Configuration["Position:Title"]}");

        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

For an example of accessing configuration using startup convenience methods, see App startup: Convenience methods.

Access configuration in Razor Pages

The following code displays configuration data in a Razor Page:

```
@page
@model Test5Model
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration

Configuration value for 'MyKey': @Configuration["MyKey"]
```

In the following code, `MyOptions` is added to the service container with Configure and bound to configuration:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<MyOptions>(Configuration.GetSection("MyOptions"));

    services.AddRazorPages();
}
```

The following markup uses the `@inject` Razor directive to resolve and display the options values:

```
@page
@model SampleApp.Pages.Test3Model
@using Microsoft.Extensions.Options
@inject IOptions<MyOptions> optionsAccessor

<p><b>Option1:</b> @optionsAccessor.Value.Option1</p>
<p><b>Option2:</b> @optionsAccessor.Value.Option2</p>
```

Access configuration in a MVC view file

The following code displays configuration data in a MVC view:

```
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration

Configuration value for 'MyKey': @Configuration["MyKey"]
```

Configure options with a delegate

Options configured in a delegate override values set in the configuration providers.

Configuring options with a delegate is demonstrated as Example 2 in the sample app.

In the following code, an IConfigureOptions<TOptions> service is added to the service container. It uses a delegate to configure values for `MyOptions`:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<MyOptions>(myOptions =>
    {
        myOptions.Option1 = "Value configured in delegate";
        myOptions.Option2 = 500;
    });

    services.AddRazorPages();
}
```

The following code displays the options values:

```
public class Test2Model : PageModel
{
    private readonly IOptions<MyOptions> _optionsDelegate;

    public Test2Model(IOptions<MyOptions> optionsDelegate )
    {
        _optionsDelegate = optionsDelegate;
    }

    public ContentResult OnGet()
    {
        return Content($"Option1: {_optionsDelegate.Value.Option1} \n" +
                       $"Option2: {_optionsDelegate.Value.Option2}");
    }
}
```

In the preceding example, the values of `Option1` and `Option2` are specified in *appsettings.json* and then overridden by the configured delegate.

Host versus app configuration

Before the app is configured and started, a *host* is configured and launched. The host is responsible for app startup and lifetime management. Both the app and the host are configured using the configuration providers described in this topic. Host configuration key-value pairs are also included in the app's configuration. For more information on how the configuration providers are used when the host is built and how configuration sources affect host configuration, see ASP.NET Core fundamentals.

Default host configuration

For details on the default configuration when using the Web Host, see the .

- Host configuration is provided from:
  - Environment variables prefixed with `DOTNET_` (for example, `DOTNET_ENVIRONMENT`) using the Environment Variables configuration provider. The prefix (`DOTNET_`) is stripped when the configuration key-value pairs are loaded.
  - Command-line arguments using the Command-line configuration provider.
- Web Host default configuration is established (`ConfigureWebHostDefaults`):
  - Kestrel is used as the web server and configured using the app's configuration providers.
  - Add Host Filtering Middleware.
  - Add Forwarded Headers Middleware if the `ASPNETCORE_FORWARDEDHEADERS_ENABLED` environment variable is set to `true`.
  - Enable IIS integration.

Other configuration

This topic only pertains to *app configuration*. Other aspects of running and hosting ASP.NET Core apps are configured using configuration files not covered in this topic:

- *launch.json/launchSettings.json* are tooling configuration files for the Development environment, described:
  - In Use multiple environments in ASP.NET Core.
  - Across the documentation set where the files are used to configure ASP.NET Core apps for Development scenarios.

- *web.config* is a server configuration file, described in the following topics:
  - Host ASP.NET Core on Windows with IIS
  - ASP.NET Core Module

Environment variables set in *launchSettings.json* override those set in the system environment.

For more information on migrating app configuration from earlier versions of ASP.NET, see Migrate from ASP.NET to ASP.NET Core.

Add configuration from an external assembly

An IHostingStartup implementation allows adding enhancements to an app at startup from an external assembly outside of the app's `Startup` class. For more information, see Use hosting startup assemblies in ASP.NET Core.

Additional resources

- Configuration source code
- Options pattern in ASP.NET Core
- ASP.NET Core Blazor configuration

App configuration in ASP.NET Core is based on key-value pairs established by *configuration providers*. Configuration providers read configuration data into key-value pairs from a variety of configuration sources:

- Azure Key Vault
- Azure App Configuration
- Command-line arguments
- Custom providers (installed or created)
- Directory files
- Environment variables
- In-memory .NET objects
- Settings files

Configuration packages for common configuration provider scenarios (Microsoft.Extensions.Configuration) are included in the Microsoft.AspNetCore.App metapackage.

Code examples that follow and in the sample app use the Microsoft.Extensions.Configuration namespace:

```
using Microsoft.Extensions.Configuration;
```

The *options pattern* is an extension of the configuration concepts described in this topic. Options use classes to represent groups of related settings. For more information, see Options pattern in ASP.NET Core.

View or download sample code (how to download)

Host versus app configuration

Before the app is configured and started, a *host* is configured and launched. The host is responsible for app startup and lifetime management. Both the app and the host are configured using the configuration providers described in this topic. Host configuration key-value pairs are

also included in the app's configuration. For more information on how the configuration providers are used when the host is built and how configuration sources affect host configuration, see ASP.NET Core fundamentals.

Other configuration

This topic only pertains to *app configuration*. Other aspects of running and hosting ASP.NET Core apps are configured using configuration files not covered in this topic:

- *launch.json/launchSettings.json* are tooling configuration files for the Development environment, described:
  - In Use multiple environments in ASP.NET Core.
  - Across the documentation set where the files are used to configure ASP.NET Core apps for Development scenarios.
- *web.config* is a server configuration file, described in the following topics:
  - Host ASP.NET Core on Windows with IIS
  - ASP.NET Core Module

For more information on migrating app configuration from earlier versions of ASP.NET, see Migrate from ASP.NET to ASP.NET Core.

Default configuration

Web apps based on the ASP.NET Core dotnet new templates call CreateDefaultBuilder when building a host. `CreateDefaultBuilder` provides default configuration for the app in the following order:

The following applies to apps using the Web Host. For details on the default configuration when using the Generic Host, see the latest version of this topic.

- Host configuration is provided from:
  - Environment variables prefixed with `ASPNETCORE_` (for example, `ASPNETCORE_ENVIRONMENT`) using the Environment Variables Configuration Provider. The prefix (`ASPNETCORE_`) is stripped when the configuration key-value pairs are loaded.
  - Command-line arguments using the Command-line Configuration Provider.
- App configuration is provided from:
  - *appsettings.json* using the File Configuration Provider.
  - *appsettings.{Environment}.json* using the File Configuration Provider.
  - Secret Manager when the app runs in the `Development` environment using the entry assembly.
  - Environment variables using the Environment Variables Configuration Provider.
  - Command-line arguments using the Command-line Configuration Provider.

Security

Adopt the following practices to secure sensitive configuration data:

- Never store passwords or other sensitive data in configuration provider code or in plain text configuration files.
- Don't use production secrets in development or test environments.
- Specify secrets outside of the project so that they can't be accidentally committed to a source code repository.

For more information, see the following topics:

- Use multiple environments in ASP.NET Core
- Safe storage of app secrets in development in ASP.NET Core: Includes advice on using environment variables to store sensitive data. The Secret Manager uses the File Configuration Provider to store user secrets in a JSON file on the local system. The File Configuration Provider is described later in this topic.

Azure Key Vault safely stores app secrets for ASP.NET Core apps. For more information, see Azure Key Vault Configuration Provider in ASP.NET Core.

Hierarchical configuration data

The Configuration API is capable of maintaining hierarchical configuration data by flattening the hierarchical data with the use of a delimiter in the configuration keys.

In the following JSON file, four keys exist in a structured hierarchy of two sections:

```
{
  "section0": {
    "key0": "value",
    "key1": "value"
  },
  "section1": {
    "key0": "value",
    "key1": "value"
  }
}
```

When the file is read into configuration, unique keys are created to maintain the original hierarchical data structure of the configuration source. The sections and keys are flattened with the use of a colon (`:`) to maintain the original structure:

- section0:key0
- section0:key1
- section1:key0
- section1:key1

GetSection and GetChildren methods are available to isolate sections and children of a section in the configuration data. These methods are described later in GetSection, GetChildren, and Exists.

Conventions

Sources and providers

At app startup, configuration sources are read in the order that their configuration providers are specified.

Configuration providers that implement change detection have the ability to reload configuration when an underlying setting is changed. For example, the File Configuration Provider (described later in this topic) and the Azure Key Vault Configuration Provider implement change detection.

IConfiguration is available in the app's dependency injection (DI) container. IConfiguration can be injected into a Razor Pages PageModel or MVC Controller to obtain configuration for the class.

In the following examples, the `_config` field is used to access configuration values:

```
public class IndexModel : PageModel
{
    private readonly IConfiguration _config;

    public IndexModel(IConfiguration config)
    {
        _config = config;
    }
}
```

```
public class HomeController : Controller
{
    private readonly IConfiguration _config;

    public HomeController(IConfiguration config)
    {
        _config = config;
    }
}
```

Configuration providers can't utilize DI, as it's not available when they're set up by the host.

Keys

Configuration keys adopt the following conventions:

- Keys are case-insensitive. For example, `ConnectionString` and `connectionstring` are treated as equivalent keys.
- If a value for the same key is set by the same or different configuration providers, the last value set on the key is the value used. For more information on duplicate JSON keys, see this GitHub issue.
- Hierarchical keys
  - Within the Configuration API, a colon separator (`:`) works on all platforms.
  - In environment variables, a colon separator may not work on all platforms. A double underscore (`__`) is supported by all platforms and is automatically converted into a colon.
  - In Azure Key Vault, hierarchical keys use `--` (two dashes) as a separator. Write code to replace the dashes with a colon when the secrets are loaded into the app's configuration.
- The ConfigurationBinder supports binding arrays to objects using array indices in configuration keys. Array binding is described in the Bind an array to a class section.

Values

Configuration values adopt the following conventions:

- Values are strings.
- Null values can't be stored in configuration or bound to objects.

Providers

The following table shows the configuration providers available to ASP.NET Core apps.

PROVIDER	PROVIDES CONFIGURATION FROM...

PROVIDER	PROVIDES CONFIGURATION FROM...
Azure Key Vault Configuration Provider (*Security* topics)	Azure Key Vault
Azure App Configuration Provider (Azure documentation)	Azure App Configuration
Command-line Configuration Provider	Command-line parameters
Custom configuration provider	Custom source
Environment Variables Configuration Provider	Environment variables
File Configuration Provider	Files (INI, JSON, XML)
Key-per-file Configuration Provider	Directory files
Memory Configuration Provider	In-memory collections
User secrets (Secret Manager) (*Security* topics)	File in the user profile directory

Configuration sources are read in the order that their configuration providers are specified at startup. The configuration providers described in this topic are described in alphabetical order, not in the order that the code arranges them. Order configuration providers in code to suit the priorities for the underlying configuration sources that the app requires.

A typical sequence of configuration providers is:

1. Files (*appsettings.json*, *appsettings.{Environment}.json*, where `{Environment}` is the app's current hosting environment)
2. Azure Key Vault
3. User secrets (Secret Manager) (Development environment only)
4. Environment variables
5. Command-line arguments

A common practice is to position the Command-line Configuration Provider last in a series of providers to allow command-line arguments to override configuration set by the other providers.

The preceding sequence of providers is used when a new host builder is initialized with `CreateDefaultBuilder`. For more information, see the Default configuration section.

Configure the host builder with UseConfiguration

To configure the host builder, call UseConfiguration on the host builder with the configuration.

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args)
{
    var dict = new Dictionary<string, string>
    {
        {"MemoryCollectionKey1", "value1"},
        {"MemoryCollectionKey2", "value2"}
    };

    var config = new ConfigurationBuilder()
        .AddInMemoryCollection(dict)
        .Build();

    return WebHost.CreateDefaultBuilder(args)
        .UseConfiguration(config)
        .UseStartup<Startup>();
}
```

ConfigureAppConfiguration

Call `ConfigureAppConfiguration` when building the host to specify the app's configuration providers in addition to those added automatically by `CreateDefaultBuilder`:

```
public class Program
{
    public static Dictionary<string, string> arrayDict =
        new Dictionary<string, string>
        {
            {"array:entries:0", "value0"},
            {"array:entries:1", "value1"},
            {"array:entries:2", "value2"},
            {"array:entries:4", "value4"},
            {"array:entries:5", "value5"}
        };

    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddInMemoryCollection(arrayDict);
                config.AddJsonFile(
                    "json_array.json", optional: false, reloadOnChange: false);
                config.AddJsonFile(
                    "starship.json", optional: false, reloadOnChange: false);
                config.AddXmlFile(
                    "tvshow.xml", optional: false, reloadOnChange: false);
                config.AddEFConfiguration(
                    options => options.UseInMemoryDatabase("InMemoryDb"));
                config.AddCommandLine(args);
            })
            .UseStartup<Startup>();
}
```

Override previous configuration with command-line arguments

To provide app configuration that can be overridden with command-line arguments, call `AddCommandLine` last:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    // Call other providers here
    config.AddCommandLine(args);
})
```

Remove providers added by CreateDefaultBuilder

To remove the providers added by `CreateDefaultBuilder`, call Clear on the IConfigurationBuilder.Sources first:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    config.Sources.Clear();
    // Add providers here
})
```

Consume configuration during app startup

Configuration supplied to the app in `ConfigureAppConfiguration` is available during the app's startup, including `Startup.ConfigureServices`. For more information, see the Access configuration during startup section.

Command-line Configuration Provider

The CommandLineConfigurationProvider loads configuration from command-line argument key-value pairs at runtime.

To activate command-line configuration, the AddCommandLine extension method is called on an instance of ConfigurationBuilder.

`AddCommandLine` is automatically called when `CreateDefaultBuilder(string [])` is called. For more information, see the Default configuration section.

`CreateDefaultBuilder` also loads:

- Optional configuration from *appsettings.json* and *appsettings.{Environment}.json* files.
- User secrets (Secret Manager) in the Development environment.
- Environment variables.

`CreateDefaultBuilder` adds the Command-line Configuration Provider last. Command-line arguments passed at runtime override configuration set by the other providers.

`CreateDefaultBuilder` acts when the host is constructed. Therefore, command-line configuration activated by `CreateDefaultBuilder` can affect how the host is configured.

For apps based on the ASP.NET Core templates, `AddCommandLine` has already been called by `CreateDefaultBuilder`. To add additional configuration providers and maintain the ability to override configuration from those providers with command-line arguments, call the app's additional providers in `ConfigureAppConfiguration` and call `AddCommandLine` last.

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    // Call other providers here
    config.AddCommandLine(args);
})
```

Example

The sample app takes advantage of the static convenience method `CreateDefaultBuilder` to build the host, which includes a call to AddCommandLine.

1. Open a command prompt in the project's directory.
2. Supply a command-line argument to the `dotnet run` command, `dotnet run CommandLineKey=CommandLineValue`.
3. After the app is running, open a browser to the app at `http://localhost:5000`.
4. Observe that the output contains the key-value pair for the configuration command-line argument provided to `dotnet run`.

Arguments

The value must follow an equals sign (`=`), or the key must have a prefix (`--` or `/`) when the value follows a space. The value isn't required if an equals sign is used (for example, `CommandLineKey=`).

KEY PREFIX	EXAMPLE
No prefix	`CommandLineKey1=value1`
Two dashes (`--`)	`--CommandLineKey2=value2`, `--CommandLineKey2 value2`
Forward slash (`/`)	`/CommandLineKey3=value3`, `/CommandLineKey3 value3`

Within the same command, don't mix command-line argument key-value pairs that use an equals sign with key-value pairs that use a space.

Example commands:

```
dotnet run CommandLineKey1=value1 --CommandLineKey2=value2 /CommandLineKey3=value3
dotnet run --CommandLineKey1 value1 /CommandLineKey2 value2
dotnet run CommandLineKey1= CommandLineKey2=value2
```

Switch mappings

Switch mappings allow key name replacement logic. When manually building configuration with a ConfigurationBuilder, provide a dictionary of switch replacements to the AddCommandLine method.

When the switch mappings dictionary is used, the dictionary is checked for a key that matches the key provided by a command-line argument. If the command-line key is found in the dictionary, the dictionary value (the key replacement) is passed back to set the key-value pair into the app's configuration. A switch mapping is required for any command-line key prefixed with a single dash (`-`).

Switch mappings dictionary key rules:

- Switches must start with a dash (`-`) or double-dash (`--`).
- The switch mappings dictionary must not contain duplicate keys.

Create a switch mappings dictionary. In the following example, two switch mappings are created:

```
public static readonly Dictionary<string, string> _switchMappings =
    new Dictionary<string, string>
    {
        { "-CLKey1", "CommandLineKey1" },
        { "-CLKey2", "CommandLineKey2" }
    };
```

When the host is built, call `AddCommandLine` with the switch mappings dictionary:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    config.AddCommandLine(args, _switchMappings);
})
```

For apps that use switch mappings, the call to `CreateDefaultBuilder` shouldn't pass arguments. The `CreateDefaultBuilder` method's `AddCommandLine` call doesn't include mapped switches, and there's no way to pass the switch mapping dictionary to `CreateDefaultBuilder`. The solution isn't to pass the arguments to `CreateDefaultBuilder` but instead to allow the `ConfigurationBuilder` method's `AddCommandLine` method to process both the arguments and the switch mapping dictionary.

After the switch mappings dictionary is created, it contains the data shown in the following table.

KEY	VALUE
`-CLKey1`	`CommandLineKey1`
`-CLKey2`	`CommandLineKey2`

If the switch-mapped keys are used when starting the app, configuration receives the configuration value on the key supplied by the dictionary:

```
dotnet run -CLKey1=value1 -CLKey2=value2
```

After running the preceding command, configuration contains the values shown in the following table.

KEY	VALUE
`CommandLineKey1`	`value1`
`CommandLineKey2`	`value2`

Environment Variables Configuration Provider

The EnvironmentVariablesConfigurationProvider loads configuration from environment variable key-value pairs at runtime.

To activate environment variables configuration, call the AddEnvironmentVariables extension method on an instance of ConfigurationBuilder.

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

Azure App Service permits setting environment variables in the Azure Portal that can override app configuration using the Environment Variables Configuration Provider. For more information, see Azure Apps: Override app configuration using the Azure Portal.

`AddEnvironmentVariables` is used to load environment variables prefixed with `ASPNETCORE_` for host configuration when a new host builder is initialized with the Web Host and `CreateDefaultBuilder` is called. For more information, see the Default configuration section.

`CreateDefaultBuilder` also loads:

- App configuration from unprefixed environment variables by calling `AddEnvironmentVariables` without a prefix.
- Optional configuration from *appsettings.json* and *appsettings.{Environment}.json* files.
- User secrets (Secret Manager) in the Development environment.
- Command-line arguments.

The Environment Variables Configuration Provider is called after configuration is established from user secrets and *appsettings* files. Calling the provider in this position allows the environment variables read at runtime to override configuration set by user secrets and *appsettings* files.

To provide app configuration from additional environment variables, call the app's additional providers in `ConfigureAppConfiguration` and call `AddEnvironmentVariables` with the prefix:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    config.AddEnvironmentVariables(prefix: "PREFIX_");
})
```

Call `AddEnvironmentVariables` last to allow environment variables with the given prefix to override values from other providers.

Example

The sample app takes advantage of the static convenience method `CreateDefaultBuilder` to build the host, which includes a call to `AddEnvironmentVariables`.

1. Run the sample app. Open a browser to the app at `http://localhost:5000`.
2. Observe that the output contains the key-value pair for the environment variable `ENVIRONMENT`. The value reflects the environment in which the app is running, typically `Development` when running locally.

To keep the list of environment variables rendered by the app short, the app filters environment variables. See the sample app's *Pages/Index.cshtml.cs* file.

To expose all of the environment variables available to the app, change the `FilteredConfiguration` in *Pages/Index.cshtml.cs* to the following:

```
FilteredConfiguration = _config.AsEnumerable();
```

Prefixes

Environment variables loaded into the app's configuration are filtered when supplying a prefix to the `AddEnvironmentVariables` method. For example, to filter environment variables on the prefix `CUSTOM_`, supply the prefix to the configuration provider:

```
var config = new ConfigurationBuilder()
    .AddEnvironmentVariables("CUSTOM_")
    .Build();
```

The prefix is stripped off when the configuration key-value pairs are created.

When the host builder is created, host configuration is provided by environment variables. For more information on the prefix used for these environment variables, see the Default configuration section.

Connection string prefixes

The Configuration API has special processing rules for four connection string environment variables involved in configuring Azure connection strings for the app environment. Environment variables with the prefixes shown in the table are loaded into the app if no prefix is supplied to `AddEnvironmentVariables`.

CONNECTION STRING PREFIX	PROVIDER
`CUSTOMCONNSTR_`	Custom provider
`MYSQLCONNSTR_`	MySQL
`SQLAZURECONNSTR_`	Azure SQL Database
`SQLCONNSTR_`	SQL Server

When an environment variable is discovered and loaded into configuration with any of the four prefixes shown in the table:

- The configuration key is created by removing the environment variable prefix and adding a configuration key section (`ConnectionStrings`).
- A new configuration key-value pair is created that represents the database connection provider (except for `CUSTOMCONNSTR_`, which has no stated provider).

ENVIRONMENT VARIABLE KEY	CONVERTED CONFIGURATION KEY	PROVIDER CONFIGURATION ENTRY
`CUSTOMCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Configuration entry not created.
`MYSQLCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName` : Value: `MySql.Data.MySqlClient`

ENVIRONMENT VARIABLE KEY	CONVERTED CONFIGURATION KEY	PROVIDER CONFIGURATION ENTRY
`SQLAZURECONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName` : Value: `System.Data.SqlClient`
`SQLCONNSTR_{KEY}`	`ConnectionStrings:{KEY}`	Key: `ConnectionStrings:{KEY}_ProviderName` : Value: `System.Data.SqlClient`

Example

A custom connection string environment variable is created on the server:

- Name: `CUSTOMCONNSTR_ReleaseDB`
- Value: `Data Source=ReleaseSQLServer;Initial Catalog=MyReleaseDB;Integrated Security=True`

If `IConfiguration` is injected and assigned to a field named `_config`, read the value:

```
_config["ConnectionStrings:ReleaseDB"]
```

File Configuration Provider

FileConfigurationProvider is the base class for loading configuration from the file system. The following configuration providers are dedicated to specific file types:

- INI Configuration Provider
- JSON Configuration Provider
- XML Configuration Provider

INI Configuration Provider

The IniConfigurationProvider loads configuration from INI file key-value pairs at runtime.

To activate INI file configuration, call the AddIniFile extension method on an instance of ConfigurationBuilder.

The colon can be used to as a section delimiter in INI file configuration.

Overloads permit specifying:

- Whether the file is optional.
- Whether the configuration is reloaded if the file changes.
- The IFileProvider used to access the file.

Call `ConfigureAppConfiguration` when building the host to specify the app's configuration:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    config.AddIniFile(
        "config.ini", optional: true, reloadOnChange: true);
})
```

A generic example of an INI configuration file:

```
[section0]
key0=value
key1=value

[section1]
subsection:key=value

[section2:subsection0]
key=value

[section2:subsection1]
key=value
```

The previous configuration file loads the following keys with `value`:

- section0:key0
- section0:key1
- section1:subsection:key
- section2:subsection0:key
- section2:subsection1:key

JSON Configuration Provider

The JsonConfigurationProvider loads configuration from JSON file key-value pairs during runtime.

To activate JSON file configuration, call the AddJsonFile extension method on an instance of ConfigurationBuilder.

Overloads permit specifying:

- Whether the file is optional.
- Whether the configuration is reloaded if the file changes.
- The IFileProvider used to access the file.

`AddJsonFile` is automatically called twice when a new host builder is initialized with `CreateDefaultBuilder`. The method is called to load configuration from:

- *appsettings.json*: This file is read first. The environment version of the file can override the values provided by the *appsettings.json* file.
- *appsettings.{Environment}.json*: The environment version of the file is loaded based on the IHostingEnvironment.EnvironmentName.

For more information, see the Default configuration section.

`CreateDefaultBuilder` also loads:

- Environment variables.
- User secrets (Secret Manager) in the Development environment.
- Command-line arguments.

The JSON Configuration Provider is established first. Therefore, user secrets, environment variables, and command-line arguments override configuration set by the *appsettings* files.

Call `ConfigureAppConfiguration` when building the host to specify the app's configuration for files other than *appsettings.json* and *appsettings.{Environment}.json*:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    config.AddJsonFile(
        "config.json", optional: true, reloadOnChange: true);
})
```

Example

The sample app takes advantage of the static convenience method `CreateDefaultBuilder` to build the host, which includes two calls to `AddJsonFile`:

- The first call to `AddJsonFile` loads configuration from *appsettings.json*:

  ```
  {
    "Logging": {
      "LogLevel": {
        "Default": "Warning"
      }
    },
    "AllowedHosts": "*"
  }
  ```

- The second call to `AddJsonFile` loads configuration from *appsettings.{Environment}.json*. For *appsettings.Development.json* in the sample app, the following file is loaded:

  ```
  {
    "Logging": {
      "LogLevel": {
        "Default": "Debug",
        "System": "Information",
        "Microsoft": "Information"
      }
    }
  }
  ```

1. Run the sample app. Open a browser to the app at `http://localhost:5000`.
2. The output contains key-value pairs for the configuration based on the app's environment. The log level for the key `Logging:LogLevel:Default` is `Debug` when running the app in the Development environment.
3. Run the sample app again in the Production environment:
   a. Open the *Properties/launchSettings.json* file.
   b. In the `ConfigurationSample` profile, change the value of the `ASPNETCORE_ENVIRONMENT` environment variable to `Production`.
   c. Save the file and run the app with `dotnet run` in a command shell.
4. The settings in the *appsettings.Development.json* no longer override the settings in *appsettings.json*. The log level for the key `Logging:LogLevel:Default` is `Warning`.

XML Configuration Provider

The XmlConfigurationProvider loads configuration from XML file key-value pairs at runtime.

To activate XML file configuration, call the AddXmlFile extension method on an instance of ConfigurationBuilder.

Overloads permit specifying:

- Whether the file is optional.

- Whether the configuration is reloaded if the file changes.
- The IFileProvider used to access the file.

The root node of the configuration file is ignored when the configuration key-value pairs are created. Don't specify a Document Type Definition (DTD) or namespace in the file.

Call `ConfigureAppConfiguration` when building the host to specify the app's configuration:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    config.AddXmlFile(
        "config.xml", optional: true, reloadOnChange: true);
})
```

XML configuration files can use distinct element names for repeating sections:

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <section0>
    <key0>value</key0>
    <key1>value</key1>
  </section0>
  <section1>
    <key0>value</key0>
    <key1>value</key1>
  </section1>
</configuration>
```

The previous configuration file loads the following keys with `value`:

- section0:key0
- section0:key1
- section1:key0
- section1:key1

Repeating elements that use the same element name work if the `name` attribute is used to distinguish the elements:

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <section name="section0">
    <key name="key0">value</key>
    <key name="key1">value</key>
  </section>
  <section name="section1">
    <key name="key0">value</key>
    <key name="key1">value</key>
  </section>
</configuration>
```

The previous configuration file loads the following keys with `value`:

- section:section0:key:key0
- section:section0:key:key1
- section:section1:key:key0
- section:section1:key:key1

Attributes can be used to supply values:

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <key attribute="value" />
  <section>
    <key attribute="value" />
  </section>
</configuration>
```

The previous configuration file loads the following keys with `value`:

- key:attribute
- section:key:attribute

Key-per-file Configuration Provider

The KeyPerFileConfigurationProvider uses a directory's files as configuration key-value pairs. The key is the file name. The value contains the file's contents. The Key-per-file Configuration Provider is used in Docker hosting scenarios.

To activate key-per-file configuration, call the AddKeyPerFile extension method on an instance of ConfigurationBuilder. The `directoryPath` to the files must be an absolute path.

Overloads permit specifying:

- An `Action<KeyPerFileConfigurationSource>` delegate that configures the source.
- Whether the directory is optional and the path to the directory.

The double-underscore (`__`) is used as a configuration key delimiter in file names. For example, the file name `Logging__LogLevel__System` produces the configuration key `Logging:LogLevel:System`.

Call `ConfigureAppConfiguration` when building the host to specify the app's configuration:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    var path = Path.Combine(
        Directory.GetCurrentDirectory(), "path/to/files");
    config.AddKeyPerFile(directoryPath: path, optional: true);
})
```

Memory Configuration Provider

The MemoryConfigurationProvider uses an in-memory collection as configuration key-value pairs.

To activate in-memory collection configuration, call the AddInMemoryCollection extension method on an instance of ConfigurationBuilder.

The configuration provider can be initialized with an `IEnumerable<KeyValuePair<String,String>>`.

Call `ConfigureAppConfiguration` when building the host to specify the app's configuration.

In the following example, a configuration dictionary is created:

```
public static readonly Dictionary<string, string> _dict =
    new Dictionary<string, string>
    {
        {"MemoryCollectionKey1", "value1"},
        {"MemoryCollectionKey2", "value2"}
    };
```

The dictionary is used with a call to `AddInMemoryCollection` to provide the configuration:

```
.ConfigureAppConfiguration((hostingContext, config) =>
{
    config.AddInMemoryCollection(_dict);
})
```

GetValue

`ConfigurationBinder.GetValue<T>` extracts a single value from configuration with a specified key and converts it to the specified noncollection type. An overload accepts a default value.

The following example:

- Extracts the string value from configuration with the key `NumberKey`. If `NumberKey` isn't found in the configuration keys, the default value of `99` is used.
- Types the value as an `int`.
- Stores the value in the `NumberConfig` property for use by the page.

```
public class IndexModel : PageModel
{
    public IndexModel(IConfiguration config)
    {
        _config = config;
    }

    public int NumberConfig { get; private set; }

    public void OnGet()
    {
        NumberConfig = _config.GetValue<int>("NumberKey", 99);
    }
}
```

GetSection, GetChildren, and Exists

For the examples that follow, consider the following JSON file. Four keys are found across two sections, one of which includes a pair of subsections:

```
{
  "section0": {
    "key0": "value",
    "key1": "value"
  },
  "section1": {
    "key0": "value",
    "key1": "value"
  },
  "section2": {
    "subsection0" : {
      "key0": "value",
      "key1": "value"
    },
    "subsection1" : {
      "key0": "value",
      "key1": "value"
    }
  }
}
```

When the file is read into configuration, the following unique hierarchical keys are created to hold the configuration values:

- section0:key0
- section0:key1
- section1:key0
- section1:key1
- section2:subsection0:key0
- section2:subsection0:key1
- section2:subsection1:key0
- section2:subsection1:key1

GetSection

IConfiguration.GetSection extracts a configuration subsection with the specified subsection key.

To return an IConfigurationSection containing only the key-value pairs in `section1`, call `GetSection` and supply the section name:

```
var configSection = _config.GetSection("section1");
```

The `configSection` doesn't have a value, only a key and a path.

Similarly, to obtain the values for keys in `section2:subsection0`, call `GetSection` and supply the section path:

```
var configSection = _config.GetSection("section2:subsection0");
```

`GetSection` never returns `null`. If a matching section isn't found, an empty `IConfigurationSection` is returned.

When `GetSection` returns a matching section, Value isn't populated. A Key and Path are returned when the section exists.

GetChildren

A call to IConfiguration.GetChildren on `section2` obtains an

`IEnumerable<IConfigurationSection>` that includes:

- `subsection0`
- `subsection1`

```
var configSection = _config.GetSection("section2");

var children = configSection.GetChildren();
```

Exists

Use ConfigurationExtensions.Exists to determine if a configuration section exists:

```
var sectionExists = _config.GetSection("section2:subsection2").Exists();
```

Given the example data, `sectionExists` is `false` because there isn't a `section2:subsection2` section in the configuration data.

Bind to an object graph

Bind is capable of binding an entire POCO object graph. As with binding a simple object, only public read/write properties are bound.

The sample contains a `TvShow` model whose object graph includes `Metadata` and `Actors` classes (*Models/TvShow.cs*):

```
public class TvShow
{
    public Metadata Metadata { get; set; }
    public Actors Actors { get; set; }
    public string Legal { get; set; }
}

public class Metadata
{
    public string Series { get; set; }
    public string Title { get; set; }
    public DateTime AirDate { get; set; }
    public int Episodes { get; set; }
}

public class Actors
{
    public string Names { get; set; }
}
```

The sample app has a *tvshow.xml* file containing the configuration data:

```
<?xml version="1.0" encoding="UTF-8"?>
<configuration>
  <tvshow>
    <metadata>
      <series>Dr. Who</series>
      <title>The Sun Makers</title>
      <airdate>11/26/1977</airdate>
      <episodes>4</episodes>
    </metadata>
    <actors>
      <names>Tom Baker, Louise Jameson, John Leeson</names>
    </actors>
    <legal>(c)1977 BBC https://www.bbc.co.uk/programmes/b006q2x0</legal>
  </tvshow>
</configuration>
```

Configuration is bound to the entire `TvShow` object graph with the `Bind` method. The bound instance is assigned to a property for rendering:

```
var tvShow = new TvShow();
_config.GetSection("tvshow").Bind(tvShow);
TvShow = tvShow;
```

`ConfigurationBinder.Get<T>` binds and returns the specified type. `Get<T>` is more convenient than using `Bind`. The following code shows how to use `Get<T>` with the preceding example:

```
TvShow = _config.GetSection("tvshow").Get<TvShow>();
```

Bind an array to a class

The sample app demonstrates the concepts explained in this section.

The Bind supports binding arrays to objects using array indices in configuration keys. Any array format that exposes a numeric key segment (`:0:` , `:1:` , ... `:{n}:`) is capable of array binding to a POCO class array.

> **NOTE**
> Binding is provided by convention. Custom configuration providers aren't required to implement array binding.

In-memory array processing

Consider the configuration keys and values shown in the following table.

KEY	VALUE
array:entries:0	value0
array:entries:1	value1
array:entries:2	value2
array:entries:4	value4

KEY	VALUE
array:entries:5	value5

These keys and values are loaded in the sample app using the Memory Configuration Provider:

```
public class Program
{
    public static Dictionary<string, string> arrayDict =
        new Dictionary<string, string>
        {
            {"array:entries:0", "value0"},
            {"array:entries:1", "value1"},
            {"array:entries:2", "value2"},
            {"array:entries:4", "value4"},
            {"array:entries:5", "value5"}
        };

    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddInMemoryCollection(arrayDict);
                config.AddJsonFile(
                    "json_array.json", optional: false, reloadOnChange: false);
                config.AddJsonFile(
                    "starship.json", optional: false, reloadOnChange: false);
                config.AddXmlFile(
                    "tvshow.xml", optional: false, reloadOnChange: false);
                config.AddEFConfiguration(
                    options => options.UseInMemoryDatabase("InMemoryDb"));
                config.AddCommandLine(args);
            })
            .UseStartup<Startup>();
}
```

The array skips a value for index #3. The configuration binder isn't capable of binding null values or creating null entries in bound objects, which becomes clear in a moment when the result of binding this array to an object is demonstrated.

In the sample app, a POCO class is available to hold the bound configuration data:

```
public class ArrayExample
{
    public string[] Entries { get; set; }
}
```

The configuration data is bound to the object:

```
var arrayExample = new ArrayExample();
_config.GetSection("array").Bind(arrayExample);
```

`ConfigurationBinder.Get<T>` syntax can also be used, which results in more compact code:

```
ArrayExample = _config.GetSection("array").Get<ArrayExample>();
```

The bound object, an instance of `ArrayExample`, receives the array data from configuration.

`ARRAYEXAMPLE.ENTRIES` INDEX	`ARRAYEXAMPLE.ENTRIES` VALUE
0	value0
1	value1
2	value2
3	value4
4	value5

Index #3 in the bound object holds the configuration data for the `array:4` configuration key and its value of `value4`. When configuration data containing an array is bound, the array indices in the configuration keys are merely used to iterate the configuration data when creating the object. A null value can't be retained in configuration data, and a null-valued entry isn't created in a bound object when an array in configuration keys skip one or more indices.

The missing configuration item for index #3 can be supplied before binding to the `ArrayExample` instance by any configuration provider that produces the correct key-value pair in configuration. If the sample included an additional JSON Configuration Provider with the missing key-value pair, the `ArrayExample.Entries` matches the complete configuration array:

missing_value.json:

```
{
  "array:entries:3": "value3"
}
```

In `ConfigureAppConfiguration`:

```
config.AddJsonFile(
    "missing_value.json", optional: false, reloadOnChange: false);
```

The key-value pair shown in the table is loaded into configuration.

KEY	VALUE
array:entries:3	value3

If the `ArrayExample` class instance is bound after the JSON Configuration Provider includes the entry for index #3, the `ArrayExample.Entries` array includes the value.

`ARRAYEXAMPLE.ENTRIES` INDEX	`ARRAYEXAMPLE.ENTRIES` VALUE
0	value0
1	value1

ARRAYEXAMPLE.ENTRIES INDEX	ARRAYEXAMPLE.ENTRIES VALUE
2	value2
3	value3
4	value4
5	value5

JSON array processing

If a JSON file contains an array, configuration keys are created for the array elements with a zero-based section index. In the following configuration file, `subsection` is an array:

```
{
  "json_array": {
    "key": "valueA",
    "subsection": [
      "valueB",
      "valueC",
      "valueD"
    ]
  }
}
```

The JSON Configuration Provider reads the configuration data into the following key-value pairs:

KEY	VALUE
json_array:key	valueA
json_array:subsection:0	valueB
json_array:subsection:1	valueC
json_array:subsection:2	valueD

In the sample app, the following POCO class is available to bind the configuration key-value pairs:

```
public class JsonArrayExample
{
    public string Key { get; set; }
    public string[] Subsection { get; set; }
}
```

After binding, `JsonArrayExample.Key` holds the value `valueA`. The subsection values are stored in the POCO array property, `Subsection`.

JSONARRAYEXAMPLE.SUBSECTION INDEX	JSONARRAYEXAMPLE.SUBSECTION VALUE
0	valueB

JSONARRAYEXAMPLE.SUBSECTION INDEX	JSONARRAYEXAMPLE.SUBSECTION VALUE
1	valueC
2	valueD

Custom configuration provider

The sample app demonstrates how to create a basic configuration provider that reads configuration key-value pairs from a database using Entity Framework (EF).

The provider has the following characteristics:

- The EF in-memory database is used for demonstration purposes. To use a database that requires a connection string, implement a secondary `ConfigurationBuilder` to supply the connection string from another configuration provider.
- The provider reads a database table into configuration at startup. The provider doesn't query the database on a per-key basis.
- Reload-on-change isn't implemented, so updating the database after the app starts has no effect on the app's configuration.

Define an `EFConfigurationValue` entity for storing configuration values in the database.

Models/EFConfigurationValue.cs:

```
public class EFConfigurationValue
{
    public string Id { get; set; }
    public string Value { get; set; }
}
```

Add an `EFConfigurationContext` to store and access the configured values.

EFConfigurationProvider/EFConfigurationContext.cs:

```
public class EFConfigurationContext : DbContext
{
    public EFConfigurationContext(DbContextOptions options) : base(options)
    {
    }

    public DbSet<EFConfigurationValue> Values { get; set; }
}
```

Create a class that implements IConfigurationSource.

EFConfigurationProvider/EFConfigurationSource.cs:

```
public class EFConfigurationSource : IConfigurationSource
{
    private readonly Action<DbContextOptionsBuilder> _optionsAction;

    public EFConfigurationSource(Action<DbContextOptionsBuilder> optionsAction)
    {
        _optionsAction = optionsAction;
    }

    public IConfigurationProvider Build(IConfigurationBuilder builder)
    {
        return new EFConfigurationProvider(_optionsAction);
    }
}
```

Create the custom configuration provider by inheriting from ConfigurationProvider. The configuration provider initializes the database when it's empty.

EFConfigurationProvider/EFConfigurationProvider.cs:

```
public class EFConfigurationProvider : ConfigurationProvider
{
    public EFConfigurationProvider(Action<DbContextOptionsBuilder> optionsAction)
    {
        OptionsAction = optionsAction;
    }

    Action<DbContextOptionsBuilder> OptionsAction { get; }

    // Load config data from EF DB.
    public override void Load()
    {
        var builder = new DbContextOptionsBuilder<EFConfigurationContext>();

        OptionsAction(builder);

        using (var dbContext = new EFConfigurationContext(builder.Options))
        {
            dbContext.Database.EnsureCreated();

            Data = !dbContext.Values.Any()
                ? CreateAndSaveDefaultValues(dbContext)
                : dbContext.Values.ToDictionary(c => c.Id, c => c.Value);
        }
    }

    private static IDictionary<string, string> CreateAndSaveDefaultValues(
        EFConfigurationContext dbContext)
    {
        // Quotes (c)2005 Universal Pictures: Serenity
        // https://www.uphe.com/movies/serenity
        var configValues =
            new Dictionary<string, string>(StringComparer.OrdinalIgnoreCase)
            {
                { "quote1", "I aim to misbehave." },
                { "quote2", "I swallowed a bug." },
                { "quote3", "You can't stop the signal, Mal." }
            };

        dbContext.Values.AddRange(configValues
            .Select(kvp => new EFConfigurationValue
                {
                    Id = kvp.Key,
                    Value = kvp.Value
                })
            .ToArray());

        dbContext.SaveChanges();

        return configValues;
    }
}
```

An `AddEFConfiguration` extension method permits adding the configuration source to a `ConfigurationBuilder`.

Extensions/EntityFrameworkExtensions.cs:

```
public static class EntityFrameworkExtensions
{
    public static IConfigurationBuilder AddEFConfiguration(
        this IConfigurationBuilder builder,
        Action<DbContextOptionsBuilder> optionsAction)
    {
        return builder.Add(new EFConfigurationSource(optionsAction));
    }
}
```

The following code shows how to use the custom `EFConfigurationProvider` in *Program.cs*:

```
public class Program
{
    public static Dictionary<string, string> arrayDict =
        new Dictionary<string, string>
        {
            {"array:entries:0", "value0"},
            {"array:entries:1", "value1"},
            {"array:entries:2", "value2"},
            {"array:entries:4", "value4"},
            {"array:entries:5", "value5"}
        };

    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddInMemoryCollection(arrayDict);
                config.AddJsonFile(
                    "json_array.json", optional: false, reloadOnChange: false);
                config.AddJsonFile(
                    "starship.json", optional: false, reloadOnChange: false);
                config.AddXmlFile(
                    "tvshow.xml", optional: false, reloadOnChange: false);
                config.AddEFConfiguration(
                    options => options.UseInMemoryDatabase("InMemoryDb"));
                config.AddCommandLine(args);
            })
            .UseStartup<Startup>();
}
```

Access configuration during startup

Inject `IConfiguration` into the `Startup` constructor to access configuration values in `Startup.ConfigureServices`. To access configuration in `Startup.Configure`, either inject `IConfiguration` directly into the method or use the instance from the constructor:

```
public class Startup
{
    private readonly IConfiguration _config;

    public Startup(IConfiguration config)
    {
        _config = config;
    }

    public void ConfigureServices(IServiceCollection services)
    {
        var value = _config["key"];
    }

    public void Configure(IApplicationBuilder app, IConfiguration config)
    {
        var value = config["key"];
    }
}
```

For an example of accessing configuration using startup convenience methods, see App startup: Convenience methods.

Access configuration in a Razor Pages page or MVC view

To access configuration settings in a Razor Pages page or an MVC view, add a using directive (C# reference: using directive) for the Microsoft.Extensions.Configuration namespace and inject IConfiguration into the page or view.

In a Razor Pages page:

```
@page
@model IndexModel
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration

<!DOCTYPE html>
<html lang="en">
<head>
    <title>Index Page</title>
</head>
<body>
    <h1>Access configuration in a Razor Pages page</h1>
    <p>Configuration value for 'key': @Configuration["key"]</p>
</body>
</html>
```

In an MVC view:

```
@using Microsoft.Extensions.Configuration
@inject IConfiguration Configuration

<!DOCTYPE html>
<html lang="en">
<head>
    <title>Index View</title>
</head>
<body>
    <h1>Access configuration in an MVC view</h1>
    <p>Configuration value for 'key': @Configuration["key"]</p>
</body>
</html>
```

Add configuration from an external assembly

An IHostingStartup implementation allows adding enhancements to an app at startup from an external assembly outside of the app's `Startup` class. For more information, see Use hosting startup assemblies in ASP.NET Core.

- Options pattern in ASP.NET Core

Options pattern in ASP.NET Core

9/22/2020 • 34 minutes to read • Edit Online

By Kirk Larkin and Rick Anderson.

The options pattern uses classes to provide strongly typed access to groups of related settings. When configuration settings are isolated by scenario into separate classes, the app adheres to two important software engineering principles:

- The Interface Segregation Principle (ISP) or Encapsulation: Scenarios (classes) that depend on configuration settings depend only on the configuration settings that they use.
- Separation of Concerns: Settings for different parts of the app aren't dependent or coupled to one another.

Options also provide a mechanism to validate configuration data. For more information, see the Options validation section.

View or download sample code (how to download)

Bind hierarchical configuration

The preferred way to read related configuration values is using the options pattern. For example, to read the following configuration values:

```
"Position": {
  "Title": "Editor",
  "Name": "Joe Smith"
}
```

Create the following `PositionOptions` class:

```
public class PositionOptions
{
    public const string Position = "Position";

    public string Title { get; set; }
    public string Name { get; set; }
}
```

An options class:

- Must be non-abstract with a public parameterless constructor.
- All public read-write properties of the type are bound.
- Fields are ***not*** bound. In the preceding code, `Position` is not bound. The `Position` property is used so the string `"Position"` doesn't need to be hard coded in the app when binding the class to a configuration provider.

The following code:

- Calls ConfigurationBinder.Bind to bind the `PositionOptions` class to the `Position` section.
- Displays the `Position` configuration data.

```
public class Test22Model : PageModel
{
    private readonly IConfiguration Configuration;

    public Test22Model(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        var positionOptions = new PositionOptions();
        Configuration.GetSection(PositionOptions.Position).Bind(positionOptions);

        return Content($"Title: {positionOptions.Title} \n" +
                       $"Name: {positionOptions.Name}");
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has started are read.

`ConfigurationBinder.Get<T>` binds and returns the specified type. `ConfigurationBinder.Get<T>` may be more convenient than using `ConfigurationBinder.Bind`. The following code shows how to use `ConfigurationBinder.Get<T>` with the `PositionOptions` class:

```
public class Test21Model : PageModel
{
    private readonly IConfiguration Configuration;
    public PositionOptions positionOptions { get; private set; }

    public Test21Model(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public ContentResult OnGet()
    {
        positionOptions = Configuration.GetSection(PositionOptions.Position)
                                                    .Get<PositionOptions>();

        return Content($"Title: {positionOptions.Title} \n" +
                       $"Name: {positionOptions.Name}");
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has started are read.

An alternative approach when using the ***options pattern*** is to bind the `Position` section and add it to the dependency injection service container. In the following code, `PositionOptions` is added to the service container with Configure and bound to configuration:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<PositionOptions>(Configuration.GetSection(
                                        PositionOptions.Position));
    services.AddRazorPages();
}
```

Using the preceding code, the following code reads the position options:

```
public class Test2Model : PageModel
{
    private readonly PositionOptions _options;

    public Test2Model(IOptions<PositionOptions> options)
    {
        _options = options.Value;
    }

    public ContentResult OnGet()
    {
        return Content($"Title: {_options.Title} \n" +
                       $"Name: {_options.Name}");
    }
}
```

In the preceding code, changes to the JSON configuration file after the app has started are ***not*** read. To read changes after the app has started, use IOptionsSnapshot.

Options interfaces

IOptions<TOptions>:

- Does ***not*** support:
  - Reading of configuration data after the app has started.
  - Named options
- Is registered as a Singleton and can be injected into any service lifetime.

IOptionsSnapshot<TOptions>:

- Is useful in scenarios where options should be recomputed on every request. For more information, see Use IOptionsSnapshot to read updated data.
- Is registered as Scoped and therefore cannot be injected into a Singleton service.
- Supports named options

IOptionsMonitor<TOptions>:

- Is used to retrieve options and manage options notifications for `TOptions` instances.
- Is registered as a Singleton and can be injected into any service lifetime.
- Supports:
  - Change notifications
  - Named options
  - Reloadable configuration
  - Selective options invalidation (IOptionsMonitorCache<TOptions>)

Post-configuration scenarios enable setting or changing options after all IConfigureOptions<TOptions> configuration occurs.

IOptionsFactory<TOptions> is responsible for creating new options instances. It has a single Create method. The default implementation takes all registered IConfigureOptions<TOptions> and IPostConfigureOptions<TOptions> and runs all the configurations first, followed by the post-configuration. It distinguishes between IConfigureNamedOptions<TOptions> and IConfigureOptions<TOptions> and only calls the appropriate interface.

IOptionsMonitorCache<TOptions> is used by IOptionsMonitor<TOptions> to cache `TOptions` instances. The IOptionsMonitorCache<TOptions> invalidates options instances in the monitor so that the value is recomputed

(TryRemove). Values can be manually introduced with TryAdd. The Clear method is used when all named instances should be recreated on demand.

Use IOptionsSnapshot to read updated data

Using IOptionsSnapshot<TOptions>, options are computed once per request when accessed and cached for the lifetime of the request. Changes to the configuration are read after the app starts when using configuration providers that support reading updated configuration values.

The difference between `IOptionsMonitor` and `IOptionsSnapshot` is that:

- `IOptionsMonitor` is a singleton service that retrieves current option values at any time, which is especially useful in singleton dependencies.
- `IOptionsSnapshot` is a scoped service and provides a snapshot of the options at the time the `IOptionsSnapshot<T>` object is constructed. Options snapshots are designed for use with transient and scoped dependencies.

The following code uses IOptionsSnapshot<TOptions>.

```
public class TestSnapModel : PageModel
{
    private readonly MyOptions _snapshotOptions;

    public TestSnapModel(IOptionsSnapshot<MyOptions> snapshotOptionsAccessor)
    {
        _snapshotOptions = snapshotOptionsAccessor.Value;
    }

    public ContentResult OnGet()
    {
        return Content($"Option1: {_snapshotOptions.Option1} \n" +
                       $"Option2: {_snapshotOptions.Option2}");
    }
}
```

The following code registers a configuration instance which `MyOptions` binds against:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<MyOptions>(Configuration.GetSection("MyOptions"));

    services.AddRazorPages();
}
```

In the preceding code, changes to the JSON configuration file after the app has started are read.

IOptionsMonitor

The following code registers a configuration instance which `MyOptions` binds against.

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<MyOptions>(Configuration.GetSection("MyOptions"));

    services.AddRazorPages();
}
```

The following example uses IOptionsMonitor<TOptions>:

```
public class TestMonitorModel : PageModel
{
    private readonly IOptionsMonitor<MyOptions> _optionsDelegate;

    public TestMonitorModel(IOptionsMonitor<MyOptions> optionsDelegate )
    {
        _optionsDelegate = optionsDelegate;
    }

    public ContentResult OnGet()
    {
        return Content($"Option1: {_optionsDelegate.CurrentValue.Option1} \n" +
                       $"Option2: {_optionsDelegate.CurrentValue.Option2}");
    }
}
```

In the preceding code, by default, changes to the JSON configuration file after the app has started are read.

Named options support using IConfigureNamedOptions

Named options:

- Are useful when multiple configuration sections bind to the same properties.
- Are case sensitive.

Consider the following *appsettings.json* file:

```
{
  "TopItem": {
    "Month": {
      "Name": "Green Widget",
      "Model": "GW46"
    },
    "Year": {
      "Name": "Orange Gadget",
      "Model": "OG35"
    }
  }
}
```

Rather than creating two classes to bind `TopItem:Month` and `TopItem:Year`, the following class is used for each section:

```
public class TopItemSettings
{
    public const string Month = "Month";
    public const string Year = "Year";

    public string Name { get; set; }
    public string Model { get; set; }
}
```

The following code configures the named options:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<TopItemSettings>(TopItemSettings.Month,
                                        Configuration.GetSection("TopItem:Month"));
    services.Configure<TopItemSettings>(TopItemSettings.Year,
                                         Configuration.GetSection("TopItem:Year"));

    services.AddRazorPages();
}
```

The following code displays the named options:

```
public class TestNOModel : PageModel
{
    private readonly TopItemSettings _monthTopItem;
    private readonly TopItemSettings _yearTopItem;

    public TestNOModel(IOptionsSnapshot<TopItemSettings> namedOptionsAccessor)
    {
        _monthTopItem = namedOptionsAccessor.Get(TopItemSettings.Month);
        _yearTopItem = namedOptionsAccessor.Get(TopItemSettings.Year);
    }

    public ContentResult OnGet()
    {
        return Content($"Month:Name {_monthTopItem.Name} \n" +
                       $"Month:Model {_monthTopItem.Model} \n\n" +
                       $"Year:Name {_yearTopItem.Name} \n" +
                       $"Year:Model {_yearTopItem.Model} \n"   );
    }
}
```

All options are named instances. IConfigureOptions<TOptions> instances are treated as targeting the `Options.DefaultName` instance, which is `string.Empty`. IConfigureNamedOptions<TOptions> also implements IConfigureOptions<TOptions>. The default implementation of the IOptionsFactory<TOptions> has logic to use each appropriately. The `null` named option is used to target all of the named instances instead of a specific named instance. ConfigureAll and PostConfigureAll use this convention.

OptionsBuilder API

OptionsBuilder<TOptions> is used to configure `TOptions` instances. `OptionsBuilder` streamlines creating named options as it's only a single parameter to the initial `AddOptions<TOptions>(string optionsName)` call instead of appearing in all of the subsequent calls. Options validation and the `ConfigureOptions` overloads that accept service dependencies are only available via `OptionsBuilder`.

`OptionsBuilder` is used in the Options validation section.

Use DI services to configure options

Services can be accessed from dependency injection while configuring options in two ways:

- Pass a configuration delegate to Configure on OptionsBuilder<TOptions>. `OptionsBuilder<TOptions>` provides overloads of Configure that allow use of up to five services to configure options:

  ```
  services.AddOptions<MyOptions>("optionalName")
      .Configure<Service1, Service2, Service3, Service4, Service5>(
          (o, s, s2, s3, s4, s5) =>
              o.Property = DoSomethingWith(s, s2, s3, s4, s5));
  ```

- Create a type that implements IConfigureOptions<TOptions> or IConfigureNamedOptions<TOptions> and register the type as a service.

We recommend passing a configuration delegate to Configure, since creating a service is more complex. Creating a type is equivalent to what the framework does when calling Configure. Calling Configure registers a transient generic IConfigureNamedOptions<TOptions>, which has a constructor that accepts the generic service types specified.

Options validation

Options validation enables option values to be validated.

Consider the following *appsettings.json* file:

```
{
  "MyConfig": {
    "Key1": "My Key One",
    "Key2": 10,
    "Key3": 32
  }
}
```

The following class binds to the `"MyConfig"` configuration section and applies a couple of `DataAnnotations` rules:

```
public class MyConfigOptions
{
    public const string MyConfig = "MyConfig";

    [RegularExpression(@"^[a-zA-Z''-'\s]{1,40}$")]
    public string Key1 { get; set; }
    [Range(0, 1000,
        ErrorMessage = "Value for {0} must be between {1} and {2}.")]
    public int Key2 { get; set; }
    public int Key3 { get; set; }
}
```

The following code:

- Calls AddOptions to get an OptionsBuilder<TOptions> that binds to the `MyConfigOptions` class.
- Calls ValidateDataAnnotations to enable validation using `DataAnnotations`.

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddOptions<MyConfigOptions>()
            .Bind(Configuration.GetSection(MyConfigOptions.MyConfig))
            .ValidateDataAnnotations();

        services.AddControllersWithViews();
    }
```

The `ValidateDataAnnotations` extension method is defined in the Microsoft.Extensions.Options.DataAnnotations NuGet package. For web apps that use the `Microsoft.NET.Sdk.Web` SDK, this package is referenced implicitly from the shared framework.

The following code displays the configuration values or the validation errors:

```
public class HomeController : Controller
{
    private readonly ILogger<HomeController> _logger;
    private readonly IOptions<MyConfigOptions> _config;

    public HomeController(IOptions<MyConfigOptions> config,
                          ILogger<HomeController> logger)
    {
        _config = config;
        _logger = logger;

        try
        {
            var configValue = _config.Value;

        }
        catch (OptionsValidationException ex)
        {
            foreach (var failure in ex.Failures)
            {
                _logger.LogError(failure);
            }
        }
    }

    public ContentResult Index()
    {
        string msg;
        try
        {
             msg = $"Key1: {_config.Value.Key1} \n" +
                   $"Key2: {_config.Value.Key2} \n" +
                   $"Key3: {_config.Value.Key3}";
        }
        catch (OptionsValidationException optValEx)
        {
            return Content(optValEx.Message);
        }
        return Content(msg);
    }
```

The following code applies a more complex validation rule using a delegate:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddOptions<MyConfigOptions>()
        .Bind(Configuration.GetSection(MyConfigOptions.MyConfig))
        .ValidateDataAnnotations()
        .Validate(config =>
        {
            if (config.Key2 != 0)
            {
                return config.Key3 > config.Key2;
            }

            return true;
        }, "Key3 must be > than Key2.");   // Failure message.

    services.AddControllersWithViews();
}
```

IValidateOptions for complex validation

The following class implements IValidateOptions<TOptions>:

```
public class MyConfigValidation : IValidateOptions<MyConfigOptions>
{
    public MyConfigOptions _config { get; private set; }

    public  MyConfigValidation(IConfiguration config)
    {
        _config = config.GetSection(MyConfigOptions.MyConfig)
            .Get<MyConfigOptions>();
    }

    public ValidateOptionsResult Validate(string name, MyConfigOptions options)
    {
        string vor=null;
        var rx = new Regex(@"^[a-zA-Z''-'\s]{1,40}$");
        var match = rx.Match(options.Key1);

        if (string.IsNullOrEmpty(match.Value))
        {
            vor = $"{options.Key1} doesn't match RegEx \n";
        }

        if ( options.Key2 < 0 || options.Key2 > 1000)
        {
            vor = $"{options.Key2} doesn't match Range 0 - 1000 \n";
        }

        if (_config.Key2 != default)
        {
            if(_config.Key3 <= _config.Key2)
            {
                vor +=  "Key3 must be > than Key2.";
            }
        }

        if (vor != null)
        {
            return ValidateOptionsResult.Fail(vor);
        }

        return ValidateOptionsResult.Success;
    }
}
```

`IValidateOptions` enables moving the validation code out of `StartUp` and into a class.

Using the preceding code, validation is enabled in `Startup.ConfigureServices` with the following code:

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<MyConfigOptions>(Configuration.GetSection(
                                        MyConfigOptions.MyConfig));
    services.TryAddEnumerable(ServiceDescriptor.Singleton<IValidateOptions
                            <MyConfigOptions>, MyConfigValidation>());
    services.AddControllersWithViews();
}
```

Options post-configuration

Set post-configuration with IPostConfigureOptions<TOptions>. Post-configuration runs after all IConfigureOptions<TOptions> configuration occurs:

```
services.PostConfigure<MyOptions>(myOptions =>
{
    myOptions.Option1 = "post_configured_option1_value";
});
```

PostConfigure is available to post-configure named options:

```
services.PostConfigure<MyOptions>("named_options_1", myOptions =>
{
    myOptions.Option1 = "post_configured_option1_value";
});
```

Use PostConfigureAll to post-configure all configuration instances:

```
services.PostConfigureAll<MyOptions>(myOptions =>
{
    myOptions.Option1 = "post_configured_option1_value";
});
```

Accessing options during startup

IOptions<TOptions> and IOptionsMonitor<TOptions> can be used in `Startup.Configure`, since services are built before the `Configure` method executes.

```
public void Configure(IApplicationBuilder app,
    IOptionsMonitor<MyOptions> optionsAccessor)
{
    var option1 = optionsAccessor.CurrentValue.Option1;
}
```

Don't use IOptions<TOptions> or IOptionsMonitor<TOptions> in `Startup.ConfigureServices`. An inconsistent options state may exist due to the ordering of service registrations.

Options.ConfigurationExtensions NuGet package

The Microsoft.Extensions.Options.ConfigurationExtensions package is implicitly referenced in ASP.NET Core apps.

The options pattern uses classes to represent groups of related settings. When configuration settings are isolated by scenario into separate classes, the app adheres to two important software engineering principles:

- The Interface Segregation Principle (ISP) or Encapsulation: Scenarios (classes) that depend on configuration settings depend only on the configuration settings that they use.
- Separation of Concerns: Settings for different parts of the app aren't dependent or coupled to one another.

Options also provide a mechanism to validate configuration data. For more information, see the Options validation section.

View or download sample code (how to download)

Prerequisites

Reference the Microsoft.AspNetCore.App metapackage or add a package reference to the Microsoft.Extensions.Options.ConfigurationExtensions package.

Options interfaces

IOptionsMonitor<TOptions> is used to retrieve options and manage options notifications for `TOptions` instances. IOptionsMonitor<TOptions> supports the following scenarios:

- Change notifications
- Named options
- Reloadable configuration
- Selective options invalidation (IOptionsMonitorCache<TOptions>)

Post-configuration scenarios allow you to set or change options after all IConfigureOptions<TOptions> configuration occurs.

IOptionsFactory<TOptions> is responsible for creating new options instances. It has a single Create method. The default implementation takes all registered IConfigureOptions<TOptions> and IPostConfigureOptions<TOptions> and runs all the configurations first, followed by the post-configuration. It distinguishes between IConfigureNamedOptions<TOptions> and IConfigureOptions<TOptions> and only calls the appropriate interface.

IOptionsMonitorCache<TOptions> is used by IOptionsMonitor<TOptions> to cache `TOptions` instances. The IOptionsMonitorCache<TOptions> invalidates options instances in the monitor so that the value is recomputed (TryRemove). Values can be manually introduced with TryAdd. The Clear method is used when all named instances should be recreated on demand.

IOptionsSnapshot<TOptions> is useful in scenarios where options should be recomputed on every request. For more information, see the Reload configuration data with IOptionsSnapshot section.

IOptions<TOptions> can be used to support options. However, IOptions<TOptions> doesn't support the preceding scenarios of IOptionsMonitor<TOptions>. You may continue to use IOptions<TOptions> in existing frameworks and libraries that already use the IOptions<TOptions> interface and don't require the scenarios provided by IOptionsMonitor<TOptions>.

General options configuration

General options configuration is demonstrated as Example 1 in the sample app.

An options class must be non-abstract with a public parameterless constructor. The following class, `MyOptions`, has two properties, `Option1` and `Option2`. Setting default values is optional, but the class constructor in the

following example sets the default value of `Option1`. `Option2` has a default value set by initializing the property directly (*Models/MyOptions.cs*):

```
public class MyOptions
{
    public MyOptions()
    {
        // Set default value.
        Option1 = "value1_from_ctor";
    }

    public string Option1 { get; set; }
    public int Option2 { get; set; } = 5;
}
```

The `MyOptions` class is added to the service container with Configure and bound to configuration:

```
// Example #1: General configuration
// Register the Configuration instance which MyOptions binds against.
services.Configure<MyOptions>(Configuration);
```

The following page model uses constructor dependency injection with IOptionsMonitor<TOptions> to access the settings (*Pages/Index.cshtml.cs*):

```
private readonly MyOptions _options;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #1: Simple options
var option1 = _options.Option1;
var option2 = _options.Option2;
SimpleOptions = $"option1 = {option1}, option2 = {option2}";
```

The sample's *appsettings.json* file specifies values for `option1` and `option2`:

```
{
  "option1": "value1_from_json",
  "option2": -1,
  "subsection": {
    "suboption1": "subvalue1_from_json",
    "suboption2": 200
  },
  "Logging": {
    "LogLevel": {
      "Default": "Warning"
    }
  },
  "AllowedHosts": "*"
}
```

When the app is run, the page model's `OnGet` method returns a string showing the option class values:

```
option1 = value1_from_json, option2 = -1
```

NOTE

When using a custom ConfigurationBuilder to load options configuration from a settings file, confirm that the base path is set correctly:

```
var configBuilder = new ConfigurationBuilder()
   .SetBasePath(Directory.GetCurrentDirectory())
   .AddJsonFile("appsettings.json", optional: true);
var config = configBuilder.Build();

services.Configure<MyOptions>(config);
```

Explicitly setting the base path isn't required when loading options configuration from the settings file via CreateDefaultBuilder.

Configure simple options with a delegate

Configuring simple options with a delegate is demonstrated as Example 2 in the sample app.

Use a delegate to set options values. The sample app uses the `MyOptionsWithDelegateConfig` class (*Models/MyOptionsWithDelegateConfig.cs*):

```
public class MyOptionsWithDelegateConfig
{
    public MyOptionsWithDelegateConfig()
    {
        // Set default value.
        Option1 = "value1_from_ctor";
    }

    public string Option1 { get; set; }
    public int Option2 { get; set; } = 5;
}
```

In the following code, a second IConfigureOptions<TOptions> service is added to the service container. It uses a delegate to configure the binding with `MyOptionsWithDelegateConfig`:

```
// Example #2: Options bound and configured by a delegate
services.Configure<MyOptionsWithDelegateConfig>(myOptions =>
{
    myOptions.Option1 = "value1_configured_by_delegate";
    myOptions.Option2 = 500;
});
```

Index.cshtml.cs:

```
private readonly MyOptionsWithDelegateConfig _optionsWithDelegateConfig;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #2: Options configured by delegate
var delegate_config_option1 = _optionsWithDelegateConfig.Option1;
var delegate_config_option2 = _optionsWithDelegateConfig.Option2;
SimpleOptionsWithDelegateConfig =
    $"delegate_option1 = {delegate_config_option1}, " +
    $"delegate_option2 = {delegate_config_option2}";
```

You can add multiple configuration providers. Configuration providers are available from NuGet packages and are applied in the order that they're registered. For more information, see Configuration in ASP.NET Core.

Each call to Configure adds an IConfigureOptions<TOptions> service to the service container. In the preceding example, the values of `Option1` and `Option2` are both specified in *appsettings.json*, but the values of `Option1` and `Option2` are overridden by the configured delegate.

When more than one configuration service is enabled, the last configuration source specified *wins* and sets the configuration value. When the app is run, the page model's `OnGet` method returns a string showing the option class values:

```
delegate_option1 = value1_configured_by_delegate, delegate_option2 = 500
```

Suboptions configuration

Suboptions configuration is demonstrated as Example 3 in the sample app.

Apps should create options classes that pertain to specific scenario groups (classes) in the app. Parts of the app that require configuration values should only have access to the configuration values that they use.

When binding options to configuration, each property in the options type is bound to a configuration key of the form `property[:sub-property:]`. For example, the `MyOptions.Option1` property is bound to the key `Option1`

, which is read from the `option1` property in *appsettings.json*.

In the following code, a third IConfigureOptions<TOptions> service is added to the service container. It binds `MySubOptions` to the section `subsection` of the *appsettings.json* file:

```
// Example #3: Suboptions
// Bind options using a sub-section of the appsettings.json file.
services.Configure<MySubOptions>(Configuration.GetSection("subsection"));
```

The `GetSection` method requires the Microsoft.Extensions.Configuration namespace.

The sample's *appsettings.json* file defines a `subsection` member with keys for `suboption1` and `suboption2`:

```
{
  "option1": "value1_from_json",
  "option2": -1,
  "subsection": {
    "suboption1": "subvalue1_from_json",
    "suboption2": 200
  },
  "Logging": {
    "LogLevel": {
      "Default": "Warning"
    }
  },
  "AllowedHosts": "*"
}
```

The `MySubOptions` class defines properties, `SubOption1` and `SubOption2`, to hold the options values (*Models/MySubOptions.cs*):

```
public class MySubOptions
{
    public MySubOptions()
    {
        // Set default values.
        SubOption1 = "value1_from_ctor";
        SubOption2 = 5;
    }

    public string SubOption1 { get; set; }
    public int SubOption2 { get; set; }
}
```

The page model's `OnGet` method returns a string with the options values (*Pages/Index.cshtml.cs*):

```
private readonly MySubOptions _subOptions;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #3: Suboptions
var subOption1 = _subOptions.SubOption1;
var subOption2 = _subOptions.SubOption2;
SubOptions = $"subOption1 = {subOption1}, subOption2 = {subOption2}";
```

When the app is run, the `OnGet` method returns a string showing the suboption class values:

```
subOption1 = subvalue1_from_json, subOption2 = 200
```

Options injection

Options injection is demonstrated as Example 4 in the sample app.

Inject IOptionsMonitor<TOptions> into:

- A Razor page or MVC view with the `@inject` Razor directive.
- A page or view model.

The following example from the sample app injects IOptionsMonitor<TOptions> into a page model (*Pages/Index.cshtml.cs*):

```
private readonly MyOptions _options;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #4: Bind options directly to the page
MyOptions = _options;
```

The sample app shows how to inject `IOptionsMonitor<MyOptions>` with an `@inject` directive:

```
@page
@model IndexModel
@using Microsoft.Extensions.Options
@inject IOptionsMonitor<MyOptions> OptionsAccessor
@{
    ViewData["Title"] = "Options Sample";
}

<h1>@ViewData["Title"]</h1>
```

When the app is run, the options values are shown in the rendered page:

Example #4: Model and injected options

Options provided by the model

Options provided by the model: `@Model.MyOptions.Option1` and `@Model.MyOptions.Option2`

Option1: value1_from_json

Option2: -1

Options injected into the page

Options injected into the page: `@inject IOptions<MyOptions> OptionsAccessor` with `@OptionsAccessor.Value.Option1` and `@OptionsAccessor.Value.Option2`

Option1: value1_from_json

Option2: -1

Reload configuration data with IOptionsSnapshot

Reloading configuration data with IOptionsSnapshot<TOptions> is demonstrated in Example 5 in the sample app.

Using IOptionsSnapshot<TOptions>, options are computed once per request when accessed and cached for the lifetime of the request.

The difference between `IOptionsMonitor` and `IOptionsSnapshot` is that:

- `IOptionsMonitor` is a singleton service that retrieves current option values at any time, which is especially useful in singleton dependencies.
- `IOptionsSnapshot` is a scoped service and provides a snapshot of the options at the time the `IOptionsSnapshot<T>` object is constructed. Options snapshots are designed for use with transient and scoped dependencies.

The following example demonstrates how a new IOptionsSnapshot<TOptions> is created after *appsettings.json* changes (*Pages/Index.cshtml.cs*). Multiple requests to the server return constant values provided by the *appsettings.json* file until the file is changed and configuration reloads.

```
private readonly MyOptions _snapshotOptions;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #5: Snapshot options
var snapshotOption1 = _snapshotOptions.Option1;
var snapshotOption2 = _snapshotOptions.Option2;
SnapshotOptions =
    $"snapshot option1 = {snapshotOption1}, " +
    $"snapshot option2 = {snapshotOption2}";
```

The following image shows the initial `option1` and `option2` values loaded from the *appsettings.json* file:

```
snapshot option1 = value1_from_json, snapshot option2 = -1
```

Change the values in the *appsettings.json* file to `value1_from_json UPDATED` and `200`. Save the *appsettings.json* file. Refresh the browser to see that the options values are updated:

```
snapshot option1 = value1_from_json UPDATED, snapshot option2 = 200
```

Named options support with IConfigureNamedOptions

Named options support with IConfigureNamedOptions<TOptions> is demonstrated as Example 6 in the sample app.

Named options support allows the app to distinguish between named options configurations. In the sample app, named options are declared with OptionsServiceCollectionExtensions.Configure, which calls the ConfigureNamedOptions<TOptions>.Configure extension method. Named options are case sensitive.

```
// Example #6: Named options (named_options_1)
// Register the ConfigurationBuilder instance which MyOptions binds against.
// Specify that the options loaded from configuration are named
// "named_options_1".
services.Configure<MyOptions>("named_options_1", Configuration);

// Example #6: Named options (named_options_2)
// Specify that the options loaded from the MyOptions class are named
// "named_options_2".
// Use a delegate to configure option values.
services.Configure<MyOptions>("named_options_2", myOptions =>
{
    myOptions.Option1 = "named_options_2_value1_from_action";
});
```

The sample app accesses the named options with Get (*Pages/Index.cshtml.cs*):

```
private readonly MyOptions _named_options_1;
private readonly MyOptions _named_options_2;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #6: Named options
var named_options_1 =
    $"named_options_1: option1 = {_named_options_1.Option1}, " +
    $"option2 = {_named_options_1.Option2}";
var named_options_2 =
    $"named_options_2: option1 = {_named_options_2.Option1}, " +
    $"option2 = {_named_options_2.Option2}";
NamedOptions = $"{named_options_1} {named_options_2}";
```

Running the sample app, the named options are returned:

```
named_options_1: option1 = value1_from_json, option2 = -1
named_options_2: option1 = named_options_2_value1_from_action, option2 = 5
```

`named_options_1` values are provided from configuration, which are loaded from the *appsettings.json* file. `named_options_2` values are provided by:

- The `named_options_2` delegate in `ConfigureServices` for `Option1`.
- The default value for `Option2` provided by the `MyOptions` class.

Configure all options with the ConfigureAll method

Configure all options instances with the ConfigureAll method. The following code configures `Option1` for all configuration instances with a common value. Add the following code manually to the `Startup.ConfigureServices` method:

```
services.ConfigureAll<MyOptions>(myOptions =>
{
    myOptions.Option1 = "ConfigureAll replacement value";
});
```

Running the sample app after adding the code produces the following result:

```
named_options_1: option1 = ConfigureAll replacement value, option2 = -1
named_options_2: option1 = ConfigureAll replacement value, option2 = 5
```

NOTE

All options are named instances. Existing IConfigureOptions<TOptions> instances are treated as targeting the `Options.DefaultName` instance, which is `string.Empty`. IConfigureNamedOptions<TOptions> also implements IConfigureOptions<TOptions>. The default implementation of the IOptionsFactory<TOptions> has logic to use each appropriately. The `null` named option is used to target all of the named instances instead of a specific named instance (ConfigureAll and PostConfigureAll use this convention).

OptionsBuilder API

OptionsBuilder<TOptions> is used to configure `TOptions` instances. `OptionsBuilder` streamlines creating named options as it's only a single parameter to the initial `AddOptions<TOptions>(string optionsName)` call instead of appearing in all of the subsequent calls. Options validation and the `ConfigureOptions` overloads that accept service dependencies are only available via `OptionsBuilder`.

```
// Options.DefaultName = "" is used.
services.AddOptions<MyOptions>().Configure(o => o.Property = "default");

services.AddOptions<MyOptions>("optionalName")
    .Configure(o => o.Property = "named");
```

Use DI services to configure options

You can access other services from dependency injection while configuring options in two ways:

- Pass a configuration delegate to Configure on OptionsBuilder<TOptions>. OptionsBuilder<TOptions> provides overloads of Configure that allow you to use up to five services to configure options:

  ```
  services.AddOptions<MyOptions>("optionalName")
      .Configure<Service1, Service2, Service3, Service4, Service5>(
          (o, s, s2, s3, s4, s5) =>
              o.Property = DoSomethingWith(s, s2, s3, s4, s5));
  ```

- Create your own type that implements IConfigureOptions<TOptions> or IConfigureNamedOptions<TOptions> and register the type as a service.

We recommend passing a configuration delegate to Configure, since creating a service is more complex. Creating your own type is equivalent to what the framework does for you when you use Configure. Calling Configure registers a transient generic IConfigureNamedOptions<TOptions>, which has a constructor that accepts the generic service types specified.

Options validation

Options validation allows you to validate options when options are configured. Call `Validate` with a validation method that returns `true` if options are valid and `false` if they aren't valid:

```
// Registration
services.AddOptions<MyOptions>("optionalOptionsName")
    .Configure(o => { }) // Configure the options
    .Validate(o => YourValidationShouldReturnTrueIfValid(o),
        "custom error");

// Consumption
var monitor = services.BuildServiceProvider()
    .GetService<IOptionsMonitor<MyOptions>>();

try
{
    var options = monitor.Get("optionalOptionsName");
}
catch (OptionsValidationException e)
{
   // e.OptionsName returns "optionalOptionsName"
   // e.OptionsType returns typeof(MyOptions)
   // e.Failures returns a list of errors, which would contain
   //     "custom error"
}
```

The preceding example sets the named options instance to `optionalOptionsName`. The default options instance is `Options.DefaultName`.

Validation runs when the options instance is created. An options instance is guaranteed to pass validation the first time it's accessed.

> **IMPORTANT**
>
> Options validation doesn't guard against options modifications after the options instance is created. For example, `IOptionsSnapshot` options are created and validated once per request when the options are first accessed. The `IOptionsSnapshot` options aren't validated again on subsequent access attempts *for the same request*.

The `Validate` method accepts a `Func<TOptions, bool>`. To fully customize validation, implement `IValidateOptions<TOptions>`, which allows:

- Validation of multiple options types:
  `class ValidateTwo : IValidateOptions<Option1>, IValidationOptions<Option2>`
- Validation that depends on another option type:
  `public DependsOnAnotherOptionValidator(IOptionsMonitor<AnotherOption> options)`

`IValidateOptions` validates:

- A specific named options instance.
- All options when `name` is `null`.

Return a `ValidateOptionsResult` from your implementation of the interface:

```
public interface IValidateOptions<TOptions> where TOptions : class
{
    ValidateOptionsResult Validate(string name, TOptions options);
}
```

Data Annotation-based validation is available from the Microsoft.Extensions.Options.DataAnnotations package by calling the ValidateDataAnnotations method on `OptionsBuilder<TOptions>`.
`Microsoft.Extensions.Options.DataAnnotations` is included in the Microsoft.AspNetCore.App metapackage.

```
using Microsoft.Extensions.DependencyInjection;

private class AnnotatedOptions
{
    [Required]
    public string Required { get; set; }

    [StringLength(5, ErrorMessage = "Too long.")]
    public string StringLength { get; set; }

    [Range(-5, 5, ErrorMessage = "Out of range.")]
    public int IntRange { get; set; }
}

[Fact]
public void CanValidateDataAnnotations()
{
    var services = new ServiceCollection();
    services.AddOptions<AnnotatedOptions>()
        .Configure(o =>
        {
            o.StringLength = "111111";
            o.IntRange = 10;
            o.Custom = "nowhere";
        })
        .ValidateDataAnnotations();

    var sp = services.BuildServiceProvider();

    var error = Assert.Throws<OptionsValidationException>(() =>
        sp.GetRequiredService<IOptionsMonitor<AnnotatedOptions>>().CurrentValue);
    ValidateFailure<AnnotatedOptions>(error, Options.DefaultName, 1,
        "DataAnnotation validation failed for members Required " +
            "with the error 'The Required field is required.'.",
        "DataAnnotation validation failed for members StringLength " +
            "with the error 'Too long.'.",
        "DataAnnotation validation failed for members IntRange " +
            "with the error 'Out of range.'.");
}
```

Eager validation (fail fast at startup) is under consideration for a future release.

Options post-configuration

Set post-configuration with IPostConfigureOptions<TOptions>. Post-configuration runs after all IConfigureOptions<TOptions> configuration occurs:

```
services.PostConfigure<MyOptions>(myOptions =>
{
    myOptions.Option1 = "post_configured_option1_value";
});
```

PostConfigure is available to post-configure named options:

```
services.PostConfigure<MyOptions>("named_options_1", myOptions =>
{
    myOptions.Option1 = "post_configured_option1_value";
});
```

Use PostConfigureAll to post-configure all configuration instances:

```
services.PostConfigureAll<MyOptions>(myOptions =>
{
    myOptions.Option1 = "post_configured_option1_value";
});
```

Accessing options during startup

IOptions<TOptions> and IOptionsMonitor<TOptions> can be used in `Startup.Configure`, since services are built before the `Configure` method executes.

```
public void Configure(IApplicationBuilder app, IOptionsMonitor<MyOptions> optionsAccessor)
{
    var option1 = optionsAccessor.CurrentValue.Option1;
}
```

Don't use IOptions<TOptions> or IOptionsMonitor<TOptions> in `Startup.ConfigureServices`. An inconsistent options state may exist due to the ordering of service registrations.

The options pattern uses classes to represent groups of related settings. When configuration settings are isolated by scenario into separate classes, the app adheres to two important software engineering principles:

- The Interface Segregation Principle (ISP) or Encapsulation: Scenarios (classes) that depend on configuration settings depend only on the configuration settings that they use.
- Separation of Concerns: Settings for different parts of the app aren't dependent or coupled to one another.

Options also provide a mechanism to validate configuration data. For more information, see the Options validation section.

View or download sample code (how to download)

Prerequisites

Reference the Microsoft.AspNetCore.App metapackage or add a package reference to the Microsoft.Extensions.Options.ConfigurationExtensions package.

Options interfaces

IOptionsMonitor<TOptions> is used to retrieve options and manage options notifications for `TOptions` instances. IOptionsMonitor<TOptions> supports the following scenarios:

- Change notifications
- Named options
- Reloadable configuration
- Selective options invalidation (IOptionsMonitorCache<TOptions>)

Post-configuration scenarios allow you to set or change options after all IConfigureOptions<TOptions> configuration occurs.

IOptionsFactory<TOptions> is responsible for creating new options instances. It has a single Create method. The default implementation takes all registered IConfigureOptions<TOptions> and IPostConfigureOptions<TOptions> and runs all the configurations first, followed by the post-configuration. It distinguishes between IConfigureNamedOptions<TOptions> and IConfigureOptions<TOptions> and only calls the appropriate interface.

IOptionsMonitorCache<TOptions> is used by IOptionsMonitor<TOptions> to cache `TOptions` instances. The

IOptionsMonitorCache<TOptions> invalidates options instances in the monitor so that the value is recomputed (TryRemove). Values can be manually introduced with TryAdd. The Clear method is used when all named instances should be recreated on demand.

IOptionsSnapshot<TOptions> is useful in scenarios where options should be recomputed on every request. For more information, see the Reload configuration data with IOptionsSnapshot section.

IOptions<TOptions> can be used to support options. However, IOptions<TOptions> doesn't support the preceding scenarios of IOptionsMonitor<TOptions>. You may continue to use IOptions<TOptions> in existing frameworks and libraries that already use the IOptions<TOptions> interface and don't require the scenarios provided by IOptionsMonitor<TOptions>.

General options configuration

General options configuration is demonstrated as Example 1 in the sample app.

An options class must be non-abstract with a public parameterless constructor. The following class, `MyOptions`, has two properties, `Option1` and `Option2`. Setting default values is optional, but the class constructor in the following example sets the default value of `Option1`. `Option2` has a default value set by initializing the property directly (*Models/MyOptions.cs*):

```
public class MyOptions
{
    public MyOptions()
    {
        // Set default value.
        Option1 = "value1_from_ctor";
    }

    public string Option1 { get; set; }
    public int Option2 { get; set; } = 5;
}
```

The `MyOptions` class is added to the service container with Configure and bound to configuration:

```
// Example #1: General configuration
// Register the Configuration instance which MyOptions binds against.
services.Configure<MyOptions>(Configuration);
```

The following page model uses constructor dependency injection with IOptionsMonitor<TOptions> to access the settings (*Pages/Index.cshtml.cs*):

```
private readonly MyOptions _options;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #1: Simple options
var option1 = _options.Option1;
var option2 = _options.Option2;
SimpleOptions = $"option1 = {option1}, option2 = {option2}";
```

The sample's *appsettings.json* file specifies values for `option1` and `option2`:

```
{
  "option1": "value1_from_json",
  "option2": -1,
  "subsection": {
    "suboption1": "subvalue1_from_json",
    "suboption2": 200
  },
  "Logging": {
    "LogLevel": {
      "Default": "Warning"
    }
  },
  "AllowedHosts": "*"
}
```

When the app is run, the page model's `OnGet` method returns a string showing the option class values:

```
option1 = value1_from_json, option2 = -1
```

NOTE

When using a custom ConfigurationBuilder to load options configuration from a settings file, confirm that the base path is set correctly:

```
var configBuilder = new ConfigurationBuilder()
   .SetBasePath(Directory.GetCurrentDirectory())
   .AddJsonFile("appsettings.json", optional: true);
var config = configBuilder.Build();

services.Configure<MyOptions>(config);
```

Explicitly setting the base path isn't required when loading options configuration from the settings file via CreateDefaultBuilder.

Configure simple options with a delegate

Configuring simple options with a delegate is demonstrated as Example 2 in the sample app.

Use a delegate to set options values. The sample app uses the `MyOptionsWithDelegateConfig` class (*Models/MyOptionsWithDelegateConfig.cs*):

```
public class MyOptionsWithDelegateConfig
{
    public MyOptionsWithDelegateConfig()
    {
        // Set default value.
        Option1 = "value1_from_ctor";
    }

    public string Option1 { get; set; }
    public int Option2 { get; set; } = 5;
}
```

In the following code, a second IConfigureOptions<TOptions> service is added to the service container. It uses a delegate to configure the binding with `MyOptionsWithDelegateConfig`:

```
// Example #2: Options bound and configured by a delegate
services.Configure<MyOptionsWithDelegateConfig>(myOptions =>
{
    myOptions.Option1 = "value1_configured_by_delegate";
    myOptions.Option2 = 500;
});
```

Index.cshtml.cs:

```
private readonly MyOptionsWithDelegateConfig _optionsWithDelegateConfig;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #2: Options configured by delegate
var delegate_config_option1 = _optionsWithDelegateConfig.Option1;
var delegate_config_option2 = _optionsWithDelegateConfig.Option2;
SimpleOptionsWithDelegateConfig =
    $"delegate_option1 = {delegate_config_option1}, " +
    $"delegate_option2 = {delegate_config_option2}";
```

You can add multiple configuration providers. Configuration providers are available from NuGet packages and are applied in the order that they're registered. For more information, see Configuration in ASP.NET Core.

Each call to Configure adds an IConfigureOptions<TOptions> service to the service container. In the preceding example, the values of `Option1` and `Option2` are both specified in *appsettings.json*, but the values of `Option1`

and `Option2` are overridden by the configured delegate.

When more than one configuration service is enabled, the last configuration source specified *wins* and sets the configuration value. When the app is run, the page model's `OnGet` method returns a string showing the option class values:

```
delegate_option1 = value1_configured_by_delegate, delegate_option2 = 500
```

Suboptions configuration

Suboptions configuration is demonstrated as Example 3 in the sample app.

Apps should create options classes that pertain to specific scenario groups (classes) in the app. Parts of the app that require configuration values should only have access to the configuration values that they use.

When binding options to configuration, each property in the options type is bound to a configuration key of the form `property[:sub-property:]`. For example, the `MyOptions.Option1` property is bound to the key `Option1`, which is read from the `option1` property in *appsettings.json*.

In the following code, a third IConfigureOptions<TOptions> service is added to the service container. It binds `MySubOptions` to the section `subsection` of the *appsettings.json* file:

```
// Example #3: Suboptions
// Bind options using a sub-section of the appsettings.json file.
services.Configure<MySubOptions>(Configuration.GetSection("subsection"));
```

The `GetSection` method requires the Microsoft.Extensions.Configuration namespace.

The sample's *appsettings.json* file defines a `subsection` member with keys for `suboption1` and `suboption2`:

```
{
  "option1": "value1_from_json",
  "option2": -1,
  "subsection": {
    "suboption1": "subvalue1_from_json",
    "suboption2": 200
  },
  "Logging": {
    "LogLevel": {
      "Default": "Warning"
    }
  },
  "AllowedHosts": "*"
}
```

The `MySubOptions` class defines properties, `SubOption1` and `SubOption2`, to hold the options values (*Models/MySubOptions.cs*):

```
public class MySubOptions
{
    public MySubOptions()
    {
        // Set default values.
        SubOption1 = "value1_from_ctor";
        SubOption2 = 5;
    }

    public string SubOption1 { get; set; }
    public int SubOption2 { get; set; }
}
```

The page model's `OnGet` method returns a string with the options values (*Pages/Index.cshtml.cs*):

```
private readonly MySubOptions _subOptions;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #3: Suboptions
var subOption1 = _subOptions.SubOption1;
var subOption2 = _subOptions.SubOption2;
SubOptions = $"subOption1 = {subOption1}, subOption2 = {subOption2}";
```

When the app is run, the `OnGet` method returns a string showing the suboption class values:

```
subOption1 = subvalue1_from_json, subOption2 = 200
```

Options provided by a view model or with direct view injection

Options provided by a view model or with direct view injection is demonstrated as Example 4 in the sample app.

Options can be supplied in a view model or by injecting IOptionsMonitor<TOptions> directly into a view (*Pages/Index.cshtml.cs*):

```
private readonly MyOptions _options;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #4: Bind options directly to the page
MyOptions = _options;
```

The sample app shows how to inject `IOptionsMonitor<MyOptions>` with an `@inject` directive:

```
@page
@model IndexModel
@using Microsoft.Extensions.Options
@inject IOptionsMonitor<MyOptions> OptionsAccessor
@{
    ViewData["Title"] = "Options Sample";
}

<h1>@ViewData["Title"]</h1>
```

When the app is run, the options values are shown in the rendered page:

Example #4: Model and injected options

Options provided by the model

Options provided by the model: `@Model.MyOptions.Option1` and `@Model.MyOptions.Option2`

Option1: value1_from_json

Option2: -1

Options injected into the page

Options injected into the page: `@inject IOptions<MyOptions> OptionsAccessor` with `@OptionsAccessor.Value.Option1` and `@OptionsAccessor.Value.Option2`

Option1: value1_from_json

Option2: -1

Reload configuration data with IOptionsSnapshot

Reloading configuration data with IOptionsSnapshot<TOptions> is demonstrated in Example 5 in the sample app.

IOptionsSnapshot<TOptions> supports reloading options with minimal processing overhead.

Options are computed once per request when accessed and cached for the lifetime of the request.

The following example demonstrates how a new IOptionsSnapshot<TOptions> is created after *appsettings.json*

changes (*Pages/Index.cshtml.cs*). Multiple requests to the server return constant values provided by the *appsettings.json* file until the file is changed and configuration reloads.

```
private readonly MyOptions _snapshotOptions;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #5: Snapshot options
var snapshotOption1 = _snapshotOptions.Option1;
var snapshotOption2 = _snapshotOptions.Option2;
SnapshotOptions =
    $"snapshot option1 = {snapshotOption1}, " +
    $"snapshot option2 = {snapshotOption2}";
```

The following image shows the initial `option1` and `option2` values loaded from the *appsettings.json* file:

```
snapshot option1 = value1_from_json, snapshot option2 = -1
```

Change the values in the *appsettings.json* file to `value1_from_json UPDATED` and `200`. Save the *appsettings.json* file. Refresh the browser to see that the options values are updated:

```
snapshot option1 = value1_from_json UPDATED, snapshot option2 = 200
```

Named options support with IConfigureNamedOptions

Named options support with IConfigureNamedOptions<TOptions> is demonstrated as Example 6 in the sample app.

Named options support allows the app to distinguish between named options configurations. In the sample app, named options are declared with OptionsServiceCollectionExtensions.Configure, which calls the ConfigureNamedOptions<TOptions>.Configure extension method. Named options are case sensitive.

```
// Example #6: Named options (named_options_1)
// Register the ConfigurationBuilder instance which MyOptions binds against.
// Specify that the options loaded from configuration are named
// "named_options_1".
services.Configure<MyOptions>("named_options_1", Configuration);

// Example #6: Named options (named_options_2)
// Specify that the options loaded from the MyOptions class are named
// "named_options_2".
// Use a delegate to configure option values.
services.Configure<MyOptions>("named_options_2", myOptions =>
{
    myOptions.Option1 = "named_options_2_value1_from_action";
});
```

The sample app accesses the named options with Get (*Pages/Index.cshtml.cs*):

```
private readonly MyOptions _named_options_1;
private readonly MyOptions _named_options_2;
```

```
public IndexModel(
    IOptionsMonitor<MyOptions> optionsAccessor,
    IOptionsMonitor<MyOptionsWithDelegateConfig> optionsAccessorWithDelegateConfig,
    IOptionsMonitor<MySubOptions> subOptionsAccessor,
    IOptionsSnapshot<MyOptions> snapshotOptionsAccessor,
    IOptionsSnapshot<MyOptions> namedOptionsAccessor)
{
    _options = optionsAccessor.CurrentValue;
    _optionsWithDelegateConfig = optionsAccessorWithDelegateConfig.CurrentValue;
    _subOptions = subOptionsAccessor.CurrentValue;
    _snapshotOptions = snapshotOptionsAccessor.Value;
    _named_options_1 = namedOptionsAccessor.Get("named_options_1");
    _named_options_2 = namedOptionsAccessor.Get("named_options_2");
}
```

```
// Example #6: Named options
var named_options_1 =
    $"named_options_1: option1 = {_named_options_1.Option1}, " +
    $"option2 = {_named_options_1.Option2}";
var named_options_2 =
    $"named_options_2: option1 = {_named_options_2.Option1}, " +
    $"option2 = {_named_options_2.Option2}";
NamedOptions = $"{named_options_1} {named_options_2}";
```

Running the sample app, the named options are returned:

```
named_options_1: option1 = value1_from_json, option2 = -1
named_options_2: option1 = named_options_2_value1_from_action, option2 = 5
```

`named_options_1` values are provided from configuration, which are loaded from the *appsettings.json* file.
`named_options_2` values are provided by:

- The `named_options_2` delegate in `ConfigureServices` for `Option1`.
- The default value for `Option2` provided by the `MyOptions` class.

Configure all options with the ConfigureAll method

Configure all options instances with the ConfigureAll method. The following code configures `Option1` for all configuration instances with a common value. Add the following code manually to the `Startup.ConfigureServices` method:

```
services.ConfigureAll<MyOptions>(myOptions =>
{
    myOptions.Option1 = "ConfigureAll replacement value";
});
```

Running the sample app after adding the code produces the following result:

```
named_options_1: option1 = ConfigureAll replacement value, option2 = -1
named_options_2: option1 = ConfigureAll replacement value, option2 = 5
```

> **NOTE**
>
> All options are named instances. Existing IConfigureOptions<TOptions> instances are treated as targeting the `Options.DefaultName` instance, which is `string.Empty`. IConfigureNamedOptions<TOptions> also implements IConfigureOptions<TOptions>. The default implementation of the IOptionsFactory<TOptions> has logic to use each appropriately. The `null` named option is used to target all of the named instances instead of a specific named instance (ConfigureAll and PostConfigureAll use this convention).

OptionsBuilder API

OptionsBuilder<TOptions> is used to configure `TOptions` instances. `OptionsBuilder` streamlines creating named options as it's only a single parameter to the initial `AddOptions<TOptions>(string optionsName)` call instead of appearing in all of the subsequent calls. Options validation and the `ConfigureOptions` overloads that accept service dependencies are only available via `OptionsBuilder`.

```
// Options.DefaultName = "" is used.
services.AddOptions<MyOptions>().Configure(o => o.Property = "default");

services.AddOptions<MyOptions>("optionalName")
    .Configure(o => o.Property = "named");
```

Use DI services to configure options

You can access other services from dependency injection while configuring options in two ways:

- Pass a configuration delegate to Configure on OptionsBuilder<TOptions>. OptionsBuilder<TOptions> provides overloads of Configure that allow you to use up to five services to configure options:

  ```
  services.AddOptions<MyOptions>("optionalName")
      .Configure<Service1, Service2, Service3, Service4, Service5>(
          (o, s, s2, s3, s4, s5) =>
              o.Property = DoSomethingWith(s, s2, s3, s4, s5));
  ```

- Create your own type that implements IConfigureOptions<TOptions> or IConfigureNamedOptions<TOptions> and register the type as a service.

We recommend passing a configuration delegate to Configure, since creating a service is more complex. Creating your own type is equivalent to what the framework does for you when you use Configure. Calling Configure registers a transient generic IConfigureNamedOptions<TOptions>, which has a constructor that

accepts the generic service types specified.

Options post-configuration

Set post-configuration with IPostConfigureOptions<TOptions>. Post-configuration runs after all IConfigureOptions<TOptions> configuration occurs:

```
services.PostConfigure<MyOptions>(myOptions =>
{
    myOptions.Option1 = "post_configured_option1_value";
});
```

PostConfigure is available to post-configure named options:

```
services.PostConfigure<MyOptions>("named_options_1", myOptions =>
{
    myOptions.Option1 = "post_configured_option1_value";
});
```

Use PostConfigureAll to post-configure all configuration instances:

```
services.PostConfigureAll<MyOptions>(myOptions =>
{
    myOptions.Option1 = "post_configured_option1_value";
});
```

Accessing options during startup

IOptions<TOptions> and IOptionsMonitor<TOptions> can be used in `Startup.Configure`, since services are built before the `Configure` method executes.

```
public void Configure(IApplicationBuilder app, IOptionsMonitor<MyOptions> optionsAccessor)
{
    var option1 = optionsAccessor.CurrentValue.Option1;
}
```

Don't use IOptions<TOptions> or IOptionsMonitor<TOptions> in `Startup.ConfigureServices`. An inconsistent options state may exist due to the ordering of service registrations.

Additional resources

- Configuration in ASP.NET Core

Use multiple environments in ASP.NET Core

9/22/2020 • 21 minutes to read • Edit Online

By Rick Anderson and Kirk Larkin

ASP.NET Core configures app behavior based on the runtime environment using an environment variable.

View or download sample code (how to download)

Environments

To determine the runtime environment, ASP.NET Core reads from the following environment variables:

1. DOTNET_ENVIRONMENT
2. `ASPNETCORE_ENVIRONMENT` when ConfigureWebHostDefaults is called. The default ASP.NET Core web app templates call `ConfigureWebHostDefaults`. The `ASPNETCORE_ENVIRONMENT` value overrides `DOTNET_ENVIRONMENT`.

`IHostEnvironment.EnvironmentName` can be set to any value, but the following values are provided by the framework:

- Development : The launchSettings.json file sets `ASPNETCORE_ENVIRONMENT` to `Development` on the local machine.
- Staging
- Production : The default if `DOTNET_ENVIRONMENT` and `ASPNETCORE_ENVIRONMENT` have not been set.

The following code:

- Calls UseDeveloperExceptionPage when `ASPNETCORE_ENVIRONMENT` is set to `Development`.
- Calls UseExceptionHandler when the value of `ASPNETCORE_ENVIRONMENT` is set to `Staging`, `Production`, or `Staging_2`.
- Injects IWebHostEnvironment into `Startup.Configure`. This approach is useful when the app only requires adjusting `Startup.Configure` for a few environments with minimal code differences per environment.
- Is similar to the code generated by the ASP.NET Core templates.

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    if (env.IsProduction() || env.IsStaging() || env.IsEnvironment("Staging_2"))
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapRazorPages();
    });
}
```

The Environment Tag Helper uses the value of IHostEnvironment.EnvironmentName to include or exclude markup in the element:

```
<environment include="Development">
    <div>The effective tag is: &lt;environment include="Development"&gt;</div>
</environment>
<environment exclude="Development">
    <div>The effective tag is: &lt;environment exclude="Development"&gt;</div>
</environment>
<environment include="Staging,Development,Staging_2">
    <div>
        The effective tag is:
        &lt;environment include="Staging,Development,Staging_2"&gt;
    </div>
</environment>
```

The About page from the sample code includes the preceding markup and displays the value of `IWebHostEnvironment.EnvironmentName`.

On Windows and macOS, environment variables and values aren't case-sensitive. Linux environment variables and values are **case-sensitive** by default.

Create EnvironmentsSample

The sample code used in this document is based on a Razor Pages project named *EnvironmentsSample*.

The following code creates and runs a web app named *EnvironmentsSample*:

```
dotnet new webapp -o EnvironmentsSample
cd EnvironmentsSample
dotnet run --verbosity normal
```

When the app runs, it displays some of the following output:

```
Using launch settings from c:\tmp\EnvironmentsSample\Properties\launchSettings.json
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:5001
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: c:\tmp\EnvironmentsSample
```

Development and launchSettings.json

The development environment can enable features that shouldn't be exposed in production. For example, the ASP.NET Core templates enable the Developer Exception Page in the development environment.

The environment for local machine development can be set in the *Properties\launchSettings.json* file of the project. Environment values set in *launchSettings.json* override values set in the system environment.

The *launchSettings.json* file:

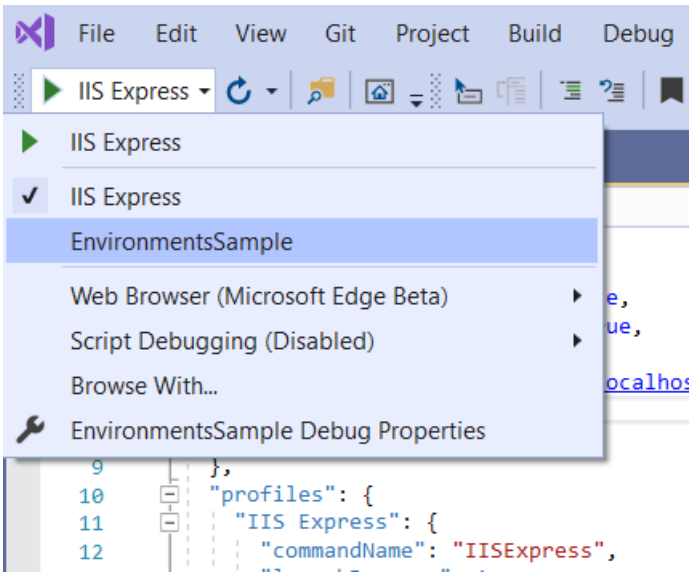
- Is only used on the local development machine.
- Is not deployed.
- contains profile settings.

The following JSON shows the *launchSettings.json* file for an ASP.NET Core web projected named *EnvironmentsSample* created with Visual Studio or `dotnet new`:

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:64645",
      "sslPort": 44366
    }
  },
  "profiles": {
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "EnvironmentsSample": {
      "commandName": "Project",
      "launchBrowser": true,
      "applicationUrl": "https://localhost:5001;http://localhost:5000",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    }
  }
}
```

The preceding markup contains two profiles:

- `IIS Express`: The default profile used when launching the app from Visual Studio. The `"commandName"` key has the value `"IISExpress"`, therefore, IISExpress is the web server. You can set the launch profile to the project or any other profile included. For example, in the image below, selecting the project name launches the Kestrel web server.

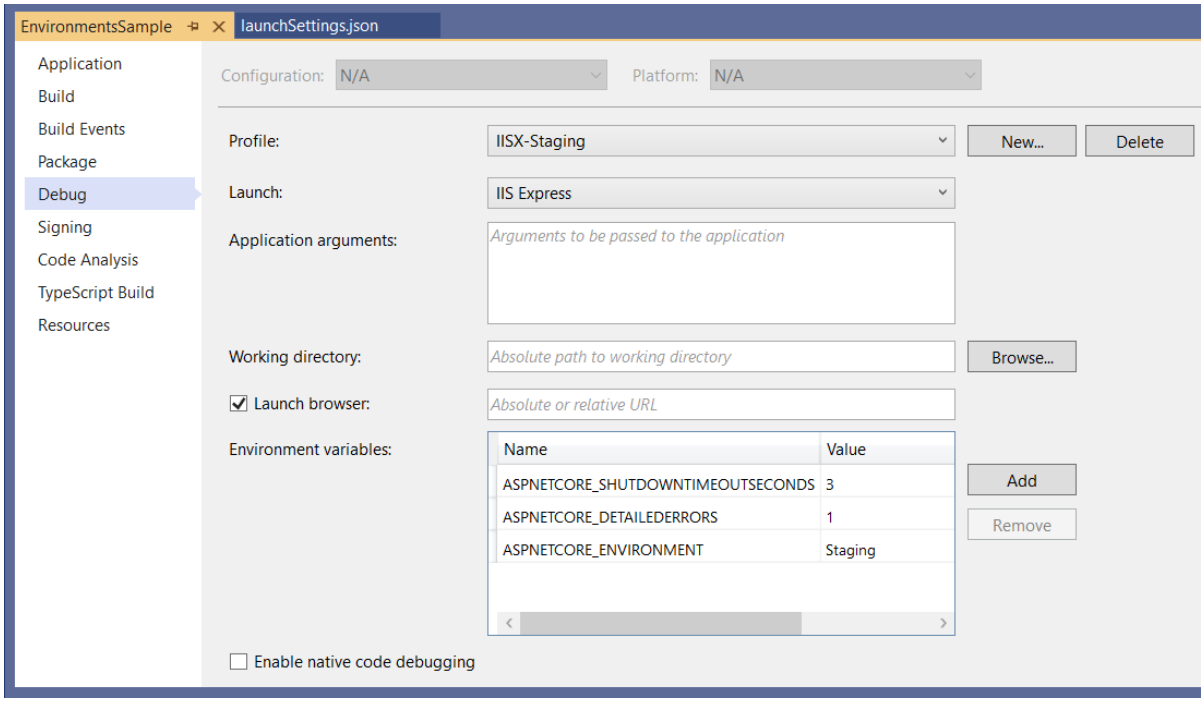


- `EnvironmentsSample`: The profile name is the project name. This profile is used by default when launching the app with `dotnet run`. The `"commandName"` key has the value `"Project"`, therefore, the Kestrel web server is launched.

The value of `commandName` can specify the web server to launch. `commandName` can be any one of the following:

- `IISExpress` : Launches IIS Express.
- `IIS` : No web server launched. IIS is expected to be available.
- `Project` : Launches Kestrel.

The Visual Studio project properties **Debug** tab provides a GUI to edit the *launchSettings.json* file. Changes made to project profiles may not take effect until the web server is restarted. Kestrel must be restarted before it can detect changes made to its environment.



The following *launchSettings.json* file contains multiple profiles:

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:64645",
      "sslPort": 44366
    }
  },
  "profiles": {
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "IISX-Production": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Production"
      }
    },
    "IISX-Staging": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Staging",
        "ASPNETCORE_DETAILEDERRORS": "1",
        "ASPNETCORE_SHUTDOWNTIMEOUTSECONDS": "3"
      }
    },
    "EnvironmentsSample": {
      "commandName": "Project",
      "launchBrowser": true,
      "applicationUrl": "https://localhost:5001;http://localhost:5000",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
      }
    },
    "KestrelStaging": {
      "commandName": "Project",
      "launchBrowser": true,
      "applicationUrl": "https://localhost:5001;http://localhost:5000",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Staging"
      }
    }
  }
}
```

Profiles can be selected:

- From the Visual Studio UI.
- Using the `dotnet run` command in a command shell with the `--launch-profile` option set to the profile's name. *This approach only supports Kestrel profiles.*

  ```
  dotnet run --launch-profile "SampleApp"
  ```

> **WARNING**
>
> *launchSettings.json* shouldn't store secrets. The Secret Manager tool can be used to store secrets for local development.

When using Visual Studio Code, environment variables can be set in the *.vscode/launch.json* file. The following example sets several Host configuration values environment variables:

```
{
    "version": "0.2.0",
    "configurations": [
        {
            "name": ".NET Core Launch (web)",
            "type": "coreclr",
            // Configuration ommitted for brevity.
            "env": {
                "ASPNETCORE_ENVIRONMENT": "Development",
                "ASPNETCORE_URLS": "https://localhost:5001",
                "ASPNETCORE_DETAILEDERRORS": "1",
                "ASPNETCORE_SHUTDOWNTIMEOUTSECONDS": "3"
            },
            // Configuration ommitted for brevity.
```

The *.vscode/launch.json* file is only used by Visual Studio Code.

Production

The production environment should be configured to maximize security, performance, and application robustness. Some common settings that differ from development include:

- Caching.
- Client-side resources are bundled, minified, and potentially served from a CDN.
- Diagnostic error pages disabled.
- Friendly error pages enabled.
- Production logging and monitoring enabled. For example, using Application Insights.

Set the environment

It's often useful to set a specific environment for testing with an environment variable or platform setting. If the environment isn't set, it defaults to `Production`, which disables most debugging features. The method for setting the environment depends on the operating system.

When the host is built, the last environment setting read by the app determines the app's environment. The app's environment can't be changed while the app is running.

The About page from the sample code displays the value of `IWebHostEnvironment.EnvironmentName`.

Azure App Service

To set the environment in Azure App Service, perform the following steps:

1. Select the app from the **App Services** blade.
2. In the **Settings** group, select the **Configuration** blade.
3. In the **Application settings** tab, select **New application setting**.
4. In the **Add/Edit application setting** window, provide `ASPNETCORE_ENVIRONMENT` for the **Name**. For **Value**, provide the environment (for example, `Staging`).
5. Select the **Deployment slot setting** check box if you wish the environment setting to remain with the

current slot when deployment slots are swapped. For more information, see Set up staging environments in Azure App Service in the Azure documentation.

6. Select **OK** to close the **Add/Edit application setting** window.
7. Select **Save** at the top of the **Configuration** blade.

Azure App Service automatically restarts the app after an app setting is added, changed, or deleted in the Azure portal.

Windows

Environment values in *launchSettings.json* override values set in the system environment.

To set the `ASPNETCORE_ENVIRONMENT` for the current session when the app is started using dotnet run, the following commands are used:

Command prompt

```
set ASPNETCORE_ENVIRONMENT=Staging
dotnet run --no-launch-profile
```

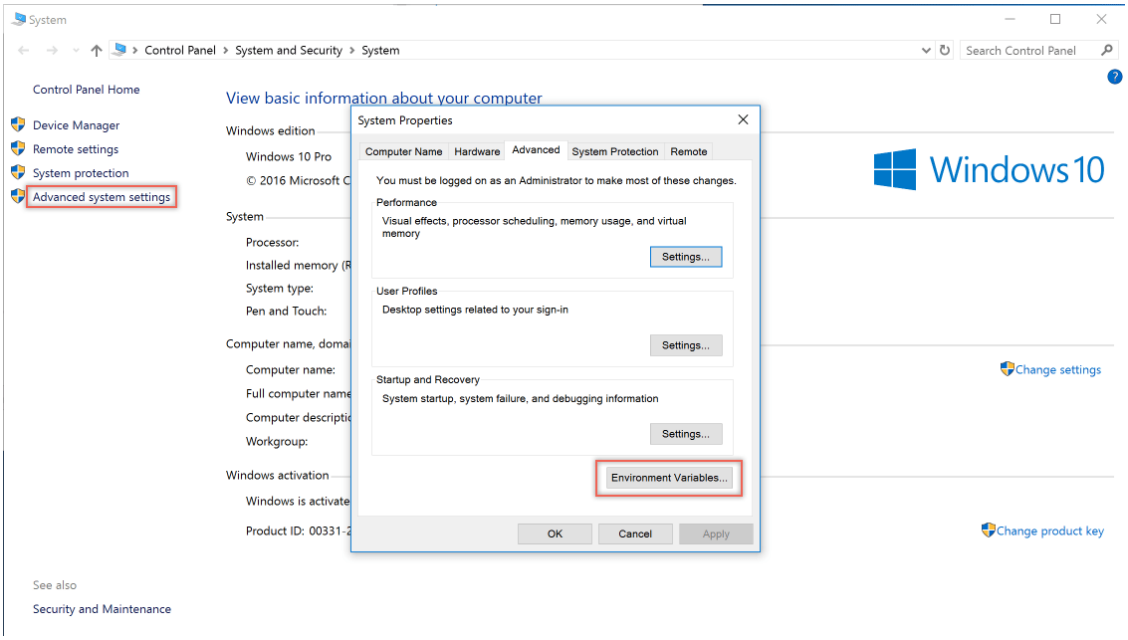
PowerShell

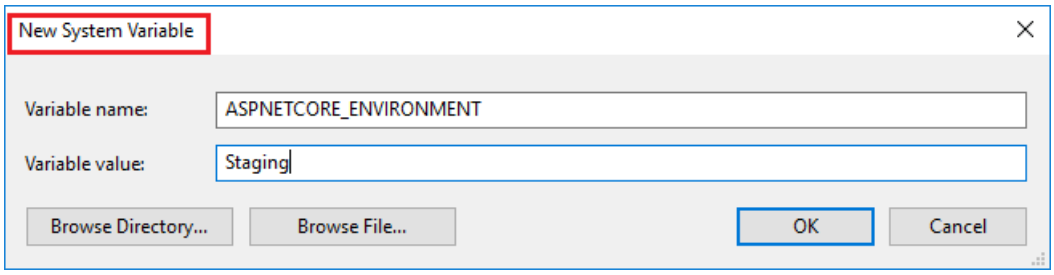
```
$Env:ASPNETCORE_ENVIRONMENT = "Staging"
dotnet run --no-launch-profile
```

The preceding command sets `ASPNETCORE_ENVIRONMENT` only for processes launched from that command window.

To set the value globally in Windows, use either of the following approaches:

- Open the **Control Panel** > **System** > **Advanced system settings** and add or edit the `ASPNETCORE_ENVIRONMENT` value:





- Open an administrative command prompt and use the `setx` command or open an administrative PowerShell command prompt and use `[Environment]::SetEnvironmentVariable`:

  Command prompt

  ```
  setx ASPNETCORE_ENVIRONMENT Staging /M
  ```

  The `/M` switch indicates to set the environment variable at the system level. If the `/M` switch isn't used, the environment variable is set for the user account.

  PowerShell

  ```
  [Environment]::SetEnvironmentVariable("ASPNETCORE_ENVIRONMENT", "Staging", "Machine")
  ```

  The `Machine` option value indicates to set the environment variable at the system level. If the option value is changed to `User`, the environment variable is set for the user account.

When the `ASPNETCORE_ENVIRONMENT` environment variable is set globally, it takes effect for `dotnet run` in any command window opened after the value is set. Environment values in *launchSettings.json* override values set in the system environment.

web.config

To set the `ASPNETCORE_ENVIRONMENT` environment variable with *web.config*, see the *Setting environment variables* section of ASP.NET Core Module.

Project file or publish profile

For Windows IIS deployments: Include the `<EnvironmentName>` property in the publish profile (.pubxml) or project file. This approach sets the environment in *web.config* when the project is published:

```
<PropertyGroup>
  <EnvironmentName>Development</EnvironmentName>
</PropertyGroup>
```

Per IIS Application Pool

To set the `ASPNETCORE_ENVIRONMENT` environment variable for an app running in an isolated Application Pool (supported on IIS 10.0 or later), see the *AppCmd.exe command* section of the Environment Variables <environmentVariables> topic. When the `ASPNETCORE_ENVIRONMENT` environment variable is set for an app pool, its value overrides a setting at the system level.

When hosting an app in IIS and adding or changing the `ASPNETCORE_ENVIRONMENT` environment variable, use any one of the following approaches to have the new value picked up by apps:

- Execute `net stop was /y` followed by `net start w3svc` from a command prompt.
- Restart the server.

macOS

Setting the current environment for macOS can be performed in-line when running the app:

```
ASPNETCORE_ENVIRONMENT=Staging dotnet run
```

Alternatively, set the environment with `export` prior to running the app:

```
export ASPNETCORE_ENVIRONMENT=Staging
```

Machine-level environment variables are set in the *.bashrc* or *.bash_profile* file. Edit the file using any text editor. Add the following statement:

```
export ASPNETCORE_ENVIRONMENT=Staging
```

Linux

For Linux distributions, use the `export` command at a command prompt for session-based variable settings and *bash_profile* file for machine-level environment settings.

Set the environment in code

Call UseEnvironment when building the host. See .NET Generic Host.

Configuration by environment

To load configuration by environment, see Configuration in ASP.NET Core.

Environment-based Startup class and methods

Inject IWebHostEnvironment into the Startup class

Inject IWebHostEnvironment into the `Startup` constructor. This approach is useful when the app requires configuring `Startup` for only a few environments with minimal code differences per environment.

In the following example:

- The environment is held in the `_env` field.
- `_env` is used in `ConfigureServices` and `Configure` to apply startup configuration based on the app's environment.

```
public class Startup
{
    public Startup(IConfiguration configuration, IWebHostEnvironment env)
    {
        Configuration = configuration;
        _env = env;
    }

    public IConfiguration Configuration { get; }
    private readonly IWebHostEnvironment _env;

    public void ConfigureServices(IServiceCollection services)
    {
        if (_env.IsDevelopment())
        {
            Console.WriteLine(_env.EnvironmentName);
        }
        else if (_env.IsStaging())
        {
            Console.WriteLine(_env.EnvironmentName);
        }
        else
        {
            Console.WriteLine("Not dev or staging");
        }

        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app)
    {
        if (_env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

Startup class conventions

When an ASP.NET Core app starts, the Startup class bootstraps the app. The app can define multiple `Startup` classes for different environments. The appropriate `Startup` class is selected at runtime. The class whose name suffix matches the current environment is prioritized. If a matching `Startup{EnvironmentName}` class isn't found, the `Startup` class is used. This approach is useful when the app requires configuring startup for several environments with many code differences per environment. Typical apps will not need this approach.

To implement environment-based `Startup` classes, create a `Startup{EnvironmentName}` classes and a fallback

`Startup` class:

```
public class StartupDevelopment
{
    public StartupDevelopment(IConfiguration configuration)
    {
        Configuration = configuration;
        Console.WriteLine(MethodBase.GetCurrentMethod().DeclaringType.Name);
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app)
    {
        app.UseDeveloperExceptionPage();

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}

public class StartupProduction
{
    public StartupProduction(IConfiguration configuration)
    {
        Configuration = configuration;
        Console.WriteLine(MethodBase.GetCurrentMethod().DeclaringType.Name);
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app)
    {

        app.UseExceptionHandler("/Error");
        app.UseHsts();

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
```

```
}

public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
        Console.WriteLine(MethodBase.GetCurrentMethod().DeclaringType.Name);
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }
}
```

Use the UseStartup(IWebHostBuilder, String) overload that accepts an assembly name:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args)
    {
        var assemblyName = typeof(Startup).GetTypeInfo().Assembly.FullName;

        return   Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup(assemblyName);
            });
    }
}
```

Startup method conventions

Configure and ConfigureServices support environment-specific versions of the form `Configure<EnvironmentName>` and `Configure<EnvironmentName>Services`. If a matching `Configure<EnvironmentName>Services` or `Configure<EnvironmentName>` method isn't found, the `ConfigureServices` or `Configure` method is used, respectively. This approach is useful when the app requires configuring startup for several environments with many code differences per environment:

```
public class Startup
{
    private void StartupConfigureServices(IServiceCollection services)
    {
        services.AddRazorPages();
    }

    public void ConfigureDevelopmentServices(IServiceCollection services)
    {
        MyTrace.TraceMessage();
        StartupConfigureServices(services);
    }

    public void ConfigureStagingServices(IServiceCollection services)
    {
        MyTrace.TraceMessage();
        StartupConfigureServices(services);
    }

    public void ConfigureProductionServices(IServiceCollection services)
    {
        MyTrace.TraceMessage();
        StartupConfigureServices(services);
    }

    public void ConfigureServices(IServiceCollection services)
    {
        MyTrace.TraceMessage();
        StartupConfigureServices(services);
    }

    public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
    {
        MyTrace.TraceMessage();

        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();

        app.UseRouting();

        app.UseAuthorization();

        app.UseEndpoints(endpoints =>
        {
            endpoints.MapRazorPages();
        });
    }

    public void ConfigureStaging(IApplicationBuilder app, IWebHostEnvironment env)
    {
```

```
            MyTrace.TraceMessage();

            app.UseExceptionHandler("/Error");
            app.UseHsts();

            app.UseHttpsRedirection();
            app.UseStaticFiles();

            app.UseRouting();

            app.UseAuthorization();

            app.UseEndpoints(endpoints =>
            {
                endpoints.MapRazorPages();
            });
        }
    }

    public static class MyTrace
    {
        public static void TraceMessage([CallerMemberName] string memberName = "")
        {
            Console.WriteLine($"Method: {memberName}");
        }
    }
```

Additional resources

- App startup in ASP.NET Core
- Configuration in ASP.NET Core
- ASP.NET Core Blazor environments

By Rick Anderson

ASP.NET Core configures app behavior based on the runtime environment using an environment variable.

View or download sample code (how to download)

Environments

ASP.NET Core reads the environment variable `ASPNETCORE_ENVIRONMENT` at app startup and stores the value in IHostingEnvironment.EnvironmentName. `ASPNETCORE_ENVIRONMENT` can be set to any value, but three values are provided by the framework:

- Development
- Staging
- Production (default)

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    if (env.IsProduction() || env.IsStaging() || env.IsEnvironment("Staging_2"))
    {
        app.UseExceptionHandler("/Error");
    }

    app.UseStaticFiles();
    app.UseMvc();
}
```

The preceding code:

- Calls UseDeveloperExceptionPage when `ASPNETCORE_ENVIRONMENT` is set to `Development`.
- Calls UseExceptionHandler when the value of `ASPNETCORE_ENVIRONMENT` is set one of the following:
  - `Staging`
  - `Production`
  - `Staging_2`

The Environment Tag Helper uses the value of `IHostingEnvironment.EnvironmentName` to include or exclude markup in the element:

```
<environment include="Development">
    <div>The effective tag is: &lt;environment include="Development"&gt;</div>
</environment>
<environment exclude="Development">
    <div>The effective tag is: &lt;environment exclude="Development"&gt;</div>
</environment>
<environment include="Staging,Development,Staging_2">
    <div>
        The effective tag is:
        &lt;environment include="Staging,Development,Staging_2"&gt;
    </div>
</environment>
```

On Windows and macOS, environment variables and values aren't case-sensitive. Linux environment variables and values are case-sensitive by default.

Development

The development environment can enable features that shouldn't be exposed in production. For example, the ASP.NET Core templates enable the Developer Exception Page in the development environment.

The environment for local machine development can be set in the *Properties\launchSettings.json* file of the project. Environment values set in *launchSettings.json* override values set in the system environment.

The following JSON shows three profiles from a *launchSettings.json* file:

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:54339/",
      "sslPort": 0
    }
  },
  "profiles": {
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_My_Environment": "1",
        "ASPNETCORE_DETAILEDERRORS": "1",
        "ASPNETCORE_ENVIRONMENT": "Staging"
      }
    },
    "EnvironmentsSample": {
      "commandName": "Project",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Staging"
      },
      "applicationUrl": "http://localhost:54340/"
    },
    "Kestrel Staging": {
      "commandName": "Project",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_My_Environment": "1",
        "ASPNETCORE_DETAILEDERRORS": "1",
        "ASPNETCORE_ENVIRONMENT": "Staging"
      },
      "applicationUrl": "http://localhost:51997/"
    }
  }
}
```

NOTE

The `applicationUrl` property in *launchSettings.json* can specify a list of server URLs. Use a semicolon between the URLs in the list:

```
"EnvironmentsSample": {
   "commandName": "Project",
   "launchBrowser": true,
   "applicationUrl": "https://localhost:5001;http://localhost:5000",
   "environmentVariables": {
     "ASPNETCORE_ENVIRONMENT": "Development"
   }
}
```

When the app is launched with dotnet run, the first profile with `"commandName": "Project"` is used. The value of `commandName` specifies the web server to launch. `commandName` can be any one of the following:

- `IISExpress`
- `IIS`
- `Project` (which launches Kestrel)

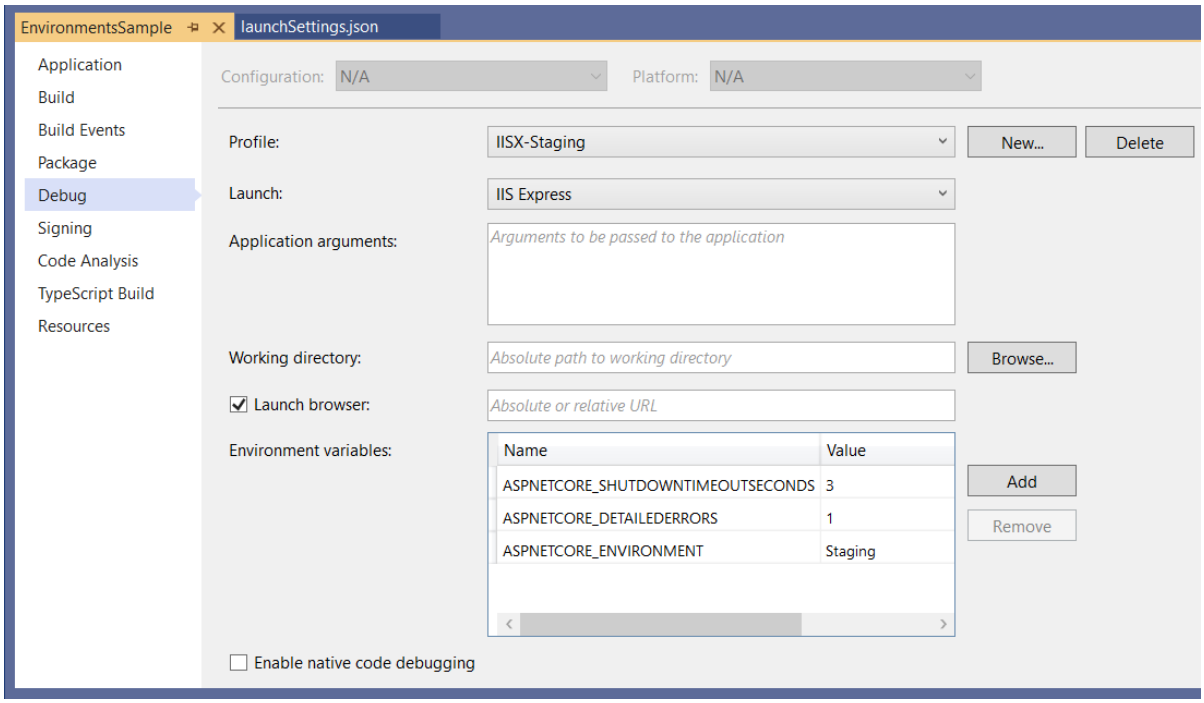
When an app is launched with dotnet run:

- *launchSettings.json* is read if available. `environmentVariables` settings in *launchSettings.json* override environment variables.
- The hosting environment is displayed.

The following output shows an app started with dotnet run:

```
PS C:\Websites\EnvironmentsSample> dotnet run
Using launch settings from C:\Websites\EnvironmentsSample\Properties\launchSettings.json...
Hosting environment: Staging
Content root path: C:\Websites\EnvironmentsSample
Now listening on: http://localhost:54340
Application started. Press Ctrl+C to shut down.
```

The Visual Studio project properties **Debug** tab provides a GUI to edit the *launchSettings.json* file:



Changes made to project profiles may not take effect until the web server is restarted. Kestrel must be restarted before it can detect changes made to its environment.

> **WARNING**
> *launchSettings.json* shouldn't store secrets. The Secret Manager tool can be used to store secrets for local development.

When using Visual Studio Code, environment variables can be set in the *.vscode/launch.json* file. The following example sets the environment to `Development`:

```
{
   "version": "0.2.0",
   "configurations": [
        {
            "name": ".NET Core Launch (web)",

            ... additional VS Code configuration settings ...

            "env": {
                "ASPNETCORE_ENVIRONMENT": "Development"
            }
        }
    ]
}
```

A *.vscode/launch.json* file in the project isn't read when starting the app with `dotnet run` in the same way as *Properties/launchSettings.json*. When launching an app in development that doesn't have a *launchSettings.json* file, either set the environment with an environment variable or a command-line argument to the `dotnet run` command.

Production

The production environment should be configured to maximize security, performance, and app robustness. Some common settings that differ from development include:

- Caching.
- Client-side resources are bundled, minified, and potentially served from a CDN.
- Diagnostic error pages disabled.
- Friendly error pages enabled.
- Production logging and monitoring enabled. For example, Application Insights.

Set the environment

It's often useful to set a specific environment for testing with an environment variable or platform setting. If the environment isn't set, it defaults to `Production`, which disables most debugging features. The method for setting the environment depends on the operating system.

When the host is built, the last environment setting read by the app determines the app's environment. The app's environment can't be changed while the app is running.

Environment variable or platform setting

Azure App Service

To set the environment in Azure App Service, perform the following steps:

1. Select the app from the **App Services** blade.
2. In the **Settings** group, select the **Configuration** blade.
3. In the **Application settings** tab, select **New application setting**.
4. In the **Add/Edit application setting** window, provide `ASPNETCORE_ENVIRONMENT` for the **Name**. For **Value**, provide the environment (for example, `Staging`).
5. Select the **Deployment slot setting** check box if you wish the environment setting to remain with the current slot when deployment slots are swapped. For more information, see Set up staging environments in Azure App Service in the Azure documentation.
6. Select **OK** to close the **Add/Edit application setting** window.
7. Select **Save** at the top of the **Configuration** blade.

Azure App Service automatically restarts the app after an app setting (environment variable) is added,

changed, or deleted in the Azure portal.

Windows

To set the `ASPNETCORE_ENVIRONMENT` for the current session when the app is started using dotnet run, the following commands are used:

Command prompt

```
set ASPNETCORE_ENVIRONMENT=Development
```

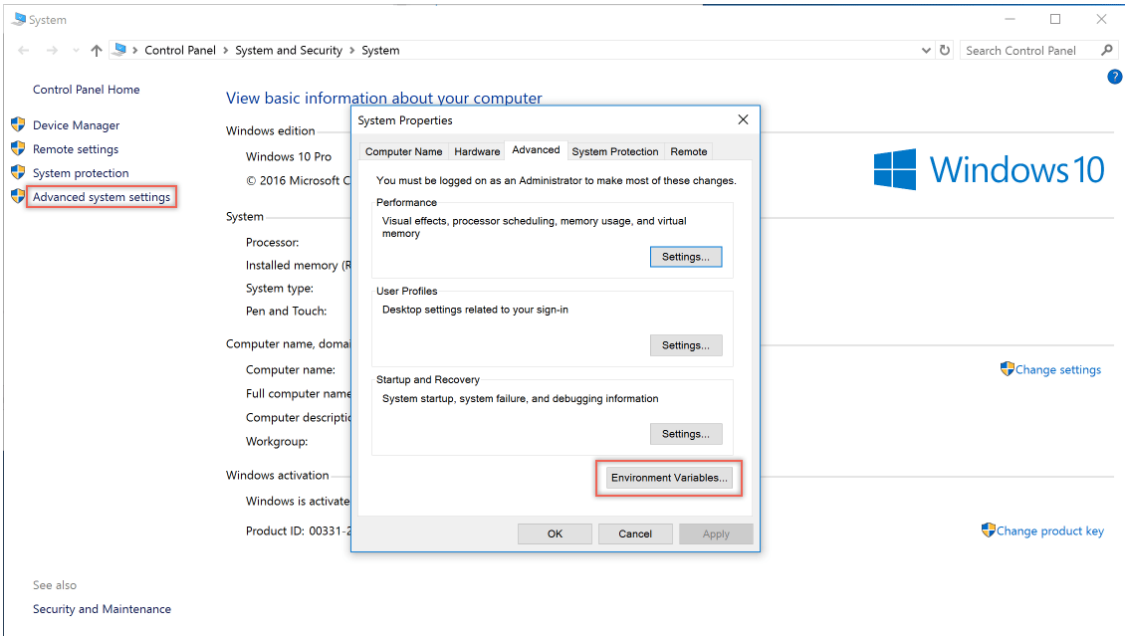
PowerShell

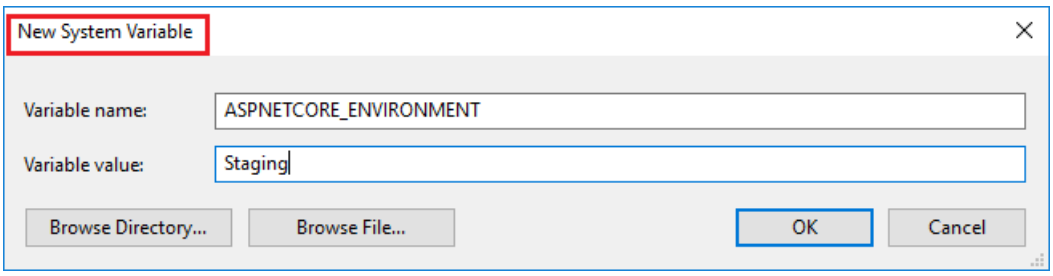
```
$Env:ASPNETCORE_ENVIRONMENT = "Development"
```

These commands only take effect for the current window. When the window is closed, the `ASPNETCORE_ENVIRONMENT` setting reverts to the default setting or machine value.

To set the value globally in Windows, use either of the following approaches:

- Open the **Control Panel** > **System** > **Advanced system settings** and add or edit the `ASPNETCORE_ENVIRONMENT` value:





- Open an administrative command prompt and use the `setx` command or open an administrative PowerShell command prompt and use `[Environment]::SetEnvironmentVariable`:

  ### Command prompt

  ```
  setx ASPNETCORE_ENVIRONMENT Development /M
  ```

The `/M` switch indicates to set the environment variable at the system level. If the `/M` switch isn't used, the environment variable is set for the user account.

PowerShell

```
[Environment]::SetEnvironmentVariable("ASPNETCORE_ENVIRONMENT", "Development", "Machine")
```

The `Machine` option value indicates to set the environment variable at the system level. If the option value is changed to `User`, the environment variable is set for the user account.

When the `ASPNETCORE_ENVIRONMENT` environment variable is set globally, it takes effect for `dotnet run` in any command window opened after the value is set.

web.config

To set the `ASPNETCORE_ENVIRONMENT` environment variable with *web.config*, see the *Setting environment variables* section of ASP.NET Core Module.

Project file or publish profile

For Windows IIS deployments: Include the `<EnvironmentName>` property in the publish profile (.pubxml) or project file. This approach sets the environment in *web.config* when the project is published:

```
<PropertyGroup>
  <EnvironmentName>Development</EnvironmentName>
</PropertyGroup>
```

Per IIS Application Pool

To set the `ASPNETCORE_ENVIRONMENT` environment variable for an app running in an isolated Application Pool (supported on IIS 10.0 or later), see the *AppCmd.exe command* section of the Environment Variables <environmentVariables> topic. When the `ASPNETCORE_ENVIRONMENT` environment variable is set for an app pool, its value overrides a setting at the system level.

> **IMPORTANT**
> When hosting an app in IIS and adding or changing the `ASPNETCORE_ENVIRONMENT` environment variable, use any one of the following approaches to have the new value picked up by apps:
>
> - Execute `net stop was /y` followed by `net start w3svc` from a command prompt.
> - Restart the server.

macOS

Setting the current environment for macOS can be performed in-line when running the app:

```
ASPNETCORE_ENVIRONMENT=Development dotnet run
```

Alternatively, set the environment with `export` prior to running the app:

```
export ASPNETCORE_ENVIRONMENT=Development
```

Machine-level environment variables are set in the *.bashrc* or *.bash_profile* file. Edit the file using any text editor. Add the following statement:

```
export ASPNETCORE_ENVIRONMENT=Development
```

Linux

For Linux distributions, use the `export` command at a command prompt for session-based variable settings and *bash_profile* file for machine-level environment settings.

Set the environment in code

Call UseEnvironment when building the host. See ASP.NET Core Web Host.

Configuration by environment

To load configuration by environment, we recommend:

- *appsettings* files (*appsettings.{Environment}.json*). See Configuration in ASP.NET Core.
- Environment variables (set on each system where the app is hosted). See ASP.NET Core Web Host and Safe storage of app secrets in development in ASP.NET Core.
- Secret Manager (in the Development environment only). See Safe storage of app secrets in development in ASP.NET Core.

Environment-based Startup class and methods

Inject IHostingEnvironment into Startup.Configure

Inject IHostingEnvironment into `Startup.Configure`. This approach is useful when the app only requires configuring `Startup.Configure` for only a few environments with minimal code differences per environment.

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env)
{
    if (env.IsDevelopment())
    {
        // Development environment code
    }
    else
    {
        // Code for all other environments
    }
}
```

Inject IHostingEnvironment into the Startup class

Inject IHostingEnvironment into the `Startup` constructor and assign the service to a field for use throughout the `Startup` class. This approach is useful when the app requires configuring startup for only a few environments with minimal code differences per environment.

In the following example:

- The environment is held in the `_env` field.
- `_env` is used in `ConfigureServices` and `Configure` to apply startup configuration based on the app's environment.

```
public class Startup
{
    private readonly IHostingEnvironment _env;

    public Startup(IHostingEnvironment env)
    {
        _env = env;
    }

    public void ConfigureServices(IServiceCollection services)
    {
        if (_env.IsDevelopment())
        {
            // Development environment code
        }
        else if (_env.IsStaging())
        {
            // Staging environment code
        }
        else
        {
            // Code for all other environments
        }
    }

    public void Configure(IApplicationBuilder app)
    {
        if (_env.IsDevelopment())
        {
            // Development environment code
        }
        else
        {
            // Code for all other environments
        }
    }
}
```

Startup class conventions

When an ASP.NET Core app starts, the Startup class bootstraps the app. The app can define separate `Startup` classes for different environments (for example, `StartupDevelopment`). The appropriate `Startup` class is selected at runtime. The class whose name suffix matches the current environment is prioritized. If a matching `Startup{EnvironmentName}` class isn't found, the `Startup` class is used. This approach is useful when the app requires configuring startup for several environments with many code differences per environment.

To implement environment-based `Startup` classes, create a `Startup{EnvironmentName}` class for each environment in use and a fallback `Startup` class:

```
// Startup class to use in the Development environment
public class StartupDevelopment
{
    public void ConfigureServices(IServiceCollection services)
    {
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
    }
}

// Startup class to use in the Production environment
public class StartupProduction
{
    public void ConfigureServices(IServiceCollection services)
    {
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
    }
}

// Fallback Startup class
// Selected if the environment doesn't match a Startup{EnvironmentName} class
public class Startup
{
    public void ConfigureServices(IServiceCollection services)
    {
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
    }
}
```

Use the UseStartup(IWebHostBuilder, String) overload that accepts an assembly name:

```
public static void Main(string[] args)
{
    CreateWebHostBuilder(args).Build().Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args)
{
    var assemblyName = typeof(Startup).GetTypeInfo().Assembly.FullName;

    return WebHost.CreateDefaultBuilder(args)
        .UseStartup(assemblyName);
}
```

Startup method conventions

Configure and ConfigureServices support environment-specific versions of the form `Configure<EnvironmentName>` and `Configure<EnvironmentName>Services`. If a matching `Configure<EnvironmentName>Services` or `Configure<EnvironmentName>` method isn't found, the `ConfigureServices` or `Configure` method is used, respectively. This approach is useful when the app requires configuring startup for several environments with many code differences per environment:

```
public class Startup
{
    public Startup(IConfiguration configuration)
    {
        Configuration = configuration;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        StartupConfigureServices(services);
    }

    public void ConfigureStagingServices(IServiceCollection services)
    {
        StartupConfigureServices(services);
    }

    private void StartupConfigureServices(IServiceCollection services)
    {
        services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            app.UseDeveloperExceptionPage();
        }

        if (env.IsProduction() || env.IsStaging() || env.IsEnvironment("Staging_2"))
        {
            app.UseExceptionHandler("/Error");
        }

        app.UseStaticFiles();
        app.UseMvc();
    }

    public void ConfigureStaging(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (!env.IsStaging())
        {
            throw new Exception("Not staging.");
        }

        app.UseExceptionHandler("/Error");
        app.UseStaticFiles();
        app.UseMvc();
    }
}
```

Logging in .NET Core and ASP.NET Core

9/22/2020 • 57 minutes to read • Edit Online

By Kirk Larkin, Juergen Gutsch and Rick Anderson

.NET Core supports a logging API that works with a variety of built-in and third-party logging providers. This article shows how to use the logging API with built-in providers.

Most of the code examples shown in this article are from ASP.NET Core apps. The logging-specific parts of these code snippets apply to any .NET Core app that uses the Generic Host. The ASP.NET Core web app templates use the Generic Host.

View or download sample code (how to download)

Logging providers

Logging providers store logs, except for the `Console` provider which displays logs. For example, the Azure Application Insights provider stores logs in Azure Application Insights. Multiple providers can be enabled.

The default ASP.NET Core web app templates:

- Use the Generic Host.
- Call CreateDefaultBuilder, which adds the following logging providers:
  - Console
  - Debug
  - EventSource
  - EventLog: Windows only

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The preceding code shows the `Program` class created with the ASP.NET Core web app templates. The next several sections provide samples based on the ASP.NET Core web app templates, which use the Generic Host. Non-host console apps are discussed later in this document.

To override the default set of logging providers added by `Host.CreateDefaultBuilder`, call `ClearProviders` and add the required logging providers. For example, the following code:

- Calls ClearProviders to remove all the ILoggerProvider instances from the builder.
- Adds the Console logging provider.

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureLogging(logging =>
        {
            logging.ClearProviders();
            logging.AddConsole();
        })
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

For additional providers, see:

- Built-in logging providers
- Third-party logging providers.

Create logs

To create logs, use an ILogger<TCategoryName> object from dependency injection (DI).

The following example:

- Creates a logger, `ILogger<AboutModel>`, which uses a log *category* of the fully qualified name of the type `AboutModel`. The log category is a string that is associated with each log.
- Calls LogInformation to log at the `Information` level. The Log *level* indicates the severity of the logged event.

```
public class AboutModel : PageModel
{
    private readonly ILogger _logger;

    public AboutModel(ILogger<AboutModel> logger)
    {
        _logger = logger;
    }
    public string Message { get; set; }

    public void OnGet()
    {
        Message = $"About page visited at {DateTime.UtcNow.ToLongTimeString()}";
        _logger.LogInformation(Message);
    }
}
```

Levels and categories are explained in more detail later in this document.

For information on Blazor, see Create logs in Blazor and Blazor WebAssembly in this document.

Create logs in Main and Startup shows how to create logs in `Main` and `Startup`.

Configure logging

Logging configuration is commonly provided by the `Logging` section of *appsettings*.`{Environment}`*.json* files. The following *appsettings.Development.json* file is generated by the ASP.NET Core web app templates:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

In the preceding JSON:

- The `"Default"`, `"Microsoft"`, and `"Microsoft.Hosting.Lifetime"` categories are specified.
- The `"Microsoft"` category applies to all categories that start with `"Microsoft"`. For example, this setting applies to the `"Microsoft.AspNetCore.Routing.EndpointMiddleware"` category.
- The `"Microsoft"` category logs at log level `Warning` and higher.
- The `"Microsoft.Hosting.Lifetime"` category is more specific than the `"Microsoft"` category, so the `"Microsoft.Hosting.Lifetime"` category logs at log level "Information" and higher.
- A specific log provider is not specified, so `LogLevel` applies to all the enabled logging providers except for the Windows EventLog.

The `Logging` property can have LogLevel and log provider properties. The `LogLevel` specifies the minimum level to log for selected categories. In the preceding JSON, `Information` and `Warning` log levels are specified. `LogLevel` indicates the severity of the log and ranges from 0 to 6:

`Trace` = 0, `Debug` = 1, `Information` = 2, `Warning` = 3, `Error` = 4, `Critical` = 5, and `None` = 6.

When a `LogLevel` is specified, logging is enabled for messages at the specified level and higher. In the preceding JSON, the `Default` category is logged for `Information` and higher. For example, `Information`, `Warning`, `Error`, and `Critical` messages are logged. If no `LogLevel` is specified, logging defaults to the `Information` level. For more information, see Log levels.

A provider property can specify a `LogLevel` property. `LogLevel` under a provider specifies levels to log for that provider, and overrides the non-provider log settings. Consider the following *appsettings.json* file:

```
{
  "Logging": {
    "LogLevel": { // All providers, LogLevel applies to all the enabled providers.
      "Default": "Error", // Default logging, Error and higher.
      "Microsoft": "Warning" // All Microsoft* categories, Warning and higher.
    },
    "Debug": { // Debug provider.
      "LogLevel": {
        "Default": "Information", // Overrides preceding LogLevel:Default setting.
        "Microsoft.Hosting": "Trace" // Debug:Microsoft.Hosting category.
      }
    },
    "EventSource": { // EventSource provider
      "LogLevel": {
        "Default": "Warning" // All categories of EventSource provider.
      }
    }
  }
}
```

Settings in `Logging.{providername}.LogLevel` override settings in `Logging.LogLevel`. In the preceding JSON, the `Debug` provider's default log level is set to `Information`:

`Logging:Debug:LogLevel:Default:Information`

The preceding setting specifies the `Information` log level for every `Logging:Debug:` category except `Microsoft.Hosting`. When a specific category is listed, the specific category overrides the default category. In the preceding JSON, the `Logging:Debug:LogLevel` categories `"Microsoft.Hosting"` and `"Default"` override the settings in `Logging:LogLevel`

The minimum log level can be specified for any of:

- Specific providers: For example, `Logging:EventSource:LogLevel:Default:Information`
- Specific categories: For example, `Logging:LogLevel:Microsoft:Warning`
- All providers and all categories: `Logging:LogLevel:Default:Warning`

Any logs below the minimum level are ***not***:

- Passed to the provider.
- Logged or displayed.

To suppress all logs, specify LogLevel.None. `LogLevel.None` has a value of 6, which is higher than `LogLevel.Critical` (5).

If a provider supports log scopes, `IncludeScopes` indicates whether they're enabled. For more information, see log scopes

The following *appsettings.json* file contains all the providers enabled by default:

```
{
  "Logging": {
    "LogLevel": { // No provider, LogLevel applies to all the enabled providers.
      "Default": "Error",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Warning"
    },
    "Debug": { // Debug provider.
      "LogLevel": {
        "Default": "Information" // Overrides preceding LogLevel:Default setting.
      }
    },
    "Console": {
      "IncludeScopes": true,
      "LogLevel": {
        "Microsoft.AspNetCore.Mvc.Razor.Internal": "Warning",
        "Microsoft.AspNetCore.Mvc.Razor.Razor": "Debug",
        "Microsoft.AspNetCore.Mvc.Razor": "Error",
        "Default": "Information"
      }
    },
    "EventSource": {
      "LogLevel": {
        "Microsoft": "Information"
      }
    },
    "EventLog": {
      "LogLevel": {
        "Microsoft": "Information"
      }
    },
    "AzureAppServicesFile": {
      "IncludeScopes": true,
      "LogLevel": {
        "Default": "Warning"
      }
    },
    "AzureAppServicesBlob": {
      "IncludeScopes": true,
      "LogLevel": {
        "Microsoft": "Information"
      }
    },
    "ApplicationInsights": {
      "LogLevel": {
        "Default": "Information"
      }
    }
  }
}
```

In the preceding sample:

- The categories and levels are not suggested values. The sample is provided to show all the default providers.
- Settings in `Logging.{providername}.LogLevel` override settings in `Logging.LogLevel`. For example, the level in `Debug.LogLevel.Default` overrides the level in `LogLevel.Default`.
- Each default provider *alias* is used. Each provider defines an *alias* that can be used in configuration in place of the fully qualified type name. The built-in providers aliases are:
  - Console
  - Debug
  - EventSource
  - EventLog

- AzureAppServicesFile
- AzureAppServicesBlob
- ApplicationInsights

Set log level by command line, environment variables, and other configuration

Log level can be set by any of the configuration providers.

The `:` separator doesn't work with environment variable hierarchical keys on all platforms. `__`, the double underscore, is:

- Supported by all platforms. For example, the `:` separator is not supported by Bash, but `__` is.
- Automatically replaced by a `:`

The following commands:

- Set the environment key `Logging:LogLevel:Microsoft` to a value of `Information` on Windows.
- Test the settings when using an app created with the ASP.NET Core web application templates. The `dotnet run` command must be run in the project directory after using `set`.

```
set Logging__LogLevel__Microsoft=Information
dotnet run
```

The preceding environment setting:

- Is only set in processes launched from the command window they were set in.
- Isn't read by browsers launched with Visual Studio.

The following setx command also sets the environment key and value on Windows. Unlike `set`, `setx` settings are persisted. The `/M` switch sets the variable in the system environment. If `/M` isn't used, a user environment variable is set.

```
setx Logging__LogLevel__Microsoft=Information /M
```

On Azure App Service, select **New application setting** on the **Settings** > **Configuration** page. Azure App Service application settings are:

- Encrypted at rest and transmitted over an encrypted channel.
- Exposed as environment variables.

For more information, see Azure Apps: Override app configuration using the Azure Portal.

For more information on setting ASP.NET Core configuration values using environment variables, see environment variables. For information on using other configuration sources, including the command line, Azure Key Vault, Azure App Configuration, other file formats, and more, see Configuration in ASP.NET Core.

How filtering rules are applied

When an ILogger<TCategoryName> object is created, the ILoggerFactory object selects a single rule per provider to apply to that logger. All messages written by an `ILogger` instance are filtered based on the selected rules. The most specific rule for each provider and category pair is selected from the available rules.

The following algorithm is used for each provider when an `ILogger` is created for a given category:

- Select all rules that match the provider or its alias. If no match is found, select all rules with an empty provider.
- From the result of the preceding step, select rules with longest matching category prefix. If no match is found, select all rules that don't specify a category.
- If multiple rules are selected, take the **last** one.
- If no rules are selected, use `MinimumLevel`.

Logging output from dotnet run and Visual Studio

Logs created with the default logging providers are displayed:

- In Visual Studio
  - In the Debug output window when debugging.
  - In the ASP.NET Core Web Server window.
- In the console window when the app is run with `dotnet run`.

Logs that begin with "Microsoft" categories are from ASP.NET Core framework code. ASP.NET Core and application code use the same logging API and providers.

Log category

When an `ILogger` object is created, a *category* is specified. That category is included with each log message created by that instance of `ILogger`. The category string is arbitrary, but the convention is to use the class name. For example, in a controller the name might be `"TodoApi.Controllers.TodoController"`. The ASP.NET Core web apps use `ILogger<T>` to automatically get an `ILogger` instance that uses the fully qualified type name of `T` as the category:

```
public class PrivacyModel : PageModel
{
    private readonly ILogger<PrivacyModel> _logger;

    public PrivacyModel(ILogger<PrivacyModel> logger)
    {
        _logger = logger;
    }

    public void OnGet()
    {
        _logger.LogInformation("GET Pages.PrivacyModel called.");
    }
}
```

To explicitly specify the category, call `ILoggerFactory.CreateLogger`:

```
public class ContactModel : PageModel
{
    private readonly ILogger _logger;

    public ContactModel(ILoggerFactory logger)
    {
        _logger = logger.CreateLogger("MyCategory");
    }

    public void OnGet()
    {
        _logger.LogInformation("GET Pages.ContactModel called.");
    }
```

Calling `CreateLogger` with a fixed name can be useful when used in multiple methods so the events can be

organized by category.

`ILogger<T>` is equivalent to calling `CreateLogger` with the fully qualified type name of `T`.

Log level

The following table lists the LogLevel values, the convenience `Log{LogLevel}` extension method, and the suggested usage:

LOGLEVEL	VALUE	METHOD	DESCRIPTION
Trace	0	LogTrace	Contain the most detailed messages. These messages may contain sensitive app data. These messages are disabled by default and should ***not*** be enabled in production.
Debug	1	LogDebug	For debugging and development. Use with caution in production due to the high volume.
Information	2	LogInformation	Tracks the general flow of the app. May have long-term value.
Warning	3	LogWarning	For abnormal or unexpected events. Typically includes errors or conditions that don't cause the app to fail.
Error	4	LogError	For errors and exceptions that cannot be handled. These messages indicate a failure in the current operation or request, not an app-wide failure.
Critical	5	LogCritical	For failures that require immediate attention. Examples: data loss scenarios, out of disk space.
None	6		Specifies that a logging category should not write any messages.

In the previous table, the `LogLevel` is listed from lowest to highest severity.

The Log method's first parameter, LogLevel, indicates the severity of the log. Rather than calling `Log(LogLevel, ...)`, most developers call the Log{LogLevel} extension methods. The `Log{LogLevel}` extension methods call the Log method and specify the LogLevel. For example, the following two logging calls are functionally equivalent and produce the same log:

```
[HttpGet]
public IActionResult Test1(int id)
{
    var routeInfo = ControllerContext.ToCtxString(id);

    _logger.Log(LogLevel.Information, MyLogEvents.TestItem, routeInfo);
    _logger.LogInformation(MyLogEvents.TestItem, routeInfo);

    return ControllerContext.MyDisplayRouteInfo();
}
```

`MyLogEvents.TestItem` is the event ID. `MyLogEvents` is part of the sample app and is displayed in the Log event ID section.

MyDisplayRouteInfo and ToCtxString are provided by the Rick.Docs.Samples.RouteInfo NuGet package. The methods display `Controller` route information.

The following code creates `Information` and `Warning` logs:

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, "Get({Id}) NOT FOUND", id);
        return NotFound();
    }

    return ItemToDTO(todoItem);
}
```

In the preceding code, the first `Log{LogLevel}` parameter, `MyLogEvents.GetItem`, is the Log event ID. The second parameter is a message template with placeholders for argument values provided by the remaining method parameters. The method parameters are explained in the message template section later in this document.

Call the appropriate `Log{LogLevel}` method to control how much log output is written to a particular storage medium. For example:

- In production:
  - Logging at the `Trace` or `Information` levels produces a high-volume of detailed log messages. To control costs and not exceed data storage limits, log `Trace` and `Information` level messages to a high-volume, low-cost data store. Consider limiting `Trace` and `Information` to specific categories.
  - Logging at `Warning` through `Critical` levels should produce few log messages.
    - Costs and storage limits usually aren't a concern.
    - Few logs allow more flexibility in data store choices.
- In development:
  - Set to `Warning`.
  - Add `Trace` or `Information` messages when troubleshooting. To limit output, set `Trace` or `Information` only for the categories under investigation.

ASP.NET Core writes logs for framework events. For example, consider the log output for:

- A Razor Pages app created with the ASP.NET Core templates.

- Logging set to `Logging:Console:LogLevel:Microsoft:Information`
- Navigation to the Privacy page:

```
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/2 GET https://localhost:5001/Privacy
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint '/Privacy'
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[3]
      Route matched with {page = "/Privacy"}. Executing page /Privacy
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[101]
      Executing handler method DefaultRP.Pages.PrivacyModel.OnGet - ModelState is Valid
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[102]
      Executed handler method OnGet, returned result .
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[103]
      Executing an implicit handler method - ModelState is Valid
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[104]
      Executed an implicit handler method, returned result Microsoft.AspNetCore.Mvc.RazorPages.PageResult.
info: Microsoft.AspNetCore.Mvc.RazorPages.Infrastructure.PageActionInvoker[4]
      Executed page /Privacy in 74.5188ms
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint '/Privacy'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 149.3023ms 200 text/html; charset=utf-8
```

The following JSON sets `Logging:Console:LogLevel:Microsoft:Information`:

```
{
  "Logging": {      // Default, all providers.
    "LogLevel": {
      "Microsoft": "Warning"
    },
    "Console": { // Console provider.
      "LogLevel": {
        "Microsoft": "Information"
      }
    }
  }
}
```

Log event ID

Each log can specify an *event ID*. The sample app uses the `MyLogEvents` class to define event IDs:

```
public class MyLogEvents
{
    public const int GenerateItems = 1000;
    public const int ListItems     = 1001;
    public const int GetItem       = 1002;
    public const int InsertItem    = 1003;
    public const int UpdateItem    = 1004;
    public const int DeleteItem    = 1005;

    public const int TestItem      = 3000;

    public const int GetItemNotFound    = 4000;
    public const int UpdateItemNotFound = 4001;
}
```

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, "Get({Id}) NOT FOUND", id);
        return NotFound();
    }

    return ItemToDTO(todoItem);
}
```

An event ID associates a set of events. For example, all logs related to displaying a list of items on a page might be 1001.

The logging provider may store the event ID in an ID field, in the logging message, or not at all. The Debug provider doesn't show event IDs. The console provider shows event IDs in brackets after the category:

```
info: TodoApi.Controllers.TodoItemsController[1002]
      Getting item 1
warn: TodoApi.Controllers.TodoItemsController[4000]
      Get(1) NOT FOUND
```

Some logging providers store the event ID in a field, which allows for filtering on the ID.

Log message template

Each log API uses a message template. The message template can contain placeholders for which arguments are provided. Use names for the placeholders, not numbers.

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, "Get({Id}) NOT FOUND", id);
        return NotFound();
    }

    return ItemToDTO(todoItem);
}
```

The order of placeholders, not their names, determines which parameters are used to provide their values. In the following code, the parameter names are out of sequence in the message template:

```
string p1 = "param1";
string p2 = "param2";
_logger.LogInformation("Parameter values: {p2}, {p1}", p1, p2);
```

The preceding code creates a log message with the parameter values in sequence:

```
Parameter values: param1, param2
```

This approach allows logging providers to implement semantic or structured logging. The arguments themselves are passed to the logging system, not just the formatted message template. This enables logging providers to store the parameter values as fields. For example, consider the following logger method:

```
_logger.LogInformation("Getting item {Id} at {RequestTime}", id, DateTime.Now);
```

For example, when logging to Azure Table Storage:

- Each Azure Table entity can have `ID` and `RequestTime` properties.
- Tables with properties simplify queries on logged data. For example, a query can find all logs within a particular `RequestTime` range without having to parse the time out of the text message.

Log exceptions

The logger methods have overloads that take an exception parameter:

```
[HttpGet("{id}")]
public IActionResult TestExp(int id)
{
    var routeInfo = ControllerContext.ToCtxString(id);
    _logger.LogInformation(MyLogEvents.TestItem, routeInfo);

    try
    {
        if (id == 3)
        {
            throw new Exception("Test exception");
        }
    }
    catch (Exception ex)
    {
        _logger.LogWarning(MyLogEvents.GetItemNotFound, ex, "TestExp({Id})", id);
        return NotFound();
    }

    return ControllerContext.MyDisplayRouteInfo();
}
```

MyDisplayRouteInfo and ToCtxString are provided by the Rick.Docs.Samples.RouteInfo NuGet package. The methods display `Controller` route information.

Exception logging is provider-specific.

Default log level

If the default log level is not set, the default log level value is `Information`.

For example, consider the following web app:

- Created with the ASP.NET web app templates.
- *appsettings.json* and *appsettings.Development.json* deleted or renamed.

With the preceding setup, navigating to the privacy or home page produces many `Trace`, `Debug`, and `Information` messages with `Microsoft` in the category name.

The following code sets the default log level when the default log level is not set in configuration:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging(logging => logging.SetMinimumLevel(LogLevel.Warning))
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

Generally, log levels should be specified in configuration and not code.

Filter function

A filter function is invoked for all providers and categories that don't have rules assigned to them by configuration or code:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging(logging =>
            {
                logging.AddFilter((provider, category, logLevel) =>
                {
                    if (provider.Contains("ConsoleLoggerProvider")
                        && category.Contains("Controller")
                        && logLevel >= LogLevel.Information)
                    {
                        return true;
                    }
                    else if (provider.Contains("ConsoleLoggerProvider")
                        && category.Contains("Microsoft")
                        && logLevel >= LogLevel.Information)
                    {
                        return true;
                    }
                    else
                    {
                        return false;
                    }
                });
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

The preceding code displays console logs when the category contains `Controller` or `Microsoft` and the log level is `Information` or higher.

Generally, log levels should be specified in configuration and not code.

ASP.NET Core and EF Core categories

The following table contains some categories used by ASP.NET Core and Entity Framework Core, with notes about the logs:

CATEGORY	NOTES
Microsoft.AspNetCore	General ASP.NET Core diagnostics.
Microsoft.AspNetCore.DataProtection	Which keys were considered, found, and used.
Microsoft.AspNetCore.HostFiltering	Hosts allowed.
Microsoft.AspNetCore.Hosting	How long HTTP requests took to complete and what time they started. Which hosting startup assemblies were loaded.
Microsoft.AspNetCore.Mvc	MVC and Razor diagnostics. Model binding, filter execution, view compilation, action selection.
Microsoft.AspNetCore.Routing	Route matching information.
Microsoft.AspNetCore.Server	Connection start, stop, and keep alive responses. HTTPS certificate information.
Microsoft.AspNetCore.StaticFiles	Files served.
Microsoft.EntityFrameworkCore	General Entity Framework Core diagnostics. Database activity and configuration, change detection, migrations.

To view more categories in the console window, set **appsettings.Development.json** to the following:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Trace",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  }
}
```

Log scopes

A *scope* can group a set of logical operations. This grouping can be used to attach the same data to each log that's created as part of a set. For example, every log created as part of processing a transaction can include the transaction ID.

A scope:

- Is an IDisposable type that's returned by the BeginScope method.
- Lasts until it's disposed.

The following providers support scopes:

- `Console`
- AzureAppServicesFile and AzureAppServicesBlob

Use a scope by wrapping logger calls in a `using` block:

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
{
    TodoItem todoItem;

    using (_logger.BeginScope("using block message"))
    {
        _logger.LogInformation(MyLogEvents.GetItem, "Getting item {Id}", id);

        todoItem = await _context.TodoItems.FindAsync(id);

        if (todoItem == null)
        {
            _logger.LogWarning(MyLogEvents.GetItemNotFound,
                "Get({Id}) NOT FOUND", id);
            return NotFound();
        }
    }

    return ItemToDTO(todoItem);
}
```

The following JSON enables scopes for the console provider:

```
{
  "Logging": {
    "Debug": {
      "LogLevel": {
        "Default": "Information"
      }
    },
    "Console": {
      "IncludeScopes": true, // Required to use Scopes.
      "LogLevel": {
        "Microsoft": "Warning",
        "Default": "Information"
      }
    },
    "LogLevel": {
      "Default": "Debug"
    }
  }
}
```

The following code enables scopes for the console provider:

```
public class Scopes
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging((hostingContext, logging) =>
            {
                logging.ClearProviders();
                logging.AddConsole(options => options.IncludeScopes = true);
                logging.AddDebug();
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

Generally, logging should be specified in configuration and not code.

Built-in logging providers

ASP.NET Core includes the following logging providers as part of the shared framework:

- Console
- Debug
- EventSource
- EventLog

The following logging providers are shipped by Microsoft, but not as part of the shared framework. They must be installed as additional nuget.

- AzureAppServicesFile and AzureAppServicesBlob
- ApplicationInsights

For information on `stdout` and debug logging with the ASP.NET Core Module, see Troubleshoot ASP.NET Core on Azure App Service and IIS and ASP.NET Core Module.

Console

The `Console` provider logs output to the console. For more information on viewing `Console` logs in development, see Logging output from dotnet run and Visual Studio.

Debug

The `Debug` provider writes log output by using the System.Diagnostics.Debug class. Calls to `System.Diagnostics.Debug.WriteLine` write to the `Debug` provider.

On Linux, the `Debug` provider log location is distribution-dependent and may be one of the following:

- */var/log/message*
- */var/log/syslog*

Event Source

The `EventSource` provider writes to a cross-platform event source with the name `Microsoft-Extensions-Logging`. On Windows, the provider uses ETW.

dotnet trace tooling

The dotnet-trace tool is a cross-platform CLI global tool that enables the collection of .NET Core traces of a running process. The tool collects Microsoft.Extensions.Logging.EventSource provider data using a LoggingEventSource.

See dotnet-trace for installation instructions.

Use the dotnet trace tooling to collect a trace from an app:

1. Run the app with the `dotnet run` command.
2. Determine the process identifier (PID) of the .NET Core app:
   - On Windows, use one of the following approaches:
     - Task Manager (Ctrl+Alt+Del)
     - tasklist command
     - Get-Process Powershell command
   - On Linux, use the pidof command.

   Find the PID for the process that has the same name as the app's assembly.
3. Execute the `dotnet trace` command.

   General command syntax:

```
dotnet trace collect -p {PID}
    --providers Microsoft-Extensions-Logging:{Keyword}:{Provider Level}
        :FilterSpecs=\"
            {Logger Category 1}:{Category Level 1};
            {Logger Category 2}:{Category Level 2};
            ...
            {Logger Category N}:{Category Level N}\"
```

   When using a PowerShell command shell, enclose the `--providers` value in single quotes (`'`):

```
dotnet trace collect -p {PID}
    --providers 'Microsoft-Extensions-Logging:{Keyword}:{Provider Level}
        :FilterSpecs=\"
            {Logger Category 1}:{Category Level 1};
            {Logger Category 2}:{Category Level 2};
            ...
            {Logger Category N}:{Category Level N}\"'
```

   On non-Windows platforms, add the `-f speedscope` option to change the format of the output trace file to `speedscope`.

   The following table defines the Keyword:

KEYWORD	DESCRIPTION
1	Log meta events about the `LoggingEventSource`. Doesn't log events from `ILogger`.
2	Turns on the `Message` event when `ILogger.Log()` is called. Provides information in a programmatic (not formatted) way.
4	Turns on the `FormatMessage` event when `ILogger.Log()` is called. Provides the formatted string version of the information.

KEYWORD	DESCRIPTION
8	Turns on the `MessageJson` event when `ILogger.Log()` is called. Provides a JSON representation of the arguments.

The following table lists the provider levels:

PROVIDER LEVEL	DESCRIPTION
0	`LogAlways`
1	`Critical`
2	`Error`
3	`Warning`
4	`Informational`
5	`Verbose`

The parsing for a category level can be either a string or a number:

CATEGORY NAMED VALUE	NUMERIC VALUE
`Trace`	0
`Debug`	1
`Information`	2
`Warning`	3
`Error`	4
`Critical`	5

The provider level and category level:

- Are in reverse order.
- The string constants aren't all identical.

If no `FilterSpecs` are specified then the `EventSourceLogger` implementation attempts to convert the provider level to a category level and applies it to all categories.

PROVIDER LEVEL	CATEGORY LEVEL
`Verbose` (5)	`Debug` (1)
`Informational` (4)	`Information` (2)
`Warning` (3)	`Warning` (3)

PROVIDER LEVEL	CATEGORY LEVEL
`Error` (2)	`Error` (4)
`Critical` (1)	`Critical` (5)

If `FilterSpecs` are provided, any category that is included in the list uses the category level encoded there, all other categories are filtered out.

The following examples assume:

- An app is running and calling `logger.LogDebug("12345")`.
- The process ID (PID) has been set via `set PID=12345`, where `12345` is the actual PID.

Consider the following command:

```
dotnet trace collect -p %PID% --providers Microsoft-Extensions-Logging:4:5
```

The preceding command:

- Captures debug messages.
- Doesn't apply a `FilterSpecs`.
- Specifies level 5 which maps category Debug.

Consider the following command:

```
dotnet trace collect -p %PID%  --providers Microsoft-Extensions-Logging:4:5:\"FilterSpecs=*:5\"
```

The preceding command:

- Doesn't capture debug messages because the category level 5 is `Critical`.
- Provides a `FilterSpecs`.

The following command captures debug messages because category level 1 specifies `Debug`.

```
dotnet trace collect -p %PID%  --providers Microsoft-Extensions-Logging:4:5:\"FilterSpecs=*:1\"
```

The following command captures debug messages because category specifies `Debug`.

```
dotnet trace collect -p %PID%  --providers Microsoft-Extensions-Logging:4:5:\"FilterSpecs=*:Debug\"
```

`FilterSpecs` entries for `{Logger Category}` and `{Category Level}` represent additional log filtering conditions. Separate `FilterSpecs` entries with the `;` semicolon character.

Example using a Windows command shell:

```
dotnet trace collect -p %PID% --providers Microsoft-Extensions-
Logging:4:2:FilterSpecs=\"Microsoft.AspNetCore.Hosting*:4\"
```

The preceding command activates:

- The Event Source logger to produce formatted strings (`4`) for errors (`2`).
- `Microsoft.AspNetCore.Hosting` logging at the `Informational` logging level (`4`).

4. Stop the dotnet trace tooling by pressing the Enter key or Ctrl+C.

The trace is saved with the name *trace.nettrace* in the folder where the `dotnet trace` command is executed.

5. Open the trace with Perfview. Open the *trace.nettrace* file and explore the trace events.

If the app doesn't build the host with `CreateDefaultBuilder`, add the Event Source provider to the app's logging configuration.

For more information, see:

- Trace for performance analysis utility (dotnet-trace) (.NET Core documentation)
- Trace for performance analysis utility (dotnet-trace) (dotnet/diagnostics GitHub repository documentation)
- LoggingEventSource Class (.NET API Browser)
- EventLevel
- LoggingEventSource reference source (3.0): To obtain reference source for a different version, change the branch to `release/{Version}`, where `{Version}` is the version of ASP.NET Core desired.
- Perfview: Useful for viewing Event Source traces.

Perfview

Use the PerfView utility to collect and view logs. There are other tools for viewing ETW logs, but PerfView provides the best experience for working with the ETW events emitted by ASP.NET Core.

To configure PerfView for collecting events logged by this provider, add the string `*Microsoft-Extensions-Logging` to the **Additional Providers** list. Don't miss the `*` at the start of the string.

Windows EventLog

The `EventLog` provider sends log output to the Windows Event Log. Unlike the other providers, the `EventLog` provider does ***not*** inherit the default non-provider settings. If `EventLog` log settings aren't specified, they default to LogLevel.Warning.

To log events lower than LogLevel.Warning, explicitly set the log level. The following example sets the Event Log default log level to LogLevel.Information:

```
"Logging": {
  "EventLog": {
    "LogLevel": {
      "Default": "Information"
    }
  }
}
```

AddEventLog overloads can pass in EventLogSettings. If `null` or not specified, the following default settings are used:

- `LogName`: "Application"
- `SourceName`: ".NET Runtime"
- `MachineName`: The local machine name is used.

The following code changes the `SourceName` from the default value of `".NET Runtime"` to `MyLogs`:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging(logging =>
            {
                logging.AddEventLog(eventLogSettings =>
                {
                    eventLogSettings.SourceName = "MyLogs";
                });
            })
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

Azure App Service

The Microsoft.Extensions.Logging.AzureAppServices provider package writes logs to text files in an Azure App Service app's file system and to blob storage in an Azure Storage account.

The provider package isn't included in the shared framework. To use the provider, add the provider package to the project.

To configure provider settings, use AzureFileLoggerOptions and AzureBlobLoggerOptions, as shown in the following example:

```
public class Scopes
{
    public class Program
    {
        public static void Main(string[] args)
        {
            CreateHostBuilder(args).Build().Run();
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureLogging(logging => logging.AddAzureWebAppDiagnostics())
                .ConfigureServices(serviceCollection => serviceCollection
                    .Configure<AzureFileLoggerOptions>(options =>
                    {
                        options.FileName = "azure-diagnostics-";
                        options.FileSizeLimit = 50 * 1024;
                        options.RetainedFileCountLimit = 5;
                    })
                    .Configure<AzureBlobLoggerOptions>(options =>
                    {
                        options.BlobName = "log.txt";
                    }))
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

When deployed to Azure App Service, the app uses the settings in the App Service logs section of the **App Service**

page of the Azure portal. When the following settings are updated, the changes take effect immediately without requiring a restart or redeployment of the app.

- **Application Logging (Filesystem)**
- **Application Logging (Blob)**

The default location for log files is in the *D:\home\LogFiles\Application* folder, and the default file name is *diagnostics-yyyymmdd.txt*. The default file size limit is 10 MB, and the default maximum number of files retained is 2. The default blob name is *{app-name}{timestamp}/yyyy/mm/dd/hh/{guid}-applicationLog.txt*.

This provider only logs when the project runs in the Azure environment.

Azure log streaming

Azure log streaming supports viewing log activity in real time from:

- The app server
- The web server
- Failed request tracing

To configure Azure log streaming:

- Navigate to the **App Service logs** page from the app's portal page.
- Set **Application Logging (Filesystem)** to **On**.
- Choose the log **Level**. This setting only applies to Azure log streaming.

Navigate to the **Log Stream** page to view logs. The logged messages are logged with the `ILogger` interface.

Azure Application Insights

The Microsoft.Extensions.Logging.ApplicationInsights provider package writes logs to Azure Application Insights. Application Insights is a service that monitors a web app and provides tools for querying and analyzing the telemetry data. If you use this provider, you can query and analyze your logs by using the Application Insights tools.

The logging provider is included as a dependency of Microsoft.ApplicationInsights.AspNetCore, which is the package that provides all available telemetry for ASP.NET Core. If you use this package, you don't have to install the provider package.

The Microsoft.ApplicationInsights.Web package is for ASP.NET 4.x, not ASP.NET Core.

For more information, see the following resources:

- Application Insights overview
- Application Insights for ASP.NET Core applications - Start here if you want to implement the full range of Application Insights telemetry along with logging.
- ApplicationInsightsLoggerProvider for .NET Core ILogger logs - Start here if you want to implement the logging provider without the rest of Application Insights telemetry.
- Application Insights logging adapters.
- Install, configure, and initialize the Application Insights SDK - Interactive tutorial on the Microsoft Learn site.

Third-party logging providers

Third-party logging frameworks that work with ASP.NET Core:

- elmah.io (GitHub repo)
- Gelf (GitHub repo)
- JSNLog (GitHub repo)
- KissLog.net (GitHub repo)

- Log4Net (GitHub repo)
- Loggr (GitHub repo)
- NLog (GitHub repo)
- PLogger (GitHub repo)
- Sentry (GitHub repo)
- Serilog (GitHub repo)
- Stackdriver (Github repo)

Some third-party frameworks can perform semantic logging, also known as structured logging.

Using a third-party framework is similar to using one of the built-in providers:

1. Add a NuGet package to your project.
2. Call an `ILoggerFactory` extension method provided by the logging framework.

For more information, see each provider's documentation. Third-party logging providers aren't supported by Microsoft.

Non-host console app

For an example of how to use the Generic Host in a non-web console app, see the *Program.cs* file of the Background Tasks sample app (Background tasks with hosted services in ASP.NET Core).

Logging code for apps without Generic Host differs in the way providers are added and loggers are created.

Logging providers

In a non-host console app, call the provider's `Add{provider name}` extension method while creating a `LoggerFactory`:

```
class Program
{
    static void Main(string[] args)
    {
        using var loggerFactory = LoggerFactory.Create(builder =>
        {
            builder
                .AddFilter("Microsoft", LogLevel.Warning)
                .AddFilter("System", LogLevel.Warning)
                .AddFilter("LoggingConsoleApp.Program", LogLevel.Debug)
                .AddConsole()
                .AddEventLog();
        });
        ILogger logger = loggerFactory.CreateLogger<Program>();
        logger.LogInformation("Example log message");
    }
}
```

Create logs

To create logs, use an ILogger<TCategoryName> object. Use the `LoggerFactory` to create an `ILogger`.

The following example creates a logger with `LoggingConsoleApp.Program` as the category.

```
class Program
{
    static void Main(string[] args)
    {
        using var loggerFactory = LoggerFactory.Create(builder =>
        {
            builder
                .AddFilter("Microsoft", LogLevel.Warning)
                .AddFilter("System", LogLevel.Warning)
                .AddFilter("LoggingConsoleApp.Program", LogLevel.Debug)
                .AddConsole()
                .AddEventLog();
        });
        ILogger logger = loggerFactory.CreateLogger<Program>();
        logger.LogInformation("Example log message");
    }
}
```

In the following example, the logger is used to create logs with `Information` as the level. The Log *level* indicates the severity of the logged event.

```
class Program
{
    static void Main(string[] args)
    {
        using var loggerFactory = LoggerFactory.Create(builder =>
        {
            builder
                .AddFilter("Microsoft", LogLevel.Warning)
                .AddFilter("System", LogLevel.Warning)
                .AddFilter("LoggingConsoleApp.Program", LogLevel.Debug)
                .AddConsole()
                .AddEventLog();
        });
        ILogger logger = loggerFactory.CreateLogger<Program>();
        logger.LogInformation("Example log message");
    }
}
```

Levels and categories are explained in more detail in this document.

Log during host construction

Logging during host construction isn't directly supported. However, a separate logger can be used. In the following example, a Serilog logger is used to log in `CreateHostBuilder`. `AddSerilog` uses the static configuration specified in `Log.Logger`:

```
using System;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args)
    {
        var builtConfig = new ConfigurationBuilder()
            .AddJsonFile("appsettings.json")
            .AddCommandLine(args)
            .Build();

        Log.Logger = new LoggerConfiguration()
            .WriteTo.Console()
            .WriteTo.File(builtConfig["Logging:FilePath"])
            .CreateLogger();

        try
        {
            return Host.CreateDefaultBuilder(args)
                .ConfigureServices((context, services) =>
                {
                    services.AddRazorPages();
                })
                .ConfigureAppConfiguration((hostingContext, config) =>
                {
                    config.AddConfiguration(builtConfig);
                })
                .ConfigureLogging(logging =>
                {
                    logging.AddSerilog();
                })
                .ConfigureWebHostDefaults(webBuilder =>
                {
                    webBuilder.UseStartup<Startup>();
                });
        }
        catch (Exception ex)
        {
            Log.Fatal(ex, "Host builder error");

            throw;
        }
        finally
        {
            Log.CloseAndFlush();
        }
    }
}
```

Configure a service that depends on ILogger

Constructor injection of a logger into `Startup` works in earlier versions of ASP.NET Core because a separate DI container is created for the Web Host. For information about why only one container is created for the Generic Host, see the breaking change announcement.

To configure a service that depends on `ILogger<T>`, use constructor injection or provide a factory method. The factory method approach is recommended only if there is no other option. For example, consider a service that needs an `ILogger<T>` instance provided by DI:

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddControllers();
    services.AddRazorPages();

    services.AddSingleton<IMyService>((container) =>
    {
        var logger = container.GetRequiredService<ILogger<MyService>>();
        return new MyService() { Logger = logger };
    });
}
```

The preceding highlighted code is a Func that runs the first time the DI container needs to construct an instance of `MyService`. You can access any of the registered services in this way.

Create logs in Main

The following code logs in `Main` by getting an `ILogger` instance from DI after building the host:

```
public static void Main(string[] args)
{
    var host = CreateHostBuilder(args).Build();

    var logger = host.Services.GetRequiredService<ILogger<Program>>();
    logger.LogInformation("Host created.");

    host.Run();
}

public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

Create logs in Startup

The following code writes logs in `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env,
                      ILogger<Startup> logger)
{
    if (env.IsDevelopment())
    {
        logger.LogInformation("In Development.");
        app.UseDeveloperExceptionPage();
    }
    else
    {
        logger.LogInformation("Not Development.");
        app.UseExceptionHandler("/Error");
        app.UseHsts();
    }

    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllers();
        endpoints.MapRazorPages();
    });
}
```

Writing logs before completion of the DI container setup in the `Startup.ConfigureServices` method is not supported:

- Logger injection into the `Startup` constructor is not supported.
- Logger injection into the `Startup.ConfigureServices` method signature is not supported

The reason for this restriction is that logging depends on DI and on configuration, which in turns depends on DI. The DI container isn't set up until `ConfigureServices` finishes.

For information on configuring a service that depends on `ILogger<T>` or why constructor injection of a logger into `Startup` worked in earlier versions, see Configure a service that depends on ILogger

No asynchronous logger methods

Logging should be so fast that it isn't worth the performance cost of asynchronous code. If a logging data store is slow, don't write to it directly. Consider writing the log messages to a fast store initially, then moving them to the slow store later. For example, when logging to SQL Server, don't do so directly in a `Log` method, since the `Log` methods are synchronous. Instead, synchronously add log messages to an in-memory queue and have a background worker pull the messages out of the queue to do the asynchronous work of pushing data to SQL Server. For more information, see this GitHub issue.

Change log levels in a running app

The Logging API doesn't include a scenario to change log levels while an app is running. However, some configuration providers are capable of reloading configuration, which takes immediate effect on logging configuration. For example, the File Configuration Provider, reloads logging configuration by default. If configuration is changed in code while an app is running, the app can call IConfigurationRoot.Reload to update the app's logging configuration.

ILogger and ILoggerFactory

The ILogger<TCategoryName> and ILoggerFactory interfaces and implementations are included in the .NET Core SDK. They are also available in the following NuGet packages:

- The interfaces are in Microsoft.Extensions.Logging.Abstractions.
- The default implementations are in Microsoft.Extensions.Logging.

Apply log filter rules in code

The preferred approach for setting log filter rules is by using Configuration.

The following example shows how to register filter rules in code:

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .ConfigureLogging(logging =>
               logging.AddFilter("System", LogLevel.Debug)
                  .AddFilter<DebugLoggerProvider>("Microsoft", LogLevel.Information)
                  .AddFilter<ConsoleLoggerProvider>("Microsoft", LogLevel.Trace))
            .ConfigureWebHostDefaults(webBuilder =>
            {
                webBuilder.UseStartup<Startup>();
            });
}
```

`logging.AddFilter("System", LogLevel.Debug)` specifies the `System` category and log level `Debug`. The filter is applied to all providers because a specific provider was not configured.

`AddFilter<DebugLoggerProvider>("Microsoft", LogLevel.Information)` specifies:

- The `Debug` logging provider.
- Log level `Information` and higher.
- All categories starting with `"Microsoft"`.

Create a custom logger

To add a custom logger, add an ILoggerProvider with ILoggerFactory:

```
public void Configure(
    IApplicationBuilder app,
    IWebHostEnvironment env,
    ILoggerFactory loggerFactory)
{
    loggerFactory.AddProvider(new CustomLoggerProvider(new CustomLoggerConfiguration()));
```

The `ILoggerProvider` creates one or more `ILogger` instances. The `ILogger` instances are used by the framework to log the information.

Sample custom logger configuration

The sample:

- Is designed to be a very basic sample that sets the color of the log console by event ID and log level. Loggers generally don't change by event ID and are not specific to log level.

- Creates different color console entries per log level and event ID using the following configuration type:

```
public class ColorConsoleLoggerConfiguration
{
    public LogLevel LogLevel { get; set; } = LogLevel.Warning;
    public int EventId { get; set; } = 0;
    public ConsoleColor Color { get; set; } = ConsoleColor.Yellow;
}
```

The preceding code sets the default level to `Warning` and the color to `Yellow`. If the `EventId` is set to 0, we will log all events.

Create the custom logger

The `ILogger` implementation category name is typically the logging source. For example, the type where the logger is created:

```
public class ColorConsoleLogger : ILogger
{
    private readonly string _name;
    private readonly ColorConsoleLoggerConfiguration _config;

    public ColorConsoleLogger(string name, ColorConsoleLoggerConfiguration config)
    {
        _name = name;
        _config = config;
    }

    public IDisposable BeginScope<TState>(TState state)
    {
        return null;
    }

    public bool IsEnabled(LogLevel logLevel)
    {
        return logLevel == _config.LogLevel;
    }

    public void Log<TState>(LogLevel logLevel, EventId eventId, TState state,
                        Exception exception, Func<TState, Exception, string> formatter)
    {
        if (!IsEnabled(logLevel))
        {
            return;
        }

        if (_config.EventId == 0 || _config.EventId == eventId.Id)
        {
            var color = Console.ForegroundColor;
            Console.ForegroundColor = _config.Color;
            Console.WriteLine($"{logLevel} - {eventId.Id} " +
                              $"- {_name} - {formatter(state, exception)}");
            Console.ForegroundColor = color;
        }
    }
}
```

The preceding code:

- Creates a logger instance per category name.
- Checks `logLevel == _config.LogLevel` in `IsEnabled`, so each `logLevel` has a unique logger. Generally, loggers should also be enabled for all higher log levels:

```
public bool IsEnabled(LogLevel logLevel)
{
    return logLevel >= _config.LogLevel;
}
```

Create the custom LoggerProvider

The `LoggerProvider` is the class that creates the logger instances. Maybe it is not needed to create a logger instance per category, but this makes sense for some Loggers, like NLog or log4net. Doing this you are also able to choose different logging output targets per category if needed:

```
public class ColorConsoleLoggerProvider : ILoggerProvider
{
    private readonly ColorConsoleLoggerConfiguration _config;
    private readonly ConcurrentDictionary<string, ColorConsoleLogger> _loggers = new
ConcurrentDictionary<string, ColorConsoleLogger>();

    public ColorConsoleLoggerProvider(ColorConsoleLoggerConfiguration config)
    {
        _config = config;
    }

    public ILogger CreateLogger(string categoryName)
    {
        return _loggers.GetOrAdd(categoryName, name => new ColorConsoleLogger(name, _config));
    }

    public void Dispose()
    {
        _loggers.Clear();
    }
}
```

In the preceding code, CreateLogger creates a single instance of the `ColorConsoleLogger` per category name and stores it in the `ConcurrentDictionary<TKey,TValue>`;

Usage and registration of the custom logger

Register the logger in the `Startup.Configure`:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env,
                      ILoggerFactory loggerFactory)
{
    // Default registration.
    loggerFactory.AddProvider(new ColorConsoleLoggerProvider(
                              new ColorConsoleLoggerConfiguration
    {
        LogLevel = LogLevel.Error,
        Color = ConsoleColor.Red
    }));

    // Custom registration with default values.
    loggerFactory.AddColorConsoleLogger();

    // Custom registration with a new configuration instance.
    loggerFactory.AddColorConsoleLogger(new ColorConsoleLoggerConfiguration
    {
        LogLevel = LogLevel.Debug,
        Color = ConsoleColor.Gray
    });

    // Custom registration with a configuration object.
    loggerFactory.AddColorConsoleLogger(c =>
    {
        c.LogLevel = LogLevel.Information;
        c.Color = ConsoleColor.Blue;
    });

    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }
    else
    {
        app.UseExceptionHandler("/Home/Error");
        app.UseHsts();
    }
    app.UseHttpsRedirection();
    app.UseStaticFiles();

    app.UseRouting();

    app.UseAuthorization();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapControllerRoute(
            name: "default",
            pattern: "{controller=Home}/{action=Index}/{id?}");
    });
}
```

For the preceding code, provide at least one extension method for the `ILoggerFactory`:

```
public static class ColorConsoleLoggerExtensions
{
    public static ILoggerFactory AddColorConsoleLogger(
                                    this ILoggerFactory loggerFactory,
                                    ColorConsoleLoggerConfiguration config)
    {
        loggerFactory.AddProvider(new ColorConsoleLoggerProvider(config));
        return loggerFactory;
    }
    public static ILoggerFactory AddColorConsoleLogger(
                                    this ILoggerFactory loggerFactory)
    {
        var config = new ColorConsoleLoggerConfiguration();
        return loggerFactory.AddColorConsoleLogger(config);
    }
    public static ILoggerFactory AddColorConsoleLogger(
                                  this ILoggerFactory loggerFactory,
                                  Action<ColorConsoleLoggerConfiguration> configure)
    {
        var config = new ColorConsoleLoggerConfiguration();
        configure(config);
        return loggerFactory.AddColorConsoleLogger(config);
    }
}
```

By Tom Dykstra and Steve Smith

.NET Core supports a logging API that works with a variety of built-in and third-party logging providers. This article shows how to use the logging API with built-in providers.

View or download sample code (how to download)

Add providers

A logging provider displays or stores logs. For example, the Console provider displays logs on the console, and the Azure Application Insights provider stores them in Azure Application Insights. Logs can be sent to multiple destinations by adding multiple providers.

To add a provider, call the provider's `Add{provider name}` extension method in *Program.cs*:

```
public static void Main(string[] args)
{
    var webHost = new WebHostBuilder()
        .UseKestrel()
        .UseContentRoot(Directory.GetCurrentDirectory())
        .ConfigureAppConfiguration((hostingContext, config) =>
        {
            var env = hostingContext.HostingEnvironment;
            config.AddJsonFile("appsettings.json", optional: true, reloadOnChange: true)
                  .AddJsonFile($"appsettings.{env.EnvironmentName}.json",
                      optional: true, reloadOnChange: true);
            config.AddEnvironmentVariables();
        })
        .ConfigureLogging((hostingContext, logging) =>
        {
            // Requires `using Microsoft.Extensions.Logging;`
            logging.AddConfiguration(hostingContext.Configuration.GetSection("Logging"));
            logging.AddConsole();
            logging.AddDebug();
            logging.AddEventSourceLogger();
        })
        .UseStartup<Startup>()
        .Build();

    webHost.Run();
}
```

The preceding code requires references to `Microsoft.Extensions.Logging` and `Microsoft.Extensions.Configuration`.

The default project template calls CreateDefaultBuilder, which adds the following logging providers:

- Console
- Debug
- EventSource (starting in ASP.NET Core 2.2)

```
public static void Main(string[] args)
{
    CreateWebHostBuilder(args).Build().Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>();
```

If you use `CreateDefaultBuilder`, you can replace the default providers with your own choices. Call ClearProviders, and add the providers you want.

```
public static void Main(string[] args)
{
    var host = CreateWebHostBuilder(args).Build();

    var todoRepository = host.Services.GetRequiredService<ITodoRepository>();
    todoRepository.Add(new Core.Model.TodoItem() { Name = "Feed the dog" });
    todoRepository.Add(new Core.Model.TodoItem() { Name = "Walk the dog" });

    var logger = host.Services.GetRequiredService<ILogger<Program>>();
    logger.LogInformation("Seeded the database.");

    host.Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureLogging(logging =>
        {
            logging.ClearProviders();
            logging.AddConsole();
        });
```

Learn more about built-in logging providers and third-party logging providers later in the article.

Create logs

To create logs, use an ILogger<TCategoryName> object. In a web app or hosted service, get an `ILogger` from dependency injection (DI). In non-host console apps, use the `LoggerFactory` to create an `ILogger`.

The following ASP.NET Core example creates a logger with `TodoApiSample.Pages.AboutModel` as the category. The log *category* is a string that is associated with each log. The `ILogger<T>` instance provided by DI creates logs that have the fully qualified name of type `T` as the category.

```
public class AboutModel : PageModel
{
    private readonly ILogger _logger;

    public AboutModel(ILogger<AboutModel> logger)
    {
        _logger = logger;
    }
```

In the following ASP.NET Core and console app examples, the logger is used to create logs with `Information` as the level. The Log *level* indicates the severity of the logged event.

```
public void OnGet()
{
    Message = $"About page visited at {DateTime.UtcNow.ToLongTimeString()}";
    _logger.LogInformation("Message displayed: {Message}", Message);
}
```

Levels and categories are explained in more detail later in this article.

Create logs in Startup

To write logs in the `Startup` class, include an `ILogger` parameter in the constructor signature:

```
public class Startup
{
    private readonly ILogger _logger;

    public Startup(IConfiguration configuration, ILogger<Startup> logger)
    {
        Configuration = configuration;
        _logger = logger;
    }

    public IConfiguration Configuration { get; }

    public void ConfigureServices(IServiceCollection services)
    {
        services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_2);

        // Add our repository type
        services.AddSingleton<ITodoRepository, TodoRepository>();
        _logger.LogInformation("Added TodoRepository to services");
    }

    public void Configure(IApplicationBuilder app, IHostingEnvironment env)
    {
        if (env.IsDevelopment())
        {
            _logger.LogInformation("In Development environment");
            app.UseDeveloperExceptionPage();
        }
        else
        {
            app.UseExceptionHandler("/Error");
            app.UseHsts();
        }

        app.UseHttpsRedirection();
        app.UseStaticFiles();
        app.UseCookiePolicy();

        app.UseMvc();
    }
}
```

Create logs in the Program class

To write logs in the `Program` class, get an `ILogger` instance from DI:

```
public static void Main(string[] args)
{
    var host = CreateWebHostBuilder(args).Build();

    var todoRepository = host.Services.GetRequiredService<ITodoRepository>();
    todoRepository.Add(new Core.Model.TodoItem() { Name = "Feed the dog" });
    todoRepository.Add(new Core.Model.TodoItem() { Name = "Walk the dog" });

    var logger = host.Services.GetRequiredService<ILogger<Program>>();
    logger.LogInformation("Seeded the database.");

    host.Run();
}

public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .UseStartup<Startup>()
        .ConfigureLogging(logging =>
        {
            logging.ClearProviders();
            logging.AddConsole();
        });
```

Logging during host construction isn't directly supported. However, a separate logger can be used. In the following example, a Serilog logger is used to log in `CreateWebHostBuilder`. `AddSerilog` uses the static configuration specified in `Log.Logger`:

```
using System;
using Microsoft.AspNetCore;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.Logging;

public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args)
    {
        var builtConfig = new ConfigurationBuilder()
            .AddJsonFile("appsettings.json")
            .AddCommandLine(args)
            .Build();

        Log.Logger = new LoggerConfiguration()
            .WriteTo.Console()
            .WriteTo.File(builtConfig["Logging:FilePath"])
            .CreateLogger();

        try
        {
            return WebHost.CreateDefaultBuilder(args)
                .ConfigureServices((context, services) =>
                {
                    services.AddMvc();
                })
                .ConfigureAppConfiguration((hostingContext, config) =>
                {
                    config.AddConfiguration(builtConfig);
                })
                .ConfigureLogging(logging =>
                {
                    logging.AddSerilog();
                })
                .UseStartup<Startup>();
        }
        catch (Exception ex)
        {
            Log.Fatal(ex, "Host builder error");

            throw;
        }
        finally
        {
            Log.CloseAndFlush();
        }
    }
}
```

No asynchronous logger methods

Logging should be so fast that it isn't worth the performance cost of asynchronous code. If your logging data store is slow, don't write to it directly. Consider writing the log messages to a fast store initially, then move them to the slow store later. For example, if you're logging to SQL Server, you don't want to do that directly in a `Log` method, since the `Log` methods are synchronous. Instead, synchronously add log messages to an in-memory queue and have a background worker pull the messages out of the queue to do the asynchronous work of pushing data to SQL Server. For more information, see this GitHub issue.

Configuration

Logging provider configuration is provided by one or more configuration providers:

- File formats (INI, JSON, and XML).
- Command-line arguments.
- Environment variables.
- In-memory .NET objects.
- The unencrypted Secret Manager storage.
- An encrypted user store, such as Azure Key Vault.
- Custom providers (installed or created).

For example, logging configuration is commonly provided by the `Logging` section of app settings files. The following example shows the contents of a typical *appsettings.Development.json* file:

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Debug",
      "System": "Information",
      "Microsoft": "Information"
    },
    "Console":
    {
      "IncludeScopes": true
    }
  }
}
```

The `Logging` property can have `LogLevel` and log provider properties (Console is shown).

The `LogLevel` property under `Logging` specifies the minimum level to log for selected categories. In the example, `System` and `Microsoft` categories log at `Information` level, and all others log at `Debug` level.

Other properties under `Logging` specify logging providers. The example is for the Console provider. If a provider supports log scopes, `IncludeScopes` indicates whether they're enabled. A provider property (such as `Console` in the example) may also specify a `LogLevel` property. `LogLevel` under a provider specifies levels to log for that provider.

If levels are specified in `Logging.{providername}.LogLevel`, they override anything set in `Logging.LogLevel`. For example, consider the following JSON:

```
{
  "Logging": {      // Default, all providers.
    "LogLevel": {
      "Microsoft": "Warning"
    },
    "Console": { // Console provider.
      "LogLevel": {
        "Microsoft": "Information"
      }
    }
  }
}
```

In the preceding JSON, the `Console` provider settings overrides the preceding (default) log level.

The Logging API doesn't include a scenario to change log levels while an app is running. However, some configuration providers are capable of reloading configuration, which takes immediate effect on logging

configuration. For example, the File Configuration Provider, which is added by `CreateDefaultBuilder` to read settings files, reloads logging configuration by default. If configuration is changed in code while an app is running, the app can call IConfigurationRoot.Reload to update the app's logging configuration.

For information on implementing configuration providers, see Configuration in ASP.NET Core.

Sample logging output

With the sample code shown in the preceding section, logs appear in the console when the app is run from the command line. Here's an example of console output:

```
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[1]
      Request starting HTTP/1.1 GET http://localhost:5000/api/todo/0
info: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[1]
      Executing action method TodoApi.Controllers.TodoController.GetById (TodoApi) with arguments (0) -
ModelState is Valid
info: TodoApi.Controllers.TodoController[1002]
      Getting item 0
warn: TodoApi.Controllers.TodoController[4000]
      GetById(0) NOT FOUND
info: Microsoft.AspNetCore.Mvc.StatusCodeResult[1]
      Executing HttpStatusCodeResult, setting HTTP status code 404
info: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[2]
      Executed action TodoApi.Controllers.TodoController.GetById (TodoApi) in 42.9286ms
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[2]
      Request finished in 148.889ms 404
```

The preceding logs were generated by making an HTTP Get request to the sample app at `http://localhost:5000/api/todo/0`.

Here's an example of the same logs as they appear in the Debug window when you run the sample app in Visual Studio:

```
Microsoft.AspNetCore.Hosting.Internal.WebHost:Information: Request starting HTTP/1.1 GET
http://localhost:53104/api/todo/0
Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker:Information: Executing action method
TodoApi.Controllers.TodoController.GetById (TodoApi) with arguments (0) - ModelState is Valid
TodoApi.Controllers.TodoController:Information: Getting item 0
TodoApi.Controllers.TodoController:Warning: GetById(0) NOT FOUND
Microsoft.AspNetCore.Mvc.StatusCodeResult:Information: Executing HttpStatusCodeResult, setting HTTP status code
404
Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker:Information: Executed action
TodoApi.Controllers.TodoController.GetById (TodoApi) in 152.5657ms
Microsoft.AspNetCore.Hosting.Internal.WebHost:Information: Request finished in 316.3195ms 404
```

The logs that are created by the `ILogger` calls shown in the preceding section begin with "TodoApi". The logs that begin with "Microsoft" categories are from ASP.NET Core framework code. ASP.NET Core and application code are using the same logging API and providers.

The remainder of this article explains some details and options for logging.

NuGet packages

The `ILogger` and `ILoggerFactory` interfaces are in Microsoft.Extensions.Logging.Abstractions, and default implementations for them are in Microsoft.Extensions.Logging.

Log category

When an `ILogger` object is created, a *category* is specified for it. That category is included with each log message

created by that instance of `ILogger`. The category may be any string, but the convention is to use the class name, such as "TodoApi.Controllers.TodoController".

Use `ILogger<T>` to get an `ILogger` instance that uses the fully qualified type name of `T` as the category:

```
public class TodoController : Controller
{
    private readonly ITodoRepository _todoRepository;
    private readonly ILogger _logger;

    public TodoController(ITodoRepository todoRepository,
        ILogger<TodoController> logger)
    {
        _todoRepository = todoRepository;
        _logger = logger;
    }
```

To explicitly specify the category, call `ILoggerFactory.CreateLogger`:

```
public class TodoController : Controller
{
    private readonly ITodoRepository _todoRepository;
    private readonly ILogger _logger;

    public TodoController(ITodoRepository todoRepository,
        ILoggerFactory logger)
    {
        _todoRepository = todoRepository;
        _logger = logger.CreateLogger("TodoApiSample.Controllers.TodoController");
    }
```

`ILogger<T>` is equivalent to calling `CreateLogger` with the fully qualified type name of `T`.

Log level

Every log specifies a LogLevel value. The log level indicates the severity or importance. For example, you might write an `Information` log when a method ends normally and a `Warning` log when a method returns a *404 Not Found* status code.

The following code creates `Information` and `Warning` logs:

```
public IActionResult GetById(string id)
{
    _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);
    var item = _todoRepository.Find(id);
    if (item == null)
    {
        _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
        return NotFound();
    }
    return new ObjectResult(item);
}
```

In the preceding code, the `MyLogEvents.GetItem` and `MyLogEvents.GetItemNotFound` parameters are the Log event ID. The second parameter is a message template with placeholders for argument values provided by the remaining method parameters. The method parameters are explained in the Log message template section in this article.

Log methods that include the level in the method name (for example, `LogInformation` and `LogWarning`) are extension methods for ILogger. These methods call a `Log` method that takes a `LogLevel` parameter. You can call

the `Log` method directly rather than one of these extension methods, but the syntax is relatively complicated. For more information, see ILogger and the logger extensions source code.

ASP.NET Core defines the following log levels, ordered here from lowest to highest severity.

- Trace = 0

  For information that's typically valuable only for debugging. These messages may contain sensitive application data and so shouldn't be enabled in a production environment. *Disabled by default.*

- Debug = 1

  For information that may be useful in development and debugging. Example: `Entering method Configure with flag set to true.` Enable `Debug` level logs in production only when troubleshooting, due to the high volume of logs.

- Information = 2

  For tracking the general flow of the app. These logs typically have some long-term value. Example: `Request received for path /api/todo`

- Warning = 3

  For abnormal or unexpected events in the app flow. These may include errors or other conditions that don't cause the app to stop but might need to be investigated. Handled exceptions are a common place to use the `Warning` log level. Example: `FileNotFoundException for file quotes.txt.`

- Error = 4

  For errors and exceptions that cannot be handled. These messages indicate a failure in the current activity or operation (such as the current HTTP request), not an app-wide failure. Example log message: `Cannot insert record due to duplicate key violation.`

- Critical = 5

  For failures that require immediate attention. Examples: data loss scenarios, out of disk space.

Use the log level to control how much log output is written to a particular storage medium or display window. For example:

- In production:
  - Logging at the `Trace` through `Information` levels produces a high-volume of detailed log messages. To control costs and not exceed data storage limits, log `Trace` through `Information` level messages to a high-volume, low-cost data store.
  - Logging at `Warning` through `Critical` levels typically produces fewer, smaller log messages. Therefore, costs and storage limits usually aren't a concern, which results in greater flexibility of data store choice.
- During development:
  - Log `Warning` through `Critical` messages to the console.
  - Add `Trace` through `Information` messages when troubleshooting.

The Log filtering section later in this article explains how to control which log levels a provider handles.

ASP.NET Core writes logs for framework events. The log examples earlier in this article excluded logs below `Information` level, so no `Debug` or `Trace` level logs were created. Here's an example of console logs produced by running the sample app configured to show `Debug` logs:

```
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[1]
      Request starting HTTP/1.1 GET http://localhost:62555/api/todo/0
dbug: Microsoft.AspNetCore.Routing.Tree.TreeRouter[1]
      Request successfully matched the route with name 'GetTodo' and template 'api/Todo/{id}'.
dbug: Microsoft.AspNetCore.Mvc.Internal.ActionSelector[2]
      Action 'TodoApi.Controllers.TodoController.Update (TodoApi)' with id '089d59b6-92ec-472d-b552-
cc613dfd625d' did not match the constraint 'Microsoft.AspNetCore.Mvc.Internal.HttpMethodActionConstraint'
dbug: Microsoft.AspNetCore.Mvc.Internal.ActionSelector[2]
      Action 'TodoApi.Controllers.TodoController.Delete (TodoApi)' with id 'f3476abe-4bd9-4ad3-9261-

info: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[1]
      Executing action method TodoApi.Controllers.TodoController.GetById (TodoApi) with arguments (0) -
ModelState is Valid
info: TodoApi.Controllers.TodoController[1002]
      Getting item 0
warn: TodoApi.Controllers.TodoController[4000]
      GetById(0) NOT FOUND
dbug: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[2]
      Executed action method TodoApi.Controllers.TodoController.GetById (TodoApi), returned result
Microsoft.AspNetCore.Mvc.NotFoundResult.
info: Microsoft.AspNetCore.Mvc.StatusCodeResult[1]
      Executing HttpStatusCodeResult, setting HTTP status code 404
info: Microsoft.AspNetCore.Mvc.Internal.ControllerActionInvoker[2]
      Executed action TodoApi.Controllers.TodoController.GetById (TodoApi) in 0.8788ms
dbug: Microsoft.AspNetCore.Server.Kestrel[9]
      Connection id "0HL6L7NEFF2QD" completed keep alive response.
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[2]
      Request finished in 2.7286ms 404
```

Log event ID

Each log can specify an *event ID*. The sample app does this by using a locally defined `LoggingEvents` class:

```
public IActionResult GetById(string id)
{
    _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);
    var item = _todoRepository.Find(id);
    if (item == null)
    {
        _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
        return NotFound();
    }
    return new ObjectResult(item);
}
```

```
public class LoggingEvents
{
    public const int GenerateItems = 1000;
    public const int ListItems = 1001;
    public const int GetItem = 1002;
    public const int InsertItem = 1003;
    public const int UpdateItem = 1004;
    public const int DeleteItem = 1005;

    public const int GetItemNotFound = 4000;
    public const int UpdateItemNotFound = 4001;
}
```

An event ID associates a set of events. For example, all logs related to displaying a list of items on a page might be

1001.

The logging provider may store the event ID in an ID field, in the logging message, or not at all. The Debug provider doesn't show event IDs. The console provider shows event IDs in brackets after the category:

```
info: TodoApi.Controllers.TodoController[1002]
      Getting item invalidid
warn: TodoApi.Controllers.TodoController[4000]
      GetById(invalidid) NOT FOUND
```

Log message template

Each log specifies a message template. The message template can contain placeholders for which arguments are provided. Use names for the placeholders, not numbers.

```
public IActionResult GetById(string id)
{
    _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);
    var item = _todoRepository.Find(id);
    if (item == null)
    {
        _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
        return NotFound();
    }
    return new ObjectResult(item);
}
```

The order of placeholders, not their names, determines which parameters are used to provide their values. In the following code, notice that the parameter names are out of sequence in the message template:

```
string p1 = "parm1";
string p2 = "parm2";
_logger.LogInformation("Parameter values: {p2}, {p1}", p1, p2);
```

This code creates a log message with the parameter values in sequence:

```
Parameter values: parm1, parm2
```

The logging framework works this way so that logging providers can implement semantic logging, also known as structured logging. The arguments themselves are passed to the logging system, not just the formatted message template. This information enables logging providers to store the parameter values as fields. For example, suppose logger method calls look like this:

```
_logger.LogInformation("Getting item {Id} at {RequestTime}", id, DateTime.Now);
```

If you're sending the logs to Azure Table Storage, each Azure Table entity can have `ID` and `RequestTime` properties, which simplifies queries on log data. A query can find all logs within a particular `RequestTime` range without parsing the time out of the text message.

Logging exceptions

The logger methods have overloads that let you pass in an exception, as in the following example:

```
catch (Exception ex)
{
    _logger.LogWarning(LoggingEvents.GetItemNotFound, ex, "GetById({Id}) NOT FOUND", id);
    return NotFound();
}
return new ObjectResult(item);
```

Different providers handle the exception information in different ways. Here's an example of Debug provider output from the code shown above.

```
TodoApiSample.Controllers.TodoController: Warning: GetById(55) NOT FOUND

System.Exception: Item not found exception.
   at TodoApiSample.Controllers.TodoController.GetById(String id) in
C:\TodoApiSample\Controllers\TodoController.cs:line 226
```

Log filtering

You can specify a minimum log level for a specific provider and category or for all providers or all categories. Any logs below the minimum level aren't passed to that provider, so they don't get displayed or stored.

To suppress all logs, specify `LogLevel.None` as the minimum log level. The integer value of `LogLevel.None` is 6, which is higher than `LogLevel.Critical` (5).

Create filter rules in configuration

The project template code calls `CreateDefaultBuilder` to set up logging for the Console, Debug, and EventSource (ASP.NET Core 2.2 or later) providers. The `CreateDefaultBuilder` method sets up logging to look for configuration in a `Logging` section, as explained earlier in this article.

The configuration data specifies minimum log levels by provider and category, as in the following example:

```
{
  "Logging": {
    "Debug": {
      "LogLevel": {
        "Default": "Information"
      }
    },
    "Console": {
      "IncludeScopes": false,
      "LogLevel": {
        "Microsoft.AspNetCore.Mvc.Razor.Internal": "Warning",
        "Microsoft.AspNetCore.Mvc.Razor.Razor": "Debug",
        "Microsoft.AspNetCore.Mvc.Razor": "Error",
        "Default": "Information"
      }
    },
    "LogLevel": {
      "Default": "Debug"
    }
  }
}
```

This JSON creates six filter rules: one for the Debug provider, four for the Console provider, and one for all providers. A single rule is chosen for each provider when an `ILogger` object is created.

Filter rules in code

The following example shows how to register filter rules in code:

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup<Startup>()
    .ConfigureLogging(logging =>
        logging.AddFilter("System", LogLevel.Debug)
               .AddFilter<DebugLoggerProvider>("Microsoft", LogLevel.Trace));
```

The second `AddFilter` specifies the Debug provider by using its type name. The first `AddFilter` applies to all providers because it doesn't specify a provider type.

How filtering rules are applied

The configuration data and the `AddFilter` code shown in the preceding examples create the rules shown in the following table. The first six come from the configuration example and the last two come from the code example.

NUMBER	PROVIDER	CATEGORIES THAT BEGIN WITH ...	MINIMUM LOG LEVEL
1	Debug	All categories	Information
2	Console	Microsoft.AspNetCore.Mvc.Razor.Internal	Warning
3	Console	Microsoft.AspNetCore.Mvc.Razor.Razor	Debug
4	Console	Microsoft.AspNetCore.Mvc.Razor	Error
5	Console	All categories	Information
6	All providers	All categories	Debug
7	All providers	System	Debug
8	Debug	Microsoft	Trace

When an `ILogger` object is created, the `ILoggerFactory` object selects a single rule per provider to apply to that logger. All messages written by an `ILogger` instance are filtered based on the selected rules. The most specific rule possible for each provider and category pair is selected from the available rules.

The following algorithm is used for each provider when an `ILogger` is created for a given category:

- Select all rules that match the provider or its alias. If no match is found, select all rules with an empty provider.
- From the result of the preceding step, select rules with longest matching category prefix. If no match is found, select all rules that don't specify a category.
- If multiple rules are selected, take the **last** one.
- If no rules are selected, use `MinimumLevel`.

With the preceding list of rules, suppose you create an `ILogger` object for category "Microsoft.AspNetCore.Mvc.Razor.RazorViewEngine":

- For the Debug provider, rules 1, 6, and 8 apply. Rule 8 is most specific, so that's the one selected.
- For the Console provider, rules 3, 4, 5, and 6 apply. Rule 3 is most specific.

The resulting `ILogger` instance sends logs of `Trace` level and above to the Debug provider. Logs of `Debug` level and above are sent to the Console provider.

Provider aliases

Each provider defines an *alias* that can be used in configuration in place of the fully qualified type name. For the built-in providers, use the following aliases:

- Console
- Debug
- EventSource
- EventLog
- TraceSource
- AzureAppServicesFile
- AzureAppServicesBlob
- ApplicationInsights

Default minimum level

There's a minimum level setting that takes effect only if no rules from configuration or code apply for a given provider and category. The following example shows how to set the minimum level:

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup<Startup>()
    .ConfigureLogging(logging => logging.SetMinimumLevel(LogLevel.Warning));
```

If you don't explicitly set the minimum level, the default value is `Information`, which means that `Trace` and `Debug` logs are ignored.

Filter functions

A filter function is invoked for all providers and categories that don't have rules assigned to them by configuration or code. Code in the function has access to the provider type, category, and log level. For example:

```
WebHost.CreateDefaultBuilder(args)
    .UseStartup<Startup>()
    .ConfigureLogging(logBuilder =>
    {
        logBuilder.AddFilter((provider, category, logLevel) =>
        {
            if (provider == "Microsoft.Extensions.Logging.Console.ConsoleLoggerProvider" &&
                category == "TodoApiSample.Controllers.TodoController")
            {
                return false;
            }
            return true;
        });
    });
```

System categories and levels

Here are some categories used by ASP.NET Core and Entity Framework Core, with notes about what logs to expect from them:

CATEGORY	NOTES
Microsoft.AspNetCore	General ASP.NET Core diagnostics.
Microsoft.AspNetCore.DataProtection	Which keys were considered, found, and used.

CATEGORY	NOTES
Microsoft.AspNetCore.HostFiltering	Hosts allowed.
Microsoft.AspNetCore.Hosting	How long HTTP requests took to complete and what time they started. Which hosting startup assemblies were loaded.
Microsoft.AspNetCore.Mvc	MVC and Razor diagnostics. Model binding, filter execution, view compilation, action selection.
Microsoft.AspNetCore.Routing	Route matching information.
Microsoft.AspNetCore.Server	Connection start, stop, and keep alive responses. HTTPS certificate information.
Microsoft.AspNetCore.StaticFiles	Files served.
Microsoft.EntityFrameworkCore	General Entity Framework Core diagnostics. Database activity and configuration, change detection, migrations.

Log scopes

A *scope* can group a set of logical operations. This grouping can be used to attach the same data to each log that's created as part of a set. For example, every log created as part of processing a transaction can include the transaction ID.

A scope is an `IDisposable` type that's returned by the BeginScope method and lasts until it's disposed. Use a scope by wrapping logger calls in a `using` block:

```
public IActionResult GetById(string id)
{
    TodoItem item;
    using (_logger.BeginScope("Message attached to logs created in the using block"))
    {
        _logger.LogInformation(LoggingEvents.GetItem, "Getting item {Id}", id);
        item = _todoRepository.Find(id);
        if (item == null)
        {
            _logger.LogWarning(LoggingEvents.GetItemNotFound, "GetById({Id}) NOT FOUND", id);
            return NotFound();
        }
    }
    return new ObjectResult(item);
}
```

The following code enables scopes for the console provider:

Program.cs:

```
.ConfigureLogging((hostingContext, logging) =>
{
    logging.AddConfiguration(hostingContext.Configuration.GetSection("Logging"));
    logging.AddConsole(options => options.IncludeScopes = true);
    logging.AddDebug();
})
```

> **NOTE**
>
> Configuring the `IncludeScopes` console logger option is required to enable scope-based logging.
>
> For information on configuration, see the Configuration section.

Each log message includes the scoped information:

```
info: TodoApiSample.Controllers.TodoController[1002]
      => RequestId:0HKV9C49II9CK RequestPath:/api/todo/0 => TodoApiSample.Controllers.TodoController.GetById
(TodoApi) => Message attached to logs created in the using block
      Getting item 0
warn: TodoApiSample.Controllers.TodoController[4000]
      => RequestId:0HKV9C49II9CK RequestPath:/api/todo/0 => TodoApiSample.Controllers.TodoController.GetById
(TodoApi) => Message attached to logs created in the using block
      GetById(0) NOT FOUND
```

Built-in logging providers

ASP.NET Core ships the following providers:

- Console
- Debug
- EventSource
- EventLog
- TraceSource
- AzureAppServicesFile
- AzureAppServicesBlob
- ApplicationInsights

For information on stdout and debug logging with the ASP.NET Core Module, see Troubleshoot ASP.NET Core on Azure App Service and IIS and ASP.NET Core Module.

Console provider

The Microsoft.Extensions.Logging.Console provider package sends log output to the console.

```
logging.AddConsole();
```

To see console logging output, open a command prompt in the project folder and run the following command:

```
dotnet run
```

Debug provider

The Microsoft.Extensions.Logging.Debug provider package writes log output by using the System.Diagnostics.Debug class (`Debug.WriteLine` method calls).

On Linux, this provider writes logs to */var/log/message*.

```
logging.AddDebug();
```

Event Source provider

The Microsoft.Extensions.Logging.EventSource provider package writes to an Event Source cross-platform with the

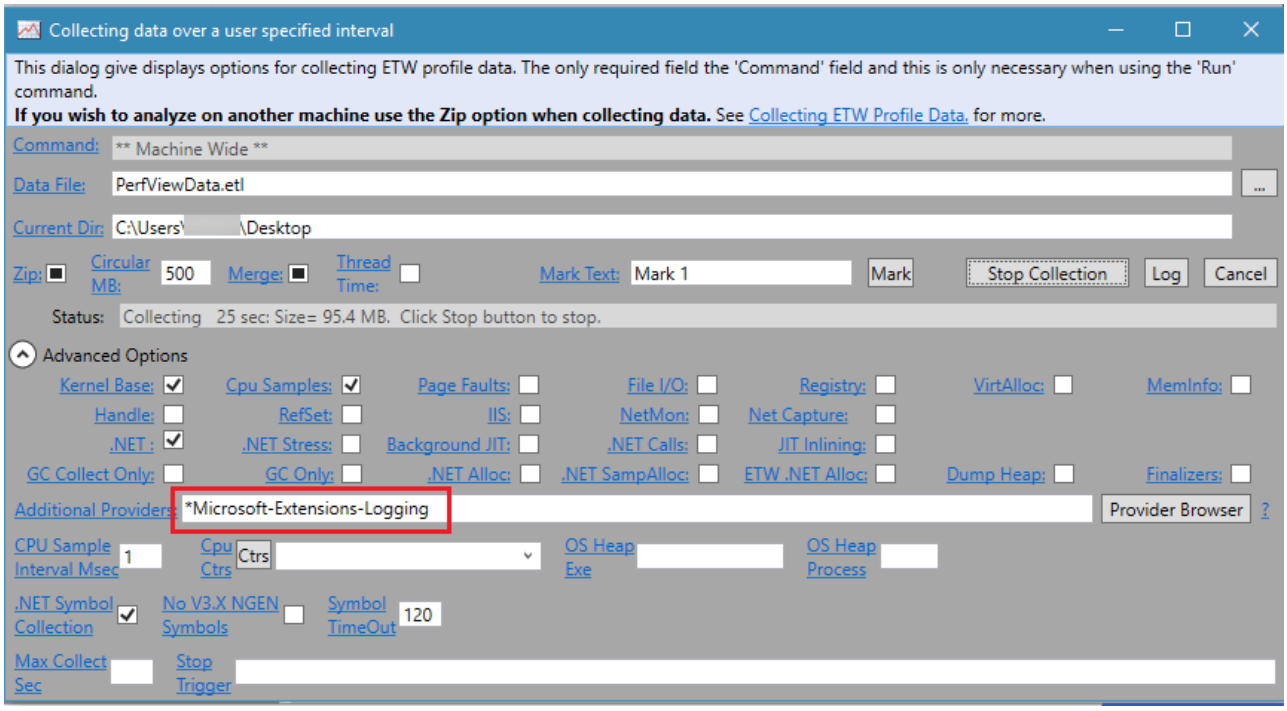
name `Microsoft-Extensions-Logging`. On Windows, the provider uses ETW.

```
logging.AddEventSourceLogger();
```

The Event Source provider is added automatically when `CreateDefaultBuilder` is called to build the host.

Use the PerfView utility to collect and view logs. There are other tools for viewing ETW logs, but PerfView provides the best experience for working with the ETW events emitted by ASP.NET Core.

To configure PerfView for collecting events logged by this provider, add the string `*Microsoft-Extensions-Logging` to the **Additional Providers** list. (Don't miss the asterisk at the start of the string.)



Windows EventLog provider

The Microsoft.Extensions.Logging.EventLog provider package sends log output to the Windows Event Log.

```
logging.AddEventLog();
```

AddEventLog overloads let you pass in EventLogSettings. If `null` or not specified, the following default settings are used:

- `LogName`: "Application"
- `SourceName`: ".NET Runtime"
- `MachineName`: The local machine name is used.

Events are logged for Warning level and higher. The following example sets the Event Log default log level to LogLevel.Information:

```
"Logging": {
  "EventLog": {
    "LogLevel": {
      "Default": "Information"
    }
  }
}
```

TraceSource provider

The Microsoft.Extensions.Logging.TraceSource provider package uses the TraceSource libraries and providers.

```
logging.AddTraceSource(sourceSwitchName);
```

AddTraceSource overloads let you pass in a source switch and a trace listener.

To use this provider, an app has to run on the .NET Framework (rather than .NET Core). The provider can route messages to a variety of listeners, such as the TextWriterTraceListener used in the sample app.

Azure App Service provider

The Microsoft.Extensions.Logging.AzureAppServices provider package writes logs to text files in an Azure App Service app's file system and to blob storage in an Azure Storage account.

```
logging.AddAzureWebAppDiagnostics();
```

The provider package isn't included in the Microsoft.AspNetCore.App metapackage. When targeting .NET Framework or referencing the `Microsoft.AspNetCore.App` metapackage, add the provider package to the project.

An AddAzureWebAppDiagnostics overload lets you pass in AzureAppServicesDiagnosticsSettings. The settings object can override default settings, such as the logging output template, blob name, and file size limit. (*Output template* is a message template that's applied to all logs in addition to what's provided with an `ILogger` method call.)

When you deploy to an App Service app, the application honors the settings in the App Service logs section of the **App Service** page of the Azure portal. When the following settings are updated, the changes take effect immediately without requiring a restart or redeployment of the app.

- **Application Logging (Filesystem)**
- **Application Logging (Blob)**

The default location for log files is in the *D:\home\LogFiles\Application* folder, and the default file name is *diagnostics-yyyymmdd.txt*. The default file size limit is 10 MB, and the default maximum number of files retained is 2. The default blob name is *{app-name}{timestamp}/yyyy/mm/dd/hh/{guid}-applicationLog.txt*.

The provider only works when the project runs in the Azure environment. It has no effect when the project is run locally—it doesn't write to local files or local development storage for blobs.

Azure log streaming

Azure log streaming lets you view log activity in real time from:

- The app server
- The web server
- Failed request tracing

To configure Azure log streaming:

- Navigate to the **App Service logs** page from your app's portal page.
- Set **Application Logging (Filesystem)** to **On**.
- Choose the log **Level**. This setting only applies to Azure log streaming, not other logging providers in the app.

Navigate to the **Log Stream** page to view app messages. They're logged by the app through the `ILogger` interface.

Azure Application Insights trace logging

The Microsoft.Extensions.Logging.ApplicationInsights provider package writes logs to Azure Application Insights.

Application Insights is a service that monitors a web app and provides tools for querying and analyzing the telemetry data. If you use this provider, you can query and analyze your logs by using the Application Insights tools.

The provider package isn't included in the shared framework. To use the provider, add the provider package to the project. The logging provider is included as a dependency of Microsoft.ApplicationInsights.AspNetCore, which is the package that provides all available telemetry for ASP.NET Core. If you use this package, you don't have to install the provider package.

Don't use the Microsoft.ApplicationInsights.Web package—that's for ASP.NET 4.x.

For more information, see the following resources:

- Application Insights overview
- Application Insights for ASP.NET Core applications - Start here if you want to implement the full range of Application Insights telemetry along with logging.
- ApplicationInsightsLoggerProvider for .NET Core ILogger logs - Start here if you want to implement the logging provider without the rest of Application Insights telemetry.
- Application Insights logging adapters.
- Install, configure, and initialize the Application Insights SDK - Interactive tutorial on the Microsoft Learn site.

Third-party logging providers

Third-party logging frameworks that work with ASP.NET Core:

- elmah.io (GitHub repo)
- Gelf (GitHub repo)
- JSNLog (GitHub repo)
- KissLog.net (GitHub repo)
- Log4Net (GitHub repo)
- Loggr (GitHub repo)
- NLog (GitHub repo)
- Sentry (GitHub repo)
- Serilog (GitHub repo)
- Stackdriver (Github repo)

Some third-party frameworks can perform semantic logging, also known as structured logging.

Using a third-party framework is similar to using one of the built-in providers:

1. Add a NuGet package to your project.
2. Call an `ILoggerFactory` or `ILoggingBuilder` extension method provided by the logging framework.

For more information, see each provider's documentation. Third-party logging providers aren't supported by Microsoft.

Routing in ASP.NET Core

9/22/2020 • 101 minutes to read • Edit Online

By Ryan Nowak, Kirk Larkin, and Rick Anderson

Routing is responsible for matching incoming HTTP requests and dispatching those requests to the app's executable endpoints. Endpoints are the app's units of executable request-handling code. Endpoints are defined in the app and configured when the app starts. The endpoint matching process can extract values from the request's URL and provide those values for request processing. Using endpoint information from the app, routing is also able to generate URLs that map to endpoints.

Apps can configure routing using:

- Controllers
- Razor Pages
- SignalR
- gRPC Services
- Endpoint-enabled middleware such as Health Checks.
- Delegates and lambdas registered with routing.

This document covers low-level details of ASP.NET Core routing. For information on configuring routing:

- For controllers, see Routing to controller actions in ASP.NET Core.
- For Razor Pages conventions, see Razor Pages route and app conventions in ASP.NET Core.

The endpoint routing system described in this document applies to ASP.NET Core 3.0 and later. For information on the previous routing system based on IRouter, select the ASP.NET Core 2.1 version using one of the following approaches:

- The version selector for a previous version.
- Select .

View or download sample code (how to download)

The download samples for this document are enabled by a specific `Startup` class. To run a specific sample, modify *Program.cs* to call the desired `Startup` class.

Routing basics

All ASP.NET Core templates include routing in the generated code. Routing is registered in the middleware pipeline in `Startup.Configure`.

The following code shows a basic example of routing:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    app.UseRouting();

    app.UseEndpoints(endpoints =>
    {
        endpoints.MapGet("/", async context =>
        {
            await context.Response.WriteAsync("Hello World!");
        });
    });
}
```

Routing uses a pair of middleware, registered by UseRouting and UseEndpoints:

- `UseRouting` adds route matching to the middleware pipeline. This middleware looks at the set of endpoints defined in the app, and selects the best match based on the request.
- `UseEndpoints` adds endpoint execution to the middleware pipeline. It runs the delegate associated with the selected endpoint.

The preceding example includes a single *route to code* endpoint using the MapGet method:

- When an HTTP `GET` request is sent to the root URL `/`:
  - The request delegate shown executes.
  - `Hello World!` is written to the HTTP response. By default, the root URL `/` is `https://localhost:5001/`.
- If the request method is not `GET` or the root URL is not `/`, no route matches and an HTTP 404 is returned.

Endpoint

The `MapGet` method is used to define an **endpoint**. An endpoint is something that can be:

- Selected, by matching the URL and HTTP method.
- Executed, by running the delegate.

Endpoints that can be matched and executed by the app are configured in `UseEndpoints`. For example, MapGet, MapPost, and similar methods connect request delegates to the routing system. Additional methods can be used to connect ASP.NET Core framework features to the routing system:

- MapRazorPages for Razor Pages
- MapControllers for controllers
- MapHub<THub> for SignalR
- MapGrpcService<TService> for gRPC

The following example shows routing with a more sophisticated route template:

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapGet("/hello/{name:alpha}", async context =>
    {
        var name = context.Request.RouteValues["name"];
        await context.Response.WriteAsync($"Hello {name}!");
    });
});
```

The string `/hello/{name:alpha}` is a **route template**. It is used to configure how the endpoint is matched. In this case, the template matches:

- A URL like `/hello/Ryan`
- Any URL path that begins with `/hello/` followed by a sequence of alphabetic characters. `:alpha` applies a route constraint that matches only alphabetic characters. Route constraints are explained later in this document.

The second segment of the URL path, `{name:alpha}`:

- Is bound to the `name` parameter.
- Is captured and stored in HttpRequest.RouteValues.

The endpoint routing system described in this document is new as of ASP.NET Core 3.0. However, all versions of ASP.NET Core support the same set of route template features and route constraints.

The following example shows routing with health checks and authorization:

```
public void Configure(IApplicationBuilder app, IWebHostEnvironment env)
{
    if (env.IsDevelopment())
    {
        app.UseDeveloperExceptionPage();
    }

    // Matches request to an endpoint.
    app.UseRouting();

    // Endpoint aware middleware.
    // Middleware can use metadata from the matched endpoint.
    app.UseAuthentication();
    app.UseAuthorization();

    // Execute the matched endpoint.
    app.UseEndpoints(endpoints =>
    {
        // Configure the Health Check endpoint and require an authorized user.
        endpoints.MapHealthChecks("/healthz").RequireAuthorization();

        // Configure another endpoint, no authorization requirements.
        endpoints.MapGet("/", async context =>
        {
            await context.Response.WriteAsync("Hello World!");
        });
    });
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

The preceding example demonstrates how:

- The authorization middleware can be used with routing.
- Endpoints can be used to configure authorization behavior.

The MapHealthChecks call adds a health check endpoint. Chaining RequireAuthorization on to this call attaches an authorization policy to the endpoint.

Calling UseAuthentication and UseAuthorization adds the authentication and authorization middleware. These middleware are placed between UseRouting and `UseEndpoints` so that they can:

- See which endpoint was selected by `UseRouting`.
